Abstract Body: The geochemical characteristics of many porphyry Cu-Au deposits reflect mantle contributions. One such characteristic is a relatively high content of PGE compared to Au-poor porphyry deposits. PGE in porphyry deposits consist mainly of Pd with lesser amounts of Pt. In porphyry Cu-Au deposits, the average Pd+Pt content of ore varies from 1 to 100 ppb. Pd to Pt ratios are typically >1 and range as high as 70. Iridium-group PGE (IPGE: Ir, Os, Ru and Rh) generally occur at very low levels and are rarely reported.

Sulphides are the major repository for PGE and Au in the mantle. Primitive mantle averages about 15 ppb Pd+Pt and 1.7 ppb Au. In contrast, Pd+Pt contents of mantle sulphides range from 500 ppb to nearly 300 ppm and Au contents vary from 30 ppb to 300 ppm. Mantle sulphides form two distinct populations. One consists of spherical Fe-Ni monosulphide solid solution (mss) inclusions primarily in olivine. These tend to be rich in IPGE and depleted in Pd relative to Pt. The second population consists of irregular-shaped, intergranular Cu and Ni sulphide grains that are Pd-rich and relatively depleted in IPGE.

Cu- and Ni-rich mantle sulphides are crystallization products of a Cu-Ni-rich sulphide melt that coexisted with mss. During partial melting in the upper mantle, mss globules remain trapped within restitic rocks, whereas the Cu-Ni sulphide droplets are entrained in mantle-derived magmas that can ascend to higher levels in the crust. If these hot mafic melts are injected into colder felsic magma, they can vesiculate as they cool, producing mafic foam of reduced bulk density that contributes to convection in the felsic magma (Eichelberger, 1980). Examples of mafic foam occur in the McGerrigle Complex in the Gaspé Peninsula. Supercritical aqueous fluids generated by vesiculation destabilize the sulphides and concentrate the metals and sulphur. These fluids are the most likely source of Pd and Pt, and also much of the Cu, Au and sulphur, in porphyry Cu-Au deposits.

Title: Contrasting Os, Ir, Ru and Rh Content between Volcanic and Plutonic Chromites: Petrogenetic and Provenance Tools

Presenter/First Author: Philippe Pagé, Sciences de la Terre, Université du Québec à Chicoutimi (UQAC), Chicoutimi,

Presenter/First Author Email: Philippe_Page@uqac.ca

Co-authors: Sarah-Jane Barnes, Université du Québec à Chicoutimi, Saguenay, QC, Canada

Abstract Body: The introduction of a new generation of LA-ICP-MS allowed us to analyze the Os, Ir, Ru and Rh (IPGE) contents of chromite from samples representative of different geological settings including MORB, boninites, komatiites, Hawaiian tholeiite, continental flood basalt picrite, and from chromitites of podiform type deposits from ophiolitic mantle section and of stratiform type deposits from large layered intrusions including Great Dyke, Stillwater, Black Thor and Bushveld complexes. In addition, chromites from ultramafic sills of the Bushveld Complex have also been analyzed as well as disseminated chromites from komatiitic massive sulfides. Our results confirm that chromite acts as an important phase in controlling the whole rock budget of Ru, but this role is generally shared with other phases like laurite (RuS2). However, chromite only plays a minor role on the fractionation of Os, Ir and Rh, accounting for < 50% of their whole-rock budgets. Other Os, Ir and Rh phases are needed to account for whole rock Os, Ir and Rh concentrations. Most primitive mantle normalized IPGE profiles of chromite show RuN>RhN with the exception of boninite and arc lavas which tend to show RuN<RhN. The chromite from each different setting has distinctive PGE normalized profiles that can be used to identify parental magma. For example the chromite from the chills of the Bushveld lies between komatiites and picrite rather than boninite. Also, sulfide segregation prior to chromite saturation has a dramatic effect on the concentration of the chalcophile elements (Os, Ir, Ru, and Rh) which preferentially partition into the sulfide melt leaving a IPGE-poor silicate melt from which chromite crystallize. The use of IPGE content of chromite as a diagnostic provenance tool is of great interest to determine geological settings and the sulfide mineralization potential of ultramafic - mafic rock assemblages of uncertain origin, and of detrital chromites from covered terrains.

Title: Fe-Ti Oxides Composition in Archean Fe–Ti–V–(P)-bearing Mafic-Ultramafic Intrusions of the Superior Province: a Geochemical Evolution Tracer

Presenter/First Author: Anne-Aurélie Sappin, Geological Survey of Canada, Québec,

Presenter/First Author Email: anne_sappin@hotmail.com

Co-authors: Michel G Houlé, Laurentian University, Sudbury, ON, Canada

Abstract Body: The concentration of trace elements in magnetite and, to lesser extent, ilmenite is controlled by their environment of formation, which makes Fe-Ti oxides useful petrogenetic tracers and suitable indicator minerals for exploration.

We report magnetite and ilmenite composition from two Neoarchean Fe–Ti–V–(P)-bearing intrusions of the Superior Province, the Big Mac mafic intrusion (McFaulds Lake area, Ontario) and the Pyroxenite de baie Chapus (James Bay, Quebec). In both intrusions, the chemical composition of Fe-Ti oxides in compatible (*e.g.*, Al, Mg, V, Ni, Cr) and incompatible elements (*e.g.*, Ti, Mn, Zn) in mafic magmas shows a strong geographic-control,

independently of the lithologies and the proportion of Fe-Ti oxides, that tracks efficiently the magmatic fractionation and indicates the way up of each intrusion. These results are also supported by lithofacies distribution, geochemistry, and silicate mineral chemistry. All together, these data help to constrain the internal stratigraphy and thus to target the most prospective areas to host Fe-Ti-V mineralization.

Furthermore, the magnetite from these intrusions has significantly lower Ti+V contents than expected and plots within the hydrothermal deposits field in the Ni/(Cr+Mn) *vs* Ti+V and Ca+Al+Mn *vs* Ti+V discrimination diagrams rather than within the Fe-Ti-V deposit field. Considering that this Fe-Ti-V deposit field was mostly defined based on Fe-oxides hosted within Proterozoic and Phanerozoic Fe-Ti deposits, preliminary results highlight the possible existence of a distinctive Archean signature of magnetite from the Fe-Ti-V oxides-bearing intrusions. In the light of these results, further investigations are needed to better understand which factors control this distinctive Archean signature of magnetite and to constrain the use of these discrimination diagrams for magnetite to fingerprint the mineral deposit types.

Title: Applications and implications of trace element chemistry and elemental mapping of ore minerals to hydrothermal ore deposit discrimination and genetic models

Presenter/First Author: Daniel Kontak, Mineral Exploration Research Centre, Sudbury, ON

Presenter/First Author Email: dkontak@laurentian.ca

Published Material: some components of this havd bee presnted at previous meetings, but the overall theme of the talk has not been presented and in that context original.

Abstract Body: Hydrothermal ore systems are the end products of thermal anomalies and fluid fluxes that result in local chemical anomalies (i.e., ore deposition and alteration zones). The magnitude and duration of these thermal anomalies vary among ore systems with, for example, orogenic gold deposits having greater longevity than magmatic driven ore systems, which also implies longer fluid flux. The advent of *in situ* micro-analysis of minerals using LA ICP-MS has provided the means to not only determine the abundances of a wide range of trace elements to low detection limits, but to also examine elemental coupling-decoupling and elemental paragenesis, the latter best portrayed with element maps. In the Chemical Fingerprinting Lab at Laurentian University, multiple projects have generated mineral-specific databases which provide the basis for: (1) assessing minerals as potential ore-deposit discriminators; and (2) interpreting the origin of elemental coupling-decoupling and paragenesis in a variety of ore minerals and deposit settings. The trace element data for chalcopyrite and scheelite, both of which have inter-deposit uniformity, are used to illustrate their ability to chemically discriminate multiple ore systems due to intra-deposit variance (e.g., orogenic gold, porphyry Cu(-Au), vein Sn-W, VMS, IOCG). In contrast to the general uniform chemistry of chalcopyrite and scheelite, that of arsenopyrite and pyrite, in particular from orogenic gold deposit settings, record large elemental variance, elemental decoupling, and complex elemental zoning. These latter observations provide indirect evidence of ore-system longevity and complexity. This new technology has provided, therefore, the means to not only geochemically discriminate ore systems using single mineral phases, but to also decipher another aspect of ore deposit models, this being their longevity and involvement of single or multiple reservoirs.

Title: Scheelite chemistry and its use as an indicator mineral for hydrothermal ore deposits

Presenter/First Author: Rémy S. Poulin, Laurentian University, Sudbury, ON

Presenter/First Author Email: RY_Poulin@laurentian.ca

Co-authors: Daniel Kontak, Mineral Exploration Research Centre, Sudbury, ON, Canada; Andy McDonald, Mineral Exploration Research Centre, Sudbury, ON, Canada; Beth McClenaghan, Geological Survey of Canada, Ottawa, ON, Canada

Abstract Body: Scheelite occurs in a variety of ore-deposit settings, including Cu-Mo-W porphyries, skarns and polymetallic veins. Furthermore, as it is resistant to both chemical and physical weathering and has a high specific density, it is often encountered in tills. As part of a comprehensive crystal-chemical study testing its use as a pathfinder and ore discriminator, scheelite from 34 deposits was examined using a variety of methods (e.g., trace elements, $\delta^{18}O$, SEM-EDS, cathodoluminescence (CL)). Despite using an extensive element list, only Mn, As, Sr, Y, Mo and the REEs showed regular and significant levels of enrichment above their LOD. Results indicate scheelite is chemically complex with broad ranges in the investigated parameters: (1) crystal zonation (absent to normal, oscillatory. discordant); (2) minor-element chemistry: Mn (≤LOD to 531 ppm, As (≤LOD to 2320 ppm), Sr (14 to 11480 ppm), Y (≤LOD to 1370 ppm) and Mo (≤LOD to 99500 ppm). This chemistry shows a small intra-deposit variance, but a large inter-deposit variance; (3) REEs data which indicate: (i) a lack of apparent correlation between REEs and the type of CL observed despite previous suggestions to the contrary; (ii) considerable variation in ∑REEs from ≤LOD to 5306 ppm; (iii) a single chondrite-normalized (CN) pattern, for a suite, but rarely a second pattern is noted; (iv) similarity of CN REE patterns (i.e., flat, convex, concave) among deposit types; and (v) both positive and negative Eu anomalies (≤ 0.1 to > 50); and (4) $\delta^{18}O$ values from -4.6 to +9.1‰. The dataset, the most comprehensive for scheelite, suggests that there is a large variation in the parameters examined and considerably expands the data base for this mineral compared to that in the present literature. This dataset may also provide insight into the fluid evolution of ore deposits possessing a complex paragenesis and will serve to establish a basis for further applied crystal-chemical studies of this mineral phase.

Title: Hydrothermal Influence on Zircon from the Kiruna IOA Ores - A Comprehensive Geochemical Study of Zircon Crystals from the Kiruna Iron Apatite Ore District in the Norrbotten Region of Northern Sweden

Presenter/First Author: Chris Richard Voisey, Memorial University of Newfoundland, Mount Pearl,

Presenter/First Author Email: crv731@mun.ca

Co-authors: Anne Westhues, Memorial University of Newfoundland, ST. John's, NL, Canada; John M. Hanchar, Memorial University of Newfoundland, St John's, NL, Canada; George R Rossman, Caltech, Pasadena, CA

Abstract Body: The iron deposits located in the Norrbotten (Kiruna) region of northern Sweden are the type-locality of apatite iron oxide (IOA) deposits. The origin of these deposits has been debated for several decades. There are two current theories of the ore genesis of the Kiruna deposits: 1) iron oxide extracted from an immiscible silicate liquid-iron oxide melt; or 2) iron oxide transported and subsequently emplaced by hydrothermal fluids. Zircon grains were separated from the Kiirunavaara ore, adjacent hanging wall and footwall host rocks, and spatially related syenite and granite intrusions. BSE and CL images of the ore zircon reveal

xenocrystic cores that are overgrown by "spongy", inclusion-rich hydrothermal rims. Zircon crystals from the syenite intrusion contain veins and patchy zones resembling alteration and resorption textures. Zircon from the host rocks and the granite exhibit typical igneous growth zoning. Selected zircon crystals were analysed using the EPMA for Zr, Si, Hf, Ca, Fe, Y, and P, and revealed the zircon grains from the volcanic host rock and granite to be of near stoichiometric composition. Zircon crystals from the ore and syenite contained elevated Fe and P concentrations and have low analytical totals. EPMA elemental X-ray maps reveal Fe rich inclusions, veins and/or zones in zircon crystals from the ore and syenite. Similar features are not found in host rock or granite zircon. FTIR spectroscopy done on selected zircon grains from the ore and syenite revealed that they contained several weight percent of H_2O. This suggests that zircon from the ore and syenite intrusion experienced post-crystallization hydrothermal fluid alteration. A high temperature (~600-700°C) magmatic fluid(s), at the magmatic-to-hydrothermal transition, possibly exsolved from the intrusions, seems the most likely heat and fluid source to have remobilised the iron, possibly locally derived, and concentrated it in the massive iron oxide deposits located at Kiirunavaara.

Title: Trace element systematics of footwall and hanging wall alteration associated with volcanogenic massive sulfide deposits of the Bathurst Mining Camp, Canada: developing LA-ICP-MS methodology for phyllosilicates and its application as geochemical vectoring tool in exploration

Presenter/First Author: Azam Soltani Dehnavi, University of New Brunswick, Fredericton, NB

Presenter/First Author Email: a.soltanidehnavi@gmail.com

Co-authors: David Richard Lentz, University of New Brunswick, Fredericton, Canada; Christopher RM McFarlane, University of New Brunswick, Fredericton, NB, Canada

Abstract Body: An innovative approach using *in situ* LA-ICP-MS of phyllosilicates in and around massive sulfide deposits of the Bathurst Mining Camp (BMC) is presented, which compliments existing work on sulfides in the same context. LA-ICP-MS is a powerful tool to study the composition, to sub-ppm levels, of phyllosilicates in fine-grained contexts. Moreover, lack of any special sample preparation (only polished thin sections) and cost efficiency for examining a large number of grains (100s of analyses per day) make this methodology practical in both academic and applied projects. The main purpose of this study is establishing trace element variations of the key hydrothermal alteration assemblages associated with VMS deposits of the BMC to introduce its application in exploration.

Chlorite and white mica are the most abundant minerals in different hydrothermal alteration assemblages throughout the BMC. Chlorite is a major silicate constituent, forming with the massive sulfides (disseminated to sub-massive sulfides) and exhalative sedimentary rocks along mineralized horizons. White mica is also ubiquitous in quartzo-feldspathic volcaniclastic rocks, clastic, and exhalative sedimentary rocks. In comparison to chlorite, white mica accommodates higher concentrations of As (from detection limit (4.13 ppm)-1.12 wt. %), Sb (<0.2-4750 ppm), Tl (<0.03-697 ppm), and Hg (0.16-67 ppm), whereas Cd (<0.07-420 ppm), In (0.02-384 ppm), and Bi (0.02-185) are more enriched in chlorite. Phyllosilicate chemical dispersals along the studied drill holes are variable for different elements.

Compositional variations of phyllosilicates demonstrate that some of trace elements, such as As, Sb, and Tl form the most extensive halos related to the mineralization. Chemical distributions in stratigraphic profiles of studied deposits display the highest anomalies proximal to the ore lenses for As, Sb, and Tl values, ranging from 11-39 ppm, 1.29 to 185 ppm, and 3 to 223 ppm, respectively. Somewhat analogous to lithogeochemistry, proximal to distal signatures of trace elements can be observed in several 10s of meters distance from the ore horizons. Therefore, this study introduces mineralogical trace element vectors in mine-scale exploration that can be potentially examine at unexplored areas of the BMC, as well as in other VMS districts.

Title: In-situ LA-ICP-MS trace elemental analyses of magnetite: the late Palaeoproterozoic SokomanIron Formation in the Labrador Trough, Canada

Presenter/First Author: Diane Chung, University of Hong Kong, Hong Kong,

Presenter/First Author Email: dianemyc@gmail.com

Co-authors: Mei-Fu Zhou, University of Hong Kong, Hong Kong, China; Jian-Feng Gao, , , ; Wei Terry Chen, University of Hong Kong, Hong Kong, China

Published Material: The findings are reported in a scientific paper which has been accepted by Ore Geology Reviews. It is available online on 16 October 2014 and will be published in March 2015. Chung, D., Zhou, M.-F., Gao, J.-F., Chen, W.T., 2015. In-situ LA-ICP-MS trace elemental analyses of magnetite: the Palaeoproterozoic Sokoman Iron Formation in the Labrador Trough, Canada. Ore Geol. Rev., 65, 917-928.

Abstract Body: The Sokoman Iron Formation in the Labrador Trough, Canada, a typical granular iron formation (GIF), is coeval with the ~ 1.88 Ga Nimish volcanic suites in the same region. It is composed of the Lower, Middle and Upper Iron Formations. In addition to primary and altered magnetite in iron formations of the Hayot Lake, Rainy Lake and Wishart Lake areas, magnetite in volcanic breccia associated with the iron formation is identified for the first time in the stratigraphy. Trace elemental compositions of the most primary, altered and volcanic brecciated magnetite of the Sokoman Iron Formation were obtained by LA–ICP-MS. Commonly detected trace elements of magnetite include Ti, Al, Mg, Mn, V, Cr, Co and Zn. These three types of magnetite have different trace elemental compositions. Primary magnetite in the iron formation has a relatively narrow range of compositions with the depletion of Ti, Pb, Mg and Al. Magnetite from volcanic breccia is rich in Ti, Al, V, Mn, Mg, Zn, Cu and Pb, indicative of crystallization from mantle-derived magmas. Altered magnetite in the iron formation shows a relatively wide range of trace elemental compositions. Mineralizing fluids associated with magmas that generated the ~ 1.88 Ga Nimish volcanic suites circulated through the sedimentary piles to further enrich the iron formations and to form magnetite with variable compositions. The comparisons of different types of primary and altered magnetite in the iron formation in the region show distinct provenance discrimination. Our findings also support the origin of iron formations in association with multiple stages of exhalative volcanic and hydrothermal processes.

Title: Magnetite chemistry as a provenance indicator in Archean metamorphosed sedimentary rocks: Implications for mineral exploration.

Presenter/First Author: Quentin Duparc, University of Quebec at Chicoutimi UQAC, Chicoutimi,

Presenter/First Author Email: quentinduparc@yahoo.fr

Co-authors: Sarah Dare, Université du Québec à Chicoutimi, Saguenay, QC, Canada; Pierre A. Cousineau, UQAC, Chicoutimi, QC, Canada; Jean Goutier, Géologie Québec, Rouyn-Noranda, QC, Canada

Abstract Body: We used magnetite compositions to determine the provenance of amphibolite metamorphic grade alluvial sediments from the Magin and Keyano formations, situated in the La Grande area of the Archean Superior Province of Canada. Magnetite is common in a wide range of depositional environments and can be formed throughout a range of temperatures, from low temperature hydrothermal to high temperature magmatic environments. We used a new analytical technique (LA-ICP-MS) to determine a wider range of trace elements at lower concentrations. The detrital magnetite data was plotted on multi-element diagrams. This revealed that the most discriminant elements that were used to differentiate four potential different sources for the Magin formation are the elements most compatible into magnetite. Overlap between the spectra of the Magin and Keyano formations prove the existence of a common source for them both. Our results show that detrital magnetites have low Ti values that could be either magmatic (felsic) or hydrothermal in origin. The spectra of detrital magnetite from the sediments were compared to magnetite spectra from fragments of banded iron formation and tonalite, which are present in the conglomerates and represent the potential sources in the study area. However, only magnetites from tonalite have a signature similar to those from the sediments. A detailed LA-ICP-MS study of magnetite from ten felsic plutons, sampled in close proximity to the sedimentary formations, allowed us to recognize that each pluton has a particular signature with a wide variation in Ni and Cr. Thus two individual plutonic sources were identified for both sedimentary formations using magnetite chemistry. Using our large dataset of magnetite from felsic rocks we have evaluated the current magnetite discrimination diagrams used for mineral exploration. We show the importance of identifying low Ti magnetite from felsic rocks which could be misidentified as magnetite from hydrothermal mineral deposits. We propose to plot magnetite data first on the Ti vs. Ni/Cr diagram which allows the identification of low Ti magnetite of felsic magmatic (low Ni/Cr) from hydrothermal (high Ni/Cr) origin. After this screening process the existing magnetite discrimination diagrams from the literature can be used with more confidence for mineral exploration.

Title: Alkali Carbonatite Melt Inclusions in Volcanic Carbonatites from Kerimasi Volcano, Tanzania

Presenter/First Author: Roger Howard Mitchell, Lakehead University, Thunder Bay,

Presenter/First Author Email: rmitchel@lakeheadu.ca

Abstract Body:

The Trig Point Hill debris flow, originating from Kerimasi volcano (Tanzania) contains numerous blocks of extrusive/pyroclastic carbonatites similar to those exposed at the rim of the currently inactive crater. The blocks of calcite carbonatite consist of: (1) large clasts of corroded and altered coarse grained calcite; (2) primary prismatic inclusion-bearing phenocrystal calcite; and (3) a matrix consisting primarily of fine grained prismatic calcite . The large clasts are inclusion free and exhibit a ‘corduroy-like” texture resulting from solution along cleavage planes. The resulting voids are filled, in part, by brown Fe-Mn- hydroxides/oxides. The prismatic or lath shaped phenocrystal calcite is not altered and contains melt inclusions consisting principally of primary Na-Ca-carbonates in which are set earlier-formed crystals of monticellite, periclase, apatite, Mn-Mg magnetite, Mn-Fe-sphalerite and Nb-perovskite. The Na-Ca-carbonates consist of (wt.%): 19-20 Na_2O; 30-31 % CaO; 2-3 % K_2O; 1-2 % SO_3; and 0.4-0.6 %SrO. Although the Na-Ca-carbonate composition is similar to that of shortite, this phase is not considered as a secondary mineral formed after nyerereite. Periclase is Fe-bearing with up to 13 wt.% FeO. The matrix in which the “corduroy” clasts and phenocrystal calcite are set consists of closely-packed small stubby prisms of calcite lacking melt inclusions, with interstitial fine grained apatite, barite, strontianite, and minor fluorite. Pore spaces are filled with secondary Mn-Fe hydroxides/oxides, anhydrite and gypsum Although the compositions of the Na-Ca carbonate inclusions do not correspond to those of nyerereite.The presence of primary K-S-bearing Na-Ca carbonates as melt inclusions suggests that the magma which formed these calcite carbonatites could differentiate to natrocarbonatite-like residua.

Title: Mineralogy, Geochemistry REE bearing Alkaline Plutons in and around Ananthapur and Chittor districts, Andhra Pradesh, India

Presenter/First Author: Raju Pvs, National Geophysical Research Institute, Hyderabad,

Presenter/First Author Email: perumala.raju@gmail.com

Abstract Body: Preliminary assessment of REE (rare earth elements) and rare-metal potential and geochemical characterization, with implications for metallogeny, is currently underway at alkaline syenite complexes in Andhra Pradesh. The alkaline complexes are located to the west and south-west of the Paleoproterozoic Cuddapah basin in the Ananthapur district. Several alkaline plutons ± nephyline syenite earlier reported by GSI, were relooked for REE bearing minerals and their REE contents. (Around Dancherla,Peddavaguru, Danduvaripalle,Reddypallae, Chintalchervu areas) and Pulikonda complex in Chittor districts of Andhra Pradesh. The main Dancherla syenite body is oval-shaped and has a total area at the current level of exposure of around 18 km2. It consists of medium- to fine grained mesocratic syenite, leucocratic, porphyritic and quartz syenite in cross-cut relations with diabase-hornblendite dyke swarms. The SEM and microscopic studies revealed REE bearing minerals like Eudeilyte, Zircon, Sphene (Fig 1), Allanite ((Fig.2), Apatite (Fig 3), REE enriched (Fig 4) with opaques and Fe oxide phases.The total REE in one of alkaline plutons with Nephline bearing syenites is 800 ppm.The Major element distributions show simple trends of decreasing MgO, FeO, P_2O_5 and TiO_2 contents with increasing SiO_2. Bulk-rock chemical analyses gave > 8 wt.% Na_2O, > 5 wt.% K_2O, low CaO and MgO contents (< 5 wt.%) and ~16 wt.% Al_2O_3. In binary Na_2O+K_2O vs. SiO_2 diagrams, the samples plot in the nepheline syenite field. Our preliminary geochemical data suggest enrichment in light REE and flat heavy-REE distribution in chondrite-normalized patterns. In some samples, positive Eu anomalies were detected, suggesting plagioclase enrichment. The maximum La and Ce concentrations recorded thus far are 200 and 350 ppm, respectively. Binary diagrams showing variations in Hf-Zr and Nb-Ta ratios show a positive correlation and indicate an overprint from externally derived fluids.

Title: The Petrosomatic Evolution of Magmatic Rocks through Distinct Mantle Pulses: Insights from Montviel Alkaline Complex, Canada

Presenter/First Author: Olivier Nadeau, Organization Not Listed, Washington, DC

Presenter/First Author Email: nadeau.oli@gmail.com

Co-authors: Michel Jebrak, UQAM, Montreal, QC, Canada; Ross Stevenson, Universite du Quebec a Montreal, Montreal, QC, Canada

Published Material: Some of these results were presented at GAC-MAC and Goldschmidt in 2014. This is now a manuscript in preparation.

Abstract Body: Magmatic volatiles are of paramount importance for the petrogenesis of igneous rocks but are so evanescent that some of the processes in which they are involved are not yet fully understood, sometimes not even recognized. Although their role is relatively well understood in some systems, more research is required to improve our understanding of their behavior in mantellic and crustal magmatic-hydrothermal systems. In order to investigate the roles of magmatic volatiles during petrogenesis, the Paleoproterozoic alkaline complex of Montviel was studied. The 1.894 Ga alkaline intrusion consists of clinopyroxenites, melteigites, ijolites, melano- to leucosyenites, riebeckite granite, silicocarbonatites, calciocarbonatites, magnesiocarbonatites, ferrocarbonatites, mixed carbonatites and a polygenic breccia and host the Montviel world-class-level, carbonatite-hosted REE-Nb deposit. Field and drill core relations and geochemical and isotopic analyses on minerals and bulk rocks suggest the alkaline complex was emplaced as three distinct mantle pulses, each of which evolved by fractional crystallization and autometasomatism. The carbonatite melt was not generated directly from partial melting of a metasomatized mantle source and carbonatite magma has separated from silicate magma so immiscibility is not ruled out.

Title: Intrusion-related Pb-Zn sulfide veins associated with an Acadian strike-slip regime in the Nicholas-Denys property, Bathurst mining camp, Canada.

Presenter/First Author: Clyde McMillan, University of Quebec at Montreal UQAM, Montreal,

Presenter/First Author Email: clyde.mcmillan@gmail.com

Co-authors: Alain Tremblay, GEOTOP, Montréal, QC, Canada; Dominique Gagné, , ,

Published Material: GSA meeting, Bretton Woods - March 2013 - Poster presentationGAC-MAC meeting, Fredericton - May 2014 - Oral presentationSEG meeting, Keystone - September 2014 - Poster presentation

Abstract Body: In northern New Brunswick, Pb-Zn-Ag epigenetic mineralization is located on the edge of the Nicholas-Denys intrusion, a lowermost Upper Devonian (ca. 381 Ma) granodioritic pluton occurring along the northern block of the Rocky Brook Millstream Fault (RBMF). The granodiorite intrudes the Nigadoo River Syncline, an east-northeast striking structure belonging to the Chaleur Bay Synclinorium that formed during the Acadian Orogeny. The RBMF strikes east-northeast and has been recognized as a major right-lateral, transpressionnal strike-slip fault.

Polymetallic veins, consistent with right-lateral shearing, are: (1) transverse tension structures in the Dante-Raya showings, and (2) longitudinal tension structures in the Hachey showing. Ore mineralogy consists of sphalerite-galena-pyrrhotite-pyrite-arsenopyrite-chalcopyrite. Euhedral epidote occurs with sulfide mineralization in all showings. Veins in the Dante-Raya showings crosscut Silurian limestone and show a coarse-grained mineralization, whereas veins in the Hachey showing, crosscutting Ordovician mudslate and pelitic schist, show a finer-grained, pyrrhotite-rich mineralization. The zonal distribution of Mo, Cu, Pb, Zn, Ag, Au and Sb as compared to regional structures is suggestive of a magmatic source, and similar polymetallic deposits have been reported along other right-lateral strike-slip faults of the area, such as the Ristigouche-Grand Pabos faults in Gaspé peninsula. Our current interpretation is in contradiction with a previous study in which the ore bodies of the Hachey showing have been interpreted as a syngenetic mineralization that has been deformed by Acadian folds and faults. Rather, we believe that these deposits are related to late-Acadian convection controlled by the activity of a hydrothermal-magmatic system related to the Nicholas-Denys pluton.

Deformed mineralization textures observed on the Hachey showing, suggests that Acadian transpressionnal deformation was still active during mineralization. The rounded shape of the intrusion suggests, however, that right-lateral shearing deformation had considerably diminished during the emplacement of the Nicholas-Denys pluton, which is consistent with its lowermost Upper Devonian age.

Title: Contribution to Geologic and metallogenic study of Bakoudou golden ore deposits (Gabon)

Presenter/First Author: Wafik Amina, Cadi Ayyad University, Marrakech,

Presenter/First Author Email: wafik@uca.ma

Co-authors: Traoré Kalidou, , , ; Saquaque Ali, , , ; Nzaou Mabika Nazaire, , ,

Published Material: RST- 27 to 31 october 2014- Pau, France

Abstract Body: The objective of This study is to determine the Bakoudou gold deposit type. So to characterize the Bakoudou gold deposit, we characterized microscopically samples of two core drilling (BA06-36: 13 and BH2: 1). ICP-MS and X-ray diffraction (XRD) Analysis were also used to characterize the gold deposit.

The main results of these studies are :

- ICP-MS results indicate that the percentages of Si02 for all samples are upper or equal to 52, implying that the facies are supersaturated with silica (intermediate to acid rock). As lithology, microscopic study has concluded that the facies granites, granodiorite or diorite quartzic.

- These rocks have undergone regional metamorphism marked by the appearanceof quartz crystals recrystallized, foliation in some rocks and start metamorphic ribbon trimming following by hydrothermal alteration process of low intensity marked by the development of chlorite and sericite.

- The spectra of X-ray diffraction have revealed the particular presence of crossite, a sodic amphibole mineral, tracer of regional metamorphism blue schist facies.

- Petrologic and metallogenic study reveals that gold, our main interest, is disseminated in free grains present in quartz, plagioclase, biotite and amphibole of surround rocks and so abundant in quartz facies, which is consistent with a magmatic origin of the gold. That does not exclude the contribution of hydrothermal because it is shown very lowly in some blades that gold is related to chlorite from hydrothermal origin. Sulphides contained in the blades are low quantities. Part of these latters is related to magmatic origin and a greater amount is related to hydrothermal origin.

Published Material: Some of the material was discussed, but not published, in a workshop in Warsaw, Poland September 2014

Abstract Body: The Robertson River igneous suite is the largest Neoproterozoic A-type granite body emplaced along the eastern Blue Ridge flank during regional Rodinia crustal extension related to the opening of Iapetus. U-Pb zircon age indicates emplacement in two magmatic pulses, 735–722 and 706–702 Ma. Metaluminous magmas were emplaced during both pulses and form most of the batholith. Peralkaline magmas comprise the final phase of activity. The peralkaline rocks have exceptionally high trace-element contents, Zr ~1000 ppm, Nb ~200 ppm, and Σ Y, Sc, REE > 1000 ppm, and a diversity of accessory phases. Zircon, the only Zr-phase observed, ranges in habit from euhedral, mm long crystals to hydrothermal amoeboid, commonly altered masses. HfO_2 content ranges from 0.49 to 3.14 wt% and the mean ΣREE, Y is 1.3 wt%; the Zr/Hf ratio (w/w) varies from 17 to 82. The major REE-bearing phases are fluorocarbonate, chevkinite group mineral, allanite, gadolinite, and a variety of Nb phases. Bastnäsite-(Ce) is the major fluorocarbonate with minor parisite-(Ce), and synchysite-(Ce). Chevkinite-(Ce) averages 11.50 wt% FeO and 2.60 wt% CaO, and is commonly altered. Allanite-(Ce) occurs in a wide variety of habits from subhedral crystals to amoeboid masses and averages 25 wt% ΣREE. Gadolinte-(Y) occurs as euhedral to subhedral crystals, sometimes zoned, and averages 52 wt% ΣREE, Y. The Nb-bearing phases occur in a wide variety of chemistry, habits, and typically show alteration, multiple generations, and deposition by late-stage fluids. Three major groups, aeschynite-euxenite, fergusonite, and samarskite were identified. The mafic assemblage in the peralkaline rocks is dominated by aegirine, riebeckite, and stilpnomelane; fluorite is ubiquitous. The mineralogy and petrography suggest Na-, Fe-, and F-rich fluids carrying REE, Y, Nb, and Zr were late-stage and moved through the rock during the early cooling process.

Title: Indium in Tin and Sn-sulfide Ores of the Deputatsky Ore District (Yakutia)

Presenter/First Author: Galina G. Pavlova, V.S. Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk,

Presenter/First Author Email: galinapavl@gmail.com

Co-authors: Alexander S. Borisenko, V.S.Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia; Andrey A. Borovikov, V.S.Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia; Andrey V. Prokopiev, Diamond and Precious Metal Geology Institute SB RAS, Yakutsk, Russia; Alexandr I. Ivanov, , ,

Published Material: New geochronological data have been reported at the scientific conference "Granites and the Earth's evolution", V.S.Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk, August 17-20, 2014. Fluid inclusions data were considered in detail at the XVI thermobarogeochemical conference, A.P. Vinogradov Institute of Geochemistry SB RAS, Irkutsk, September 10-14, 2014.

Abstract Body: Deposits with Q-cassiterite (Sn) and cassiterite-sulfide (Sn-sulfide) mineralization associated with or followed the Cretaceous subduction and later post-collisional rifting are known in the Deputatsky ore district (Northern Yakutia). The Sn-sulfide deposits are located to the south (Ege-Khaya, Kester, Honorskoe, Ilintass, Anomalnoe, Vysokogornoe) in the ore districts with only collision impact. During collision, Kolyma-Omolon superterrane worked as a hard indenter that resulted in the intense folding of the Verkhoyansk passive margin terrigenous rocks of the North Asia craton and transverse fault zones formation along which post-collisional granite porphyry stocks and alkaline mafic dikes were intruded. The large Sn-Ag Deputatsky ore cluster comprises: 1) Sn (111-108 Ma), 2) Sn-sulfide and low temperature Sn-Ag (106-100 Ma) mineralization. The Sn deposits (<100 g/t In) are linked with granite magmatism (112 Ma). The In-bearing Sn-sulfide mineralization (400 g/t In) coincides with lamprophyre and rhyolite porphyry intrusions (106 Ma). Fluid inclusion study in quartz from the Sn and Sn-sulfide veins using LA-ICP-MS and Raman-spectroscopy shows that ore-forming fluid of the Sn stage was enriched in Sn, W, and As. Minerals of the Sn-sulfide veins deposited from the chloride-carbonate

hydrothermal fluid (siderite daughter minerals) rich in Fe, Mn, Zn, In (7 ppm), Ag (160 ppm). Indium occurs as impurity in sulfides and does not form own minerals. At the low Cu, Zn and Pb contents, alabandite (MnS) veins hosted by volcanic rocks at the Vysokogornoe deposit contain In-minerals. Mid-Cretaceous and Paleocene Sn, Sn-sulfide, and Sn-Ag ores linked with granites and K-monzonite-syenites were formed in the Russian Far East in a continental margin setting. Granites are usually followed by Q-cassiterite veins, while bimodal magmatism (alkaline basite+granite/rhyolite) in a rifting setting led to the Sn-sulfide mineralization forming. Large Sn-Ag ore clusters were formed due to superposition of Sn-sulfide and Sn mineralization with contribution from crustal and mantle sources.

Title: Mineralogy of the Clay-Howells Magnetite Carbonatite: An A-type Granite-Related 'Carbonatite'

Presenter/First Author: Shannon E Zurevinski, Lakehead University, Thunder Bay, ON

Presenter/First Author Email: shay@lakeheadu.ca

Co-authors: Roger Howard Mitchell, Lakehead University, Thunder Bay, Canada

Abstract Body: The Clay-Howells complex (NW Ontario) consists predominantly of fayalite augite amphibole syenite. A sinuous c. 1km long, dike-like body of magnetite carbonatite apparently intrudes the syenite at the southeast margin of the intrusion. The carbonatite exhibits pronounced modal layering with respect to magnetite and carbonates, with magnetite ranging from 10-90 vol.%. Both minerals exhibit allotriomorphic granular textures. The magnetite is a Mn-bearing (2-3 wt.% MnO), Ti-poor (< 0.3 wt.% TiO_2) variety intergrown with manganoan fayalite ($Fa_{47}Tp_{30}$ Fo_{24}). It typically contains numerous small (< 50 micron) round inclusions of Pb-bearing thorianite and micro-inclusions (< 5 micron) of manganoan ferrocolumbite, fersmite, hercynite, and gahnite. The carbonate-rich parts of the carbonatite consist predominantly of co-existing calcian rhodocrosite, Mn-poor Sr-bearing calcite, magnetite, apatite, biotite, fluorite, and quartz in diverse modal amounts. Sr and Y-bearing fluorapatite typically exhibits complex resorption and mantling textures reflecting light REE compositional variation. Accessory minerals occurring interstitially between magnetite and carbonates as thin veins include fluor-thoro-britholite, thorite, pyrochlore, niobo-aeschynite, Sn-bearing manganocolumbite, baddelyeite, ferroan sphalerite, kinoshitalite, diverse zeolites and strontianite. Pyrochlore group minerals are Na-, Th, U, and REE-poor calciopyrochlores, and U-Ta-bearing pyrochlores. Pyrochlores and aeschynites are commonly altered by deuteric fluids to complex intergrowths of unidentifiable secondary Nb- and Th-bearing minerals. The minor and accessory mineral paragenesis is similar to that occurring in mineralized A-type granitoids. As undersaturated alkaline rocks of the ijolite and melilitite suites are not present at Clay-Howells we consider that this magnetite carbonatite is a derivative of an A-type granitoid magma and is not formed from a undersaturated mantle-derived magma.

Title: Tracking the Evolution of the Metal and Volatile Budget of the Magma Reservoir Underneath the World-Class Porphyry Cu-Au Mineralization at Bingham Canyon, Utah, USA

Presenter/First Author: Carter Grondahl, University of Toronto, York,

Presenter/First Author Email: carter.grondahl@mail.utoronto.ca

Co-authors: Zoltán Zajacz, University of Toronto, Toronto, ON, Canada; Jeffrey D. Keith, , Provo, UT

Abstract Body: Introduction of a primitive, Cu, S and CO_2-rich magma to a partly crystallized felsic magma chamber has been suggested as a crucial step in the formation of the world-class Bingham Canyon Cu-Au-Mo deposit. This interpretation is based partly on mafic lava flows identical in age to the mineralization, preserved within the remaining volcanics of the eroded Bingham stratovolcano. Rocks from basanite to rhyolite in composition have been sampled from the volcanic edifice. We have identified mineral decomposition textures in many intermediate and felsic rocks, suggestive of olivine phenocrysts introduced into a melt with which they were at a strong disequilibrium. Specifically, symplectites consisting of vermiculitic magnetite and orthopyroxene are occasionally found throughout the mineralization-aged volcanics. In the well-developed examples, an outer zone of orthopyroxene surrounds the inner symplectite. This outer orthopyroxene occasionally hosts sulfide inclusions, an evidence of magmatic sulfide saturation which have affected the availability of ore metals for exsolving fluids. These symplectites provide direct evidence for magma mixing. Additionally, the volcanics are rich in apatite, which displays significant compositional variability. Scanning electron microscope (SEM) and electron microprobe (EMP) analyses revealed that the apatites (<200 um) are Fe-bearing, either Cl- or F-rich, and exhibit variable S concentrations. Some Cl-apatites display a spotty exsolution trellis of iron sulfides. Abundant silicate melt and fluid inclusions are present in several hosts including pyroxene, amphibole, plagioclase, biotite, and apatite. Further work will include homogenization experiments, and the analysis of metal and volatile concentrations in silicate melt and sulfide inclusions by methods including Laser Ablation ICP-MS, Fourier Transform Infrared Spectroscopy, SEM, and EMP as well as detailed investigation of the chemical zonation of the phenocrysts.

Abstract Body: Lode field of Roc Blanc is located in the Hercynian massive of Jebilet, a few kilometers northwest of Marrakech city. It is steep-sided in a marine sedimentary series of Visean higher-Namurian age, the Sarhlef series is the central group of this massive. Sulphide mineralization of Roc Blanc is a polyphased mineralization, lithologically associated with speckled schists with cordierite in the contact metamorphic aureole of granodiorite pluton. It is a lode mineralization structurally controlled, formed by veins or lenses and has a banded or brecciated structure. The metallic mineral association consists of pyrrhotite, pyrite, arsenopyrite, chalcopyrite, sphalerite, galena, gray copper, argentite, pyrargyrite, owyheeite, polybasite and native silver. We can subdivide into: 1) An early metamorphic episode in the black shales facies. This stage characterized by sulfides of Fe and Cu. 2) A hydrothermal episode in the black shale facies (chlorite, muscovite and sericite). It is characterized by silver mineralization as sulfides and sulfosalts and native silver. This episode defines as a holding economical mineralization in the deposit. It is characterized by three mineralized phases: i) A phase with pyrrhotite, pyrite, chalcopyrite, arsenopyrite and sphalerite. ii) A phase with pyrite, sphalerite and galena, copper, gray and owyheeite into beds or flies scattered in the milky quartz. iii) A phase with pyrite or often chalcopyrite, black silver, red or native silver localized in the geodic quartz associated with carbonates. The presence of sulfides, sulfosalts of bases metal and silver indicated that is a hydrothermal fluid circulation warm (chlorite, quartz and muscovite), acid and reducers (sulfides) formed under mesothermal at epithermal conditions.

Title: Role of hypabyssal subvolcanic magmas in the genesis of the Albany graphite deposit

Presenter/First Author: Andrew George Conly, Lakehead University, Thunder Bay,

Presenter/First Author Email: andrew.conly@lakeheadu.ca

Co-authors: Lindsay C Moore, Zenyatta Ventures Ltd., Thunder Bay, ON, Canada

Abstract Body: The Albany graphite deposit comprises two breccia pipes within the Albany Alkalic Complex; a satellite igneous complex situated along the southern margin of the larger Nagagami River Alkali Rock Complex. The deposit is interpreted as near surface volcanic vent breccias formed by the ascent of carbonaceous fluids separated from alkali magmas. The graphite-hosting "syenite" ranges in composition from quartz syenite to diorite, with quartz monzonite being the most common composition. The "syenite" is considered to have a passive role in graphite formation; however, it is suspected that a recently identified porphyritic, hypabyssal subvolcanic monzodiorite/foid monzodiorite may have played a critical role. A hypabyssal origin is inferred from the occurrence of: i) aphanitic groundmass consisting of albite, paragasite and minor nepheline; ii) embayed and sericitized albite xenocrysts with discontinuous, epitaxial overgrowths of sanidine; and, iii) corona textured magmaclasts (consisting of a core of variably altered groundmass, an intermediate zone of subhedral euhedral phlogopite and rimmed by anhedral to subhedal and radiating paragasite ± phologopite). The hypabyssal facies has only been identified along the margins of the western breccia pipe where it intruded Archean country rocks and brecciated and non-brecciated facies of the Albany "syenite". We postulate that orthomagmatic CO_2-dominant fluid and aqueous fluid originated from the hypabyssal magma. The inferred alteration of an unidentified anhydrous phase to biotite + paragasite by reaction with a hydrous fluid could have generated H_2, with the subsequent reaction of this H_2 with orthomagmatic CO_2 to form CH_4 via Fischer-Tropsch synthesis. Graphite crystallization was induced by rapid depressurization and cooling of a CH4-CO_2 fluid in response to explosive surface venting. This reaction mechanism is supported by estimated temperatures for graphite mineralization of 485 to 555°C and an initial carbon isotope value of -16.9‰ for graphite.

Title: Genesis of the Pd-Cu Mineralization at the Marathon Deposit, Ontario: Preliminary Insights from Oxide Chemistry

Presenter/First Author: Matthew Jacek Brzozowski, University of Windsor, Windsor,

Presenter/First Author Email: brzozowm@uwindsor.ca

Co-authors: Iain M. Samson, University of Windsor, Windsor, ON, Canada; Joel E Gagnon, University of Windsor, Windsor, ON, Canada; David John Good, University of Western Ontario, London, ON, Canada; Robert Linnen, University of Western Ontario, London, Canada

Abstract Body: The Marathon Cu-Pd deposit is hosted by the Two Duck Lake Intrusion (TDLI), a late phase of the Eastern Gabbro (EG) in the Coldwell Complex. The EG is subdivided into the Fine-Grained Series, Layered Series, and Marathon Series, with the latter hosting all of the Cu-PGE mineralization. Magnetite is ubiquitous in all rock series, which, along with the sensitivity of magnetite chemistry to its environment of crystallization, make it a suitable mineral to help understand the genesis of the EG and the mineralization.

Magnetite is disseminated in most gabbros, but can occur in (semi-)massive layers. Two types of magnetite are present. Interstitial, magmatic magnetite always contains very fine lamellae of Fe-Ti oxides ≤ 1 µm across. Analyses thus represent a mineral mixture rather than homogeneous magnetite, which has implications for the internal standard chosen for LA-ICP-MS. Thick (5-20 µm) lamellae and euhedral to subhedral crystals of ilmenite are also typically present in the magnetite. Late magnetite is less abundant than interstitial magnetite and lacks exsolution. It commonly occurs as a replacement of sulphides, but can occur in patches and veinlets in silicates.

Preliminary LA-ICP-MS analyses of magnetite and ilmenite show that late magnetite has the lowest concentration of trace metals, except for Ge, Pb, and Th, which are present in greater concentrations. Magnetite hosted by Fine-Grained Series has the highest Cr, Ni, and Pt concentrations of the EG. Those hosted by Layered Series have the highest Mo and Pd, but lowest Cr and Ni concentrations. Magnetite hosted by Marathon Series has Cr, Ni, Mo, and Pt concentrations intermediate to the other rock series. Magnetite hosted by mineralized TDLI has distinctly higher Cr, Ni, and Au concentrations, but lower Mo than those hosted by barren TDLI. These results suggest that magnetite chemistry can distinguish between various rock series and between barren and mineralized TDLI.

Title: Mineral Chemistry of Magnetite from Kiruna Magnetite-Apatite Ores and their Host Rocks from the Norrbotten Region, Northern Sweden

Presenter/First Author: Shannon Gaynell Broughm, Memorial University of Newfoundland, St. John's,

Presenter/First Author Email: s.g.broughm@mun.ca

Co-authors: John M. Hanchar, Memorial University of Newfoundland, St John's, NL, Canada; Fernando Tornos, CSIC-INTA, Madrid, Spain

Abstract Body: Magnetite-apatite deposits (MAD), also called Kiruna-type or iron oxide apatite (IOA) deposits, are major producers of iron ore that often primarily consist of the mineral magnetite (Fe_3O_4). It remains unclear whether these deposits are hydrothermal or magmatic in origin and this issue has been debated for several decades. MAD deposits are considered an end member in a continuum of iron oxide deposits; with the opposite end member being iron oxide copper gold (IOCG) deposits. The type locality, from which the name "Kiruna-type" is derived, for this style of mineral deposit are the deposits in the vicinity of the town of Kiruna,

located in the Norrbotten region of northern Sweden. The main deposit in this region is the Kiirunavaara MAD deposit (~ 2 billion tons of iron ore, extracted and in reserve) and magnetite chemistry from this deposit is the focus of this project. Magnetite samples from smaller nearby MAD deposits in the Kiruna region (e.g., the Per Geijer ores) will also be investigated. Magnetite is sensitive to fluctuating physiochemical conditions in which it forms (such as temperature, pressure and fO_2) and may contain distinct minor and trace element concentrations depending on the environment in which it formed, making it a useful geochemical indicator for understanding the genesis of MAD deposits. Several ore samples as well as samples from the adjacent hanging wall and footwall host rocks will be examined. For this study, magnetite will be investigated using an electron probe microanalyzer (EPMA) for major and minor element quantitative chemical analyses, X-ray maps, and back-scattered electron (BSE) images. Additionally, laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) analyses will be done to determine the minor and trace element concentration of the same magnetite samples and to determine the inter- and intra- sample variation in the magnetite chemistry.

Title: Discrimination between different VMS deposit subtypes in the Bathurst Mining Camp using the trace element composition of magnetite

Presenter/First Author: Sheida Makvandi, Laval University, Quebec,

Presenter/First Author Email: sh.makvandi@gmail.com

Co-authors: Georges Beaudoin, Laval University, Quebec City, QC, Canada; Massoud Ghasemzadeh-Barvarz, , , ; Eric C Grunsky, Geological Survey of Canada, Ottawa, ON, Canada

Abstract Body: Magnetite grains from 4 felsic-siliciclastic VMS subtypes including Austin Brook deposit, Brunswick #12, Brunswick #6, and Halfmile Lake deposit and the respective alteration zone, and from a mafic VMS subtype, Turgeon deposit, have been examined by the EPMA and the LA-ICP-MS for their major and trace element composition. The geochemical censored data were investigated using the robComposition package implemented in the software R. The data analysis was done using Partial Least Square-Discriminant Analysis (PLS-DA) to reveal hidden correlations among elements in magnetite composition causing discrimination between different VMS deposits. Petrographic studies distinguish 2 magnetite types: 1) magmatic magnetite characterized by ulvöspinel exsolution in Halfmile Lake gossan; and 2) hydrothermal magnetite formed by replacement of sulfides and/or silicates in the other VMS deposits, and in the Halfmile Lake respective alteration zone.

PLS-DA of magnetite composition from the selected VMS deposits shows that magnetite from Halfmile Lake gossan, grains from Halfmile Lake magnetite alteration zone, and magnetite from Turgeon deposit form distinct clusters. Magnetite grains from Austin Brook, Brunswick #6 and Brunswick #12 form overlapping clusters. However, the contribution score plots show that each of these clusters can be discriminated by a distinct mean composition (MC). Positive contribution of Al, Zn and Zr mainly characterize the Austin Brook MC, whereas the MC of Brunswick #6 is mainly discriminated by positive contribution of Zr, Mn and Zn. Positive contribution of Zn and negative contribution of Al are main factors in isolation of the MC of Brunswick #12. The contribution score plots suggest that magmatic magnetite from Halfmile Lake gossan is relatively enriched in Ga and depleted in Si, Ca and Mg, whereas hydrothermal magnetite from Halfmile Lake MAZ is relatively depleted in Mn and Zn, and enriched in Si, Al, and Mg. The MC of Turgeon cluster is mainly characterized by positive contribution of Ca and Mg and negative contribution of Ga. The results show that the chemistry of magnetite can be used to discriminate between felsic-siliciclastic and mafic VMS subtypes, and to distinguish different VMS deposits.

Title: Remobilization of PGE and Other Chalcophile Elements During the Metamorphism of the Massive Sulfide of the Delta Deposit (Raglan Area, Northern Quebec)

Presenter/First Author: Pierre-Jean Misson, PhD student, Chicoutimi, QC

Presenter/First Author Email: misson.pierrejean@gmail.com

Co-authors: Sarah-Jane Barnes, Université du Québec à Chicoutimi, Saguenay, QC, Canada; Philippe Pagé, Sciences de la Terre, Université du Québec à Chicoutimi (UQAC), Chicoutimi, Canada

Abstract Body: The Cape Smith Belt (ca. 1.9 Ga) in northern Quebec contains numerous Ni-Cu-PGE (platinum-group element) deposits associated with komatiitic basalts. The entire belt has then been affected by the Trans-Hudson orogen and the regional metamorphism in the Cape Smith Belt reached the upper greenschist-lower amphibolite facies (~450°C). The Delta deposit is composed of several lenses two of which are located in a fault zone. We have investigated whether there is remobilization of the PGE and chalcophile elements during the metamorphism and deformation of the massive sulfides.

Petrographical observations revealed that the ore is composed of pyrrhotite, pentlandite and chalcopyrite in magmatic proportions, thus major elements have not been affected. The pyrrhotite and pentlandite have recrystallized and the chalcopyrite contains deformation textures. The mantle-normalized patterns show that some fractionated samples (high Pd/Ir, low Cu) are as Pd, Pt-rich as the Cu-rich samples (residual sulfide liquid). In addition, the enrichment of some chalcophile elements (As, Sb, Cd) in Cu-poor samples compared to Cu-rich sample suggests that some elements have been mobile during the metamorphism. The LA-ICP-MS analyses reveal the presence of micro-inclusions (a few microns in size) of PGM within the recrystallized pyrrhotite or pentlandite. These micro-inclusions are mostly sperrylite ($PtAs_2$) in which signals for the IPGE (Os, Ir or Ru) are detected. This suggests that these PGM could be secondary exsolutions. Compared to other massive sulfide deposits (Aguablanca, Sudbury), the mass-balances reveal a strong control of the Pd by the pentlandite with close to 80% of the Pd being present in the pentlandite in the mss-cumulus samples. This is much more than observed in the other

massive deposits and could suggest the remobilization of the Pd into the pentlandite.

Our results are encouraging and tend to show there is a beginning of remobilization of metals within Ni-Cu-PGE massive sulfide at the upper greenschist facies.

Title: "White mica chemistry by *in-situ* LA-ICP-MS techniques: variation of volatile trace elements and its application in VMS deposit exploration"

Presenter/First Author: Azam Soltani Dehnavi, University of New Brunswick, Fredericton, NB

Presenter/First Author Email: a.soltanidehnavi@gmail.com

Co-authors: Christopher RM McFarlane, University of New Brunswick, Fredericton, NB, Canada; David Richard Lentz, University of New Brunswick, Fredericton, Canada

Abstract Body: *White mica is ubiquitous phase throughout the altered rocks enveloping the massive sulphide deposits of the Bathurst Mining Camp, Canada. It occurs largely as a potassic (sericitic) alteration product of quartzo-feldspathic volcaniclastic rocks, and as a pelagic component in clastic and exhalative sedimentary rocks. In this study a new tactic has been developed to quantify the composition of white mica by in situ LA-ICP-MS. The* high sensitivity of the LA-ICP-MS method allows the detection of trace elements at the sub-ppm level. Lack of any especial sample preparation and cost efficiency for examining a large number of grains make this methodology appropriate in academic and industrial applications. *LA-ICP-MS is an efficient method for examining fine grained phases in complex matrices by using <30 µm laser craters*. In this study, calibration was performed using NIST 610 as external standard, and an assumed stoichimetric Si concentration as internal standard.

The composition of white mica is defined as solid solution between muscovite and celadonite (phengitic) in the BMC. White mica shows extensive systematic substitutions (e.g., Tschermak substitution) allowing it to host a wide range of trace elements. Analyzing a large number of white mica by LA-ICP-MS demonstrates lattice-bound occurrence for the volatile trace elements. White mica accommodates high quantities of As (up to 1.12 wt.%), Sb (up to 4750 ppm), Tl (up to 697 ppm), and In (up to563), whereas Cd (from detection limit (0.14)-225 ppm), Hg (<0.16-67 ppm), and Bi (<0.04-49), occur in moderate values. Anomalous values recorded in the Louvicourt and Brunswick No. 12 deposits can be related to their genetic manifestation, for instance the former has signature analogous to high sulphidation VMS deposits. Compositional variations of white mica exhibit vectors for some of trace elements such as arsenic, antimony and thallium related to the mineralization. By proximity to the sulfide horizons, increasing values of As, Sb and Tl form the most extensive halos. Consequently, the results of this study indicate the existing of white mica trace element vectors at the deposit-scale. Application of this approach to the BMC as well as areas outside the camp demonstrates its prospective application in VMS exploration worldwide.

Title: Fingerprinting and Tracing the Signature of Basement Hosted Unconformity-type Uranium Alteration Through Thick Tills: an Example from the Thelon Basin, Nunavut

Presenter/First Author: Aaron Bustard, University of Waterloo, Waterloo,

Presenter/First Author Email: a.bustard@gmail.com

Co-authors: Martin Ross, University of Waterloo, Waterloo, ON, Canada; Brian Kendall, University of Waterloo, Waterloo, ON, Canada

Published Material: Preliminary results were presented as a poster at the 2014 GAC-MAC conference in Fredericton, NB.

Abstract Body: The Thelon Basin of Nunavut and the Northwest Territories exhibits great potential to host the next generation of unconformity-type uranium deposits. Exploration in the Thelon Basin is often complicated by nearly continuous cover of Quaternary sediments and lack of subcropping mineralization. Our investigation southeast of Aberdeen Lake is focused on deeper basement-hosted unconformity-type uranium mineralization with a subcropping alteration halo buried by till successions ranging from 12 to 34 m in thickness. The alteration haloes in the area are characterized by intense illitic alteration and present promising geochemical exploration targets. The goals of the study are 1) to fingerprint the alteration signature in the tills, 2) map the dispersion patterns, and 3) establish whether the alteration footprint in the till reaches the ground surface. Drill core samples of till combined with surficial mudboil sampling over the subcropping alteration allows for 3D modelling of glacial dispersal of material from the halo. Geochemical data is complemented by textural, pebble lithological, and clay mineralogical data to define alteration trends in the till. Analysis of the data using multivariate statistics, including principal component analysis, has proven to be useful for discriminating till units and identifying alteration signatures. The strongest observed geochemical signatures of alteration include enrichment in B, Al and K, with depletions in Na, Ba, Mn, and Sr. Tracing the dispersal of the alteration signature is complicated by the presence of multiple till units deposited during different ice flow events. The elusive 'secondary' alteration footprint and the complex nature of glacial dispersal patterns in the study area highlights the need for enhanced integration of data, methods, and knowledge into exploration programs, especially in areas of thick Quaternary sediment cover.

Title: The Brucejack Intermediate Sulfidation Epithermal Au-Ag Deposit, Northwestern British Columbia

Presenter/First Author: Sean Patrick Tombe, University of Alberta, Edmonton,

Presenter/First Author Email: stombe@ualberta.ca

Co-authors: Jeremy P. Richards, University of Alberta, Edmonton, AB, Canada; Charles James Greig, Pretivm Resources Inc, Vancouver, BC, Canada; Warwick S Board, Pretivm Resources Inc, Vancouver, BC, Canada; Robert A Creaser, University of Alberta, Edmonton, AB, Canada; Richard M Freidman, , , ; Peter B Larson, Washington State Univ, Pullman, WA

Published Material: GAC Fredericton Meeting May 2014- findings are not yet under review and have not been accepted by a scientific journal

Abstract Body: The Brucejack intermediate-sulfidation epithermal Au-Ag deposit is one of many world-class porphyry and epithermal deposits that formed in association with extensive volcanic arc-related magmatism in Late Triassic–Early Jurassic time in the Canadian Cordillera. Mineralization at Brucejack is hosted by Early Jurassic porphyritic latite flows, block and ash flows, and volcanic sandstones, siltstones and conglomerates. Oldest estimates for these variably altered and mineralized porphyritic flows are 196.4 ± 0.7 Ma (U-Pb zircon). Age estimates for mineralization at Brucejack range between 191.7 ± 0.8 Ma and 188.9 ± 0.8 Ma (Re-Os molybdenite).

Brucejack is crosscut by late stage trachybasaltic dykes dated at 182.7 ± 1.0 Ma (U-Pb zircon), which truncate all mineralized veins, and are crosscut by barren (post-mineralization) quartz-dominated veins. Six vein stages have been recognized at Brucejack, with high-grade Au mineralization occurring in stages II, III, and IV. Fluid inclusions within these auriferous high-grade veins have relatively low homogenization temperatures (~160˚C) and broad ranges in salinity (0.5 to 15.5 wt. % NaCl equiv.), suggesting fluid mixing. Evidence for boiling is recognized in all mineralized veins, and is thought to be the principal mechanism for Au mineralization deposition. Temperature-corrected oxygen isotopic compositions of Au-bearing vein quartz and vein calcite indicate $d^{18}O_{fluid}$ values of -1.5 to -8.0 ‰ and 1.4 to -10.2 ‰ respectively, ranging from modified magmatic to meteoric water values, and suggesting mixing between these fluid sources. Carbon (vein calcite: $d^{13}C_{CO2}$ = -8.4 ± 0.2 ‰, *n*= 22) and sulfur (vein pyrite, sphalerite, and galena: $d^{34}S$= -0.8 ± 0.3 ‰, *n*= 10) isotopic compositions also suggest a magmatic source for these elements, possibly with a minor crustal component. Gold is inferred to have been sourced from these magmatic fluids.

Title: Stratigraphy and structure of Archean lode gold deposits in the southeastern Rice Lake greenstone belt, southeastern Manitoba, Canada

Presenter/First Author: Xiaohui Zhou, Wuhan University, Wuhan,

Presenter/First Author Email: xiaohui.zhou@uwaterloo.ca

Co-authors: Shoufa Lin, University of Waterloo, Waterloo, ON, Canada; Scott D Anderson, Manitoba Geological Survey, Winnipeg, MB, Canada

Published Material: I reported part of the study as a poster at the Manitoba Minerals and Mining Convention 2014 and as an oral presentation at the Canadian Tectonic Group meeting 2014. Currently they are not under review or accepted by any scientific journal yet.

Abstract Body: The Central Manitoba and Ogama-Rockland gold deposits are located in the southeastern portion of the Archean Rice Lake greenstone belt in the Uchi Subprovince of the western Superior Province. These two deposits were investigated in the aspects of host-rock stratigraphy, deformation structure and vein systems through detailed bedrock mapping. Four generations (G_1–G_4) of deformation structures are recognized in the study area based on overprinting relationships.

The Central Manitoba deposit is hosted by quartz veins in feldspathic wacke, basalt and gabbroic sills within the Bidou assemblage of the Rice Lake belt. Stratigraphic sequence of host rocks is typically south facing. Auriferous massive quartz veins are dominantly hosted by west-trending dextral G_4 shear zones. Free gold is present in contacts with quartz, pyrrhotite and tellurobismuthite. Chlorite-sericite alteration is typically associated with mineralization.

The Ogama-Rockland deposit is hosted by quartz (-carbonate) veins in tonalite of the Ross River pluton (~2724–2728 Ma). Three vein sets (V_1–V_3) were identified based on crosscutting relations. Auriferous massive V_3 veins were likely emplaced late during the G_4 shearing, and are hosted by a conjugate set of north-to-northeast–trending sinistral shear zones and west-to-northwest–trending dextral shear zones. Free gold and minor gold inclusions are present within fractured pyrite, chalcopyrite and quartz. Chlorite-carbonate-sericite alteration is common. Mutual crosscutting relationships, gradational transitions and quartz segregations in the center of aplite dikes suggest a close temporal and possibly genetic relationship between quartz veins and aplite dikes.

In spite of contrasting host rocks, ore style and alteration, the two gold deposits share identical host-rock structure and structural timing of mineralization, indicating that gold mineralization shares a similar structural setting.

Title: The structural and geochronological evolution of the auriferous Santoy shear zone, northeastern Glennie domain, Saskatchewan

Presenter/First Author: Chase Robertson Wood, University of Regina, Regina,

Presenter/First Author Email: woodchase08@gmail.com

Co-authors: Kathryn M Bethune, University of Regina, Regina, SK, Canada; Michael A. Hamilton, University of Toronto, Toronto, ON, Canada

Abstract Body: The study area lies within the Pine Lake Greenstone belt of the Glennie domain, 125 km northeast of LaRonge, SK. The Santoy shear zone (SSZ) hosts the Santoy 7, Santoy 8/8 east, and “Santoy Gap” gold deposits. This shear zone was studied using a structural and geochronological (ID-TIMS) approach in order to decipher its complex relationship with plutonism, deformation, alteration and gold mineralization.

Surface and subsurface mapping reveals that the SSZ and deposits therein show a clear structural relationship towards the F_3 Carruthers Lake Synform. The Santoy 7, Santoy “Gap”, and Santoy 8 deposits lie along the western limb of this structure while Santoy 8 east has been reoriented by north trending 45° plunging S folds. The plunges of the ore shoots are parallel to this and coaxial to the plunge of the Carruthers Lake Synform. Appropriately oriented plutonic intrusions acted as structural anisotropies that nucleated shear zones and auriferous fault fill quartz veins along their margins during D_{3A} dextral reverse oblique slip movement. The age of these intrusions (1874.6±2.9 Ma and 1874.6±1.9 Ma) serves as a maximum mineralization age for these deposits. Geomagnetic anomaly data suggest that a quartz syenite pluton in the area acted as a buttress during D_3 and produced a compressional jog in the SSZ and increased fracture density and fluid flow during mineralization. The age of this intrusion (1807±7Ma) serves as a maximum age for the development of this flexure. Gold mineralization is closely associated with a calc-silicate alteration assemblage. This assemblage occurs synchronously with the main stage mineralization event. Titanite and zircon within this assemblage was dated to 1755±8 Ma indicating Syn-D_3 deposit formation and providing the most accurate age date for gold mineralization in the Glennie domain proposed to date. Beriliferous pegmatite dykes display an F_3 axial planar cleavage and crosscut auriferous zones. An age of 1736.1±1.9Ma for the dyke represents a minimum mineralization age for this system and a new minimum age for regional D_3 deformation in the Glennie domain.

Title: The Lower Detour Lake Au Discovery, Ontario, Canada: A High-Grade Oxidized Intrusion-Related Au Deposit

Presenter/First Author: Kelly James Malcolm, Mineral Exploration Research Centre, Sudbury, ON

Presenter/First Author Email: kj_malcolm@laurentian.ca

Co-authors: Daniel Kontak, Mineral Exploration Research Centre, Sudbury, ON, Canada; Douglas K Tinkham, Mineral Exploration Research Centre,

Sudbury, ON, Canada; John A Ayer, Laurentian University, Sudbury, ON, Canada; Guy MacGillivray, , ,

Abstract Body: Newly discovered (2014) high-grade Au mineralization in the Lower Detour Lake region of the Archean Detour Lake mining camp (NW part of the Abitibi Greenstone Belt, Canada) is hosted within high-level felsic porphyries located 7 km south of the spatially associated world-class orogenic-type Detour Lake Au deposit (15.5Moz Au at 1.02 g/t reserves, 4.8Moz at 1.11g/t resources, as of January 2014). The Au mineralization is hosted by a coalesced swarm of felsic dikes that intrude 2.72 Ga mafic volcanic rocks of the Deloro Assemblage, parallel to the main E-W structural fabric of the area. Within these felsic dikes, the Au mineralization is centered on widespread zones of phyllic alteration hosting arrays of vein quartz. The leucocratic dikes are variably feldspar phyric with Plg≥Kspar, have a range of Qtz:Plg ratios, and chemically are enriched in LILE with strongly fractionated REE patterns ($(La/Lu)_N \approx 8$-10)) and lack Eu anomalies ($Eu_N/Eu^* \approx 1$). Thus, the petrology of the dikes reflects melt extraction from an underlying magmatic source that evolved over time. The Au mineralization, which is characterized by a Bi ± W ± Te ± Ag elemental association, is localized to brittle-ductile zones flooded by quartz ± carbonate ± tourmaline ± pyrite veins with alteration halos enriched in sericite ± quartz ± carbonate ± pyrite ± albite ± chlorite ± biotite ± titanite ± epidote which reflect differing fluid:rock ratios and wall-rock bulk composition. The presence of inter-mineralized felsic dikes cross-cutting the mineralization suggests both a spatial and temporal relationship between the Au event and magmatism. Both the intrusive host rocks and mineralization/alteration have textures reflecting an intense ductile overprint. The characteristics of the Au mineralization and setting suggest affinities to the syenite-associated style of mineralization (e.g., Kirkland Lake) versus the orogenic style seen in the Detour Lake deposit, thus the new discovery equates to an oxidized intrusion-type gold deposit.

Title: Deformational and Metamorphic Processes in the Formation of the Bellechasse-Timmins Orogenic Gold Deposit, Southern Québec Appalachians, Canada

Presenter/First Author: Manon Valette, University of Quebec at Montreal, Montreal, QC

Presenter/First Author Email: amodulysse@yahoo.fr

Co-authors: Alain Tremblay, GEOTOP, Montréal, QC, Canada; Dany Boilard, , ,

Published Material: GAC-MAC 2014 - PosterGSA 2015 Northeastern part - Poster

Abstract Body: The Bellechasse-Timmins (BT) gold deposit is located 110 Km south of Québec City. It is hosted by the Ordovician Magog Group, a synorogenic forearc basin sequence in the Dunnage Zone of the Québec Appalachians, which has been deformed and metamorphosed at greenschist facies during the Acadian orogeny.

The Au mineralization is developed in diorite sills (and dykes) crosscutting the Upper Ordovician (Caradocian) Etchemin Formation, as the result of fracturing and variations in hydrothermal fluid pressure during regional metamorphism and deformation. The BT deposit consists of Au-rich quartz veins and stockwork hosted by faults and anastomosing shear zones formed at or above the brittle-ductile transition. Our structural analysis shows that both the intrusions and hosting sedimentary rocks are crosscut by a steeply-dipping, NE-trending axial-planar schistosity (S_1) and by 50 cm-to 2 metres-wide shear zones subparallel to that S_1schistosity. The shear zones host steeply-plunging slickenlines/lineations and preserved structural evidence for reverse faulting, mainly due to flattening and "locking up" of fold hinges, which have been sheared out by high-angle reverse faults. Subhorizontal lineations/fault striae are also locally found, suggesting late-stage strike-slip motion.

There are 3 main orientations of auriferous veins, almost perpendicular to each other, suggesting that the overall geometry of the ore zones is mainly controlled by and coeval with the regional folding event. It basically represents the product of hydrothermal circulation and fracturing related to regional metamorphism and folding affecting the diorite dykes/sills and the formation of saddle-reef and related structures. Fluids migrated along faults/shear zones and other weakness planes during folding and precipitated in favourable low-pressure dilation zones (e.g. faults, bedding planes, fold axes) created when the hydraulic pressure of trapped fluids exceeded the lithostatic pressure.

Title: Gold mineralization of the archean Orfée showing, Baie-James, Québec

Presenter/First Author: Adina Bogatu, Laval University, Quebec,

Presenter/First Author Email: adina.bogatu.1@ulaval.ca

Co-authors: François Huot, Laval University, Québec, QC, Canada; Carl Guilmette, Université Laval, Québec, QC, Canada; Jean Goutier, Géologie Québec, Rouyn-Noranda, QC, Canada; Georges Beaudoin, Laval University, Quebec City, QC, Canada; Antoine Rhéaume Ouellet, Laval University, Québec, Canada

Published Material: I presented a scientific poster with the data I obtained during Québec Mines of last year (2014).

Abstract Body: The Orfée gold deposit (~0.2 Mt at 14.5 g/t Au) is part of the La Grande Subprovince, in the Baie-James region. Discontinuous gold-rich zones are associated with an oxidized/silicate iron formation and with graphitic sediments containing up to 20% disseminated to massive pyrrhotite and pyrite, and are edged by basaltic amphibolites to the north and by wackes to the south. The graphitic sediments enclose <1% visible gold, as well a maximum gold content of 54.6 g/t in a gold-rich mylonitic corridor. The mineralization and its hostrocks, metamorphosed to the amphibolite facies, is 300 m north of the La Grande and Opinaca Subprovinces contact. The basaltic amphibolites are composed of hornblende, plagioclase and, locally, of biotite and garnet, and have an east-west oriented foliation. Plagioclase glomeroporphyritic horizons have been observed in the basaltic amphibolite unit. Tholeiitic and calc-alkaline geochemical signatures divide the basaltic amphibolites into two populations. Weakly plagioclase-phyric dioritic dykes, containing fine-grained mafic enclaves, cut across the amphibolites. These east-west foliated dykes intersect a pervasive garnet, hornblende, chlorite and pyrrhotite alteration affecting the amphibolites. The oxidized/silicate iron formation displays alternation facies characterized by quartz-plagioclase-rich, magnetite-rich and grunerite-hedenbergite-hornblende-garnet-sulphide-rich bands. The sub-vertical regional fabric was affected by a late dextral strike-slip movement, which explains the local thickening and boudinage of the iron formation. The wackes are composed of quartz, plagioclase and biotite and are affected by a S1 schistosity and a S2 foliation. Most of the wackes have geochemical signatures suggesting sources-derived intermediate component, while a small percentage have relatively high Mg, Cr, Ni content suggesting some sources-derived ultramafic component. The amphibolites, iron formation and wackes have been injected by a wide variety of deformed sterile quartz veins. Sheared and boudinaged pegmatite cuts across the wacke and amphibolite units. The metallogenic study of the Orfée showing will enable us to develop a model for the gold mineralization paragenesis, in relation with the geodynamic history of the La Grande – Opinaca contact.

Title: Geology of the metamorphosed Roberto gold deposit and tonalite-hosted Cheechoo discovery, Superior Province, James Bay Region, Québec, Canada

Presenter/First Author: Arnaud Fontaine, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City,

Presenter/First Author Email: arnaud.fontaine@ete.inrs.ca

Co-authors: Benoît Dubé, Geological Survey of Canada, Québec, Canada; Michel Malo, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, Canada; Vicki McNicoll, Geological Survey of Canada, Ottawa, Canada, ON, Canada; Tony Brisson, , , ; Dominique Doucet, Ressources Sirios Inc, Montréal, QC, Canada

Abstract Body: The world-class Roberto gold deposit, with resources of 4.03 Moz at 6.49 g/t Au and reserves of 4.10 Moz at 9.63 g/t Au, is a major discovery in the James Bay Region, located a few km south of the boundary between the La Grande and the Opinaca sub-provinces. Hosted by <2675 Ma sedimentary rocks, a structurally complex ≤ 70-80 m wide N-S trending mineralized envelope hosts various styles of mineralization. A large hydrothermal system is defined by distal calcium-rich metasomatism, proximal potassic alteration and Au-As-Sb-B signature. The main ore zones are characterized by quartz-dravite-microcline-phlogopite-arsenopyrite stockwork and replacement zones and by quartz-diopside-schorl-arsenopyrite veins while the high-grade zone is locally hosted by paragneiss. The bulk of the gold mineralization is confined within a steeply plunging ore shoot coaxial with an F_2 fold hinge.

Diversity of ore styles, mineralogy and geometry is in part related to i) lithological heterogeneity, ii) proximity to a granulitic metamorphic front, and iii) syn- to late magmatism. Paragneiss (<2685 Ma), which recorded a complex D_2 deformation, is exposed 1km east of the main ore zone illustrating the steep metamorphic gradient towards the Opinaca sub-province. Magmatism in the vicinity of the deposit includes granitic pegmatites (2620-2603 Ma), most of which have recorded the main phase of deformation (D_2) and postdate the bulk of the ore; however, some are undeformed, cut the main Roberto ore zone and contain clasts of foliated ore. Locally pegmatites host significant gold mineralization. The newly discovered CHEECHOO showing (up to 7.24 g/t Au over 7.9 m) is located about 10 km southeast of the Roberto deposit. The host tonalite yielded a preliminary U-Pb ID-TIMS zircon crystallization age of 2612 Ma. This age is similar to the pegmatites at Roberto, illustrating the complexity of the tectono-metamorphic setting and late-magmatic activity in the area, as well as the complex protracted or multi-stage nature of auriferous events.

Although clearly deformed and metamorphosed, the bulk of the gold mineralization is hosted by Timiskaming-age sediments, near the boundary between sub-provinces marked by a strong strain and metamorphic gradient, magmatism, local conglomerate, and therefore shares analogies with most Archean gold deposits

Title: Gold Metallogeny of the Southern Swayze Greenstone Belt: Poor or Rich Cousin to the Abitibi?

Presenter/First Author: Evan Carman George Hastie, Laurentian University, Sudbury,

Presenter/First Author Email: ehastie@laurentian.ca

Co-authors: Daniel Kontak, Mineral Exploration Research Centre, Sudbury, ON, Canada; Bruno Lafrance, MERC, The Goodman School of Mines, Laurentian University, Sudbury, ON, Canada

Abstract Body: The southern Swayze greenstone belt (SGB) is located approximately 40 km west of Shining Tree in northern Ontario and represents the southwestern extension of the Abitibi greenstone belt (AGB). The general consensus, based on years of mineral exploration and prospecting, is that the SGB is not as richly endowed as the AGB. The SGB and AGB share similar lithologies, stratigraphy, and deformation history. Two gold-rich fault systems, named the 'Rundle high strain zone' and the 'Ridout high strain zone', extend across the central and southern portions of the SGB, respectively, and represent the possible westward extensions of the Cadillac-Larder Lake deformation zone. Both of these high strain zones show spatial and temporal relationships to Timiskaming-like rocks and gold mineralization. Thus, these latter relationships together with the presence of the recently discovered world-class 2740 Ma intrusion-related Côté Gold deposit (indicated resource of 7.6 M oz. as of February, 2012) collectively suggest that the SGB may be as prospective as the AGB and offers an opportunity for new insights into Archean gold in a belt that is presently underexplored. To further our understanding of the Au metallogeny of the SGB, two deposits, the Jerome and 4K deposits, that constitute part of a regional Au metallogenic study of the SGB are discussed. The Jerome deposit is located within the Ridout high strain zone ≈ 20 km along strike ENE from the Côté Gold deposit. Given that this deposit is hosted in Timiskaming-like rocks that are cut by felsic porphyries, and is spatially related to a major deformation zone, it has obvious analogies to gold mineralization in the AGB, in particular Kirkland Lake area. The 4K deposit, located in a southern lobe of the SGB, represents epigenetic-type Au mineralization. In this case, Au occurs proximal to gr-grt-amph layers within banded iron formation, which is an important Archean-age Au deposit type globally (e.g., Musselwhite, Beardmore-Geraldton, Homestake). Despite the similarities between the SGB and the AGB, their gold endowments vary considerably and it is the goal of this project to determine reasons for this.

Title: Genesis of silver mineralization associated with the Anvil Batholith, Mt Mye Trend, Yukon, Canada

Presenter/First Author: Michael Rogers, Ithaca College, Ithaca, NY

Presenter/First Author Email: marogers@ualberta.ca

Co-authors: Sarah Gleeson, , , ; Matthew Dumala, Archer Cathro, Vancouver, BC, Canada

Abstract Body: The Keg Property is located 20km north of the mining town of Faro in south-central Yukon. It lies along the Mount Mye trend, a structural trend predominantly contained within the Cretaceous Anvil Batholith. The Hammer Zone, an epithermal style Ag±Zn-Pb system, is one of the most interesting prospects within the Mount Mye trend; assays of the Hammer Zone have produced silver grades in the thousands of grams per ton. In this study, the mineralization and alteration at the Hammer Zone are evaluated to determine the relationship between deposit and batholith, and to develop a deposit model.

The Hammer Zone prospect comprises three discrete ten to fifteen centimeter, sulfide bearing quartz-carbonate veins emplaced in a granodiorite host rock. The veins run almost N-S and are associated with sericitic, propylitic and argillic alteration. They were emplaced late in the development of the batholith and crosscut many late features such as pegmatites.

Transmitted and reflected light microscopy work, supported by analysis of mineral chemistry using the electron probe micro-analyzer, has yielded a paragenesis. There are two main sulfide events in the Hammer zone veins; (1) a carbonate hosted pyrrhotite stage associated with silver deposition, and (2) a quartz hosted pyrite stage. These are preceded by barren brecciation phases and post-dated by a chlorite- and hematite-forming event. Silver is present in stage 1 principally in sulfide form, although some oxidized forms exist. The silver-bearing mineral is freibergite, although there are also small amounts of Ag-bearing galena and other silver-bearing phases. Stable isotope work has been completed on the carbonate phases, and yielded $\delta^{13}C_{PDB}$ values of -9.0‰ to 2.8‰, and $\delta^{18}O_{SMOW}$ values of -2‰ to 9‰. Stable isotope work is currently ongoing for the vein quartz. Fluid inclusion analysis will constrain the temperature and salinity of the stage (1) carbonate and stage (2) quartz. These temperatures can be used to further understand the $\delta^{18}O_{SMOW}$ values of the mineralizing fluids and to assess the importance of boiling versus mixing in silver precipitation.

Title: A Nanoparticulate Origin for Orogenic Gold

Presenter/First Author: Mark A Pearce, CSIRO Earth Science and Resource Engineering Perth, Kensington, WA

Presenter/First Author Email: mark.pearce@csiro.au

Co-authors: Michael F Gazley, CSIRO Mineral Resources Flagship, Perth, Australia; Robert Hough, CSIRO (CESRE), Perth, WA, Australia; Martin Saunders, , , ; Louise Fisher, , , ; Charlie Kong, , , ; Guillaume Duclaux, CSIRO, North Ryde, NSW, Australia

Abstract Body: Gold concentrations in gold deposits are several orders of magnitude higher than in most ore forming fluids and up to five orders of magnitude more concentrated than in typical crustal rocks. At such low concentrations, vast quantities of fluids must pass through small rock volumes to deposit the metal found in even a modest deposit. Nanoparticulate suspensions or colloids present an alternative transport medium to the aqueous ionic gold complexes that are typically considered to have formed gold deposits. By combining micro-and nano-scale characterisation of the crystallographic and chemical variation in gold grains from the Plutonic Gold Mine, Western Australia, we present the first direct evidence that large, high economic grade, orogenic gold deposits may form from gold nanoparticles.

Electron backscatter diffraction (EBSD) shows that there micron-scale domains of orientation variation within the grain. At the sub-micron-scale these domains contain grains on the order of 50 – 100 nm that have a strong crystallographic texture. In between the gold nanoparticles are nanoparticles of platinum and platinum-iron alloy that have crystallised with the gold. 10 micron-scale inclusions of Fe-Ca aluminosilicate are also present within the gold grains. The inclusions contain nanoparticulate mixtures of gold, Fe-Ca-Al oxide and SiO_2, derived from the same transport medium as the gold. This hypothesis is supported by the strong spatial correlation between calcium-aluminium silicate alteration and gold throughout the deposit. The mixture of oxide and metal/alloy nanoparticles shows that large quantities of gold can be transported as mixed colloids with gold nanoparticles being prevented from coagulating by the oxides at temperatures in excess of 350°C. Post-depositional annealing of the nanoparticulate microstructure has not gone to completion meaning that we have the first evidence that colloids play an important role in orogenic gold deposits.

Title: Gold Mineralization and Genetic Evaluation in the North Khentei Gold Belt, Central Northern Mongolia

Presenter/First Author: Chinbat Khishgee, Mongolian University of Science and Technology, Ulaanbaatar,

Presenter/First Author Email: chinbat0905@yahoo.com

Co-authors: Masahide Akasaka, Shimane University, Matsue, Japan

Published Material: Khishgee, C., Akasaka, M., Ohira, H. and Sereenen, J. (2014) Gold mineralization of the Gatsuurt deposit in the North Khentei gold belt, central northern Mongolia. Resource Geology, 64, 1-16.

Abstract Body: Gold mineralization and crystallization sequences of ore-forming minerals in representative deposits of the North Khentei gold belt of Mongolia were investigated to characterize the ore genesis. The Au mineralization occurs as two ore types: I) disseminated and stockwork ores; and II) auriferous quartz-veins. Type-I mineralization in the ^{1}Boroo, ^{2}Gatsuurt and ^{3}Ulaanbulag deposits is composed of four distinct stages: (i) ^{1,2,3}pyrite-I + ^{1,2,3}arsenopyrite-I, (ii) ^{1,2,3}pyrite-II + ^{1,2,3}arsenopyrite-II, (iii) ^{1,2,3}sphalerite + ^{1,2,3}galena + ^{1,2,3}chalcopyrite + ^{1,2}tetrahedrite + ^{1,2}bournonite + ^{1,2}boulangerite + ^{2}jamesonite + ^{2}scheelite + ^{1}alloclasite + ^{1}native gold and (iv) ^{1,2,3}native gold. In Type-II mineralization, five, four and four crystallization stages are also recognized in these deposits, respectively: (i) ^{1,2,3}pyrite-I + ^{1,3}arsenopyrite, (ii) ^{1,2,3}pyrite-II + ^{1,2,3}arsenopyrite + ^{2}galena + ^{2}tetrahedrite-tennantite, + ^{2}sphalerite + ^{2}chalcopyrite + ^{2,3}bournonite, (iii) ^{1,3}sphalerite + ^{1,3}galena + ^{1,3}chalcopyrite + ^{2}geocronite + ^{2}geerite + ^{2}native gold, (iv) ^{1}tetrahedrite-tennantite + ^{1}bournonite + ^{1}geerite + ^{1,2,3}native gold, and (v) ^{1}electrum. Both ore types are associated with sericitic and siliceous alteration. At Boroo and Gatsuurt both ore types contain coexisting CO_2-rich and aqueous fluid inclusions. The inclusions in the Type-I ores homogenized between 254–362ºC, whereas Boroo Type-II ore inclusions homogenized between 237–305ºC. Fluid salinities in both ore types range from 3–6 wt% (NaCl equiv.). The U-Pb age of zircons from Boroo host granites of 472.5 ± 6.9 Ma is much older than previously defined alteration minerals ages (Fig.1). The results indicate that these gold deposits can be classified as contiguous orogenic-type gold mineralization that developed in two stages. Type-I ores are early stage, formed by hydrothermal metasomatic alteration, and Type-II ores are later stage, deposited due to rapidly cooling temperature of the hydrothermal fluids.

Title: Gold and Trace-element Content of Copper Sulphides of the Far Southeast Porphyry Cu-Au Deposit, Philippines

Presenter/First Author: Matt Bunce, University of Ottawa, Ottawa,

Presenter/First Author Email: mbunc048@uottawa.ca

Co-authors: Jeffrey W Hedenquist, , , ; Keiko Hattori, University of Ottawa, Ottawa, ON, Canada; Simon Jackson, Natural Resources Canada, Geological Survey of Canada, Ottawa, Canada

Abstract Body: The Far-Southeast porphyry Cu-Au deposit, northern Luzon, Philippines, is hosted within the Imbanguila diorite – dacite intrusion complex and formed at 1.3-1.4 Ma, making this one of the youngest porphyry deposits in the world. Far Southeast Gold Resources Inc, a joint venture of Lepanto Consolidated Mining Company and Gold Fields Ltd, recently completed 102 km of underground drilling and confirmed a resource of 892 Mt at 0.7 g/t Au and 0.5 wt% Cu. Previous studies identified native gold as blebs in sulphides, and also proposed the presence of gold micro-inclusions in sulfides. The present study focused on gold deportment using microscopy, SEM with EDS, and LA-ICP-MS. Bornite, chalcopyrite, pyrite, covellite and chalcocite (the latter two replacing bornite) were analyzed in samples that ranged in depth from ~1100 to 1550 m below surface. Gold occurs in or on the margins of sulphides as blebs (<10 um) of native gold (with ~8-15 wt% Ag), krennerite (Au_3AgTe_8) and petzite (Ag_3AuTe_2). LA-ICP-MS analyses of 28 points on sulphide grains that are free of mineral inclusions under SEM indicate that bornite has the highest Au content (≤8 ppm) in its crystal structure; Au in other sulphide minerals is <1 ppm. Locally high Au spikes in bornite are due to micro-inclusions (<1 um), mainly Au tellurides; Te is <1-58 ppm in the crystal structure (i.e., without a discernable phase) and correlates with Au content. High values of Bi (≤ 2160 ppm), Se (≤ 680 ppm) and Pb (≤ 1270 ppm) in bornite tend to correlate; high values of Bi (≤ 482 ppm) and Se (≤685 ppm) in covellite are associated with Pb (≤4 ppm). High Se (133-560 ppm) and Bi (147-5680 ppm) in bornite correlates with high Ag (70-180 ppm). Values of >550 ppm Se and Pb each in sulphides are due to micrometre-size inclusions of clausthalite (PbSe). Sn in bornite is <1 to 22 ppm and in covellite is ≤90 ppm; all sulphides contain <2 ppm Mo and As. We conclude that blebs of native gold and Au tellurides (most ≤10 um to inclusions <1 um in size) are responsible for much of the Au in the deposit.

Title: The Eocene Morrison porphyry Cu-Au-Mo deposit, Babine Lake area, British Columbia

Presenter/First Author: Lijuan Liu, USTC University of Science and Technology of China, Hefei,

Presenter/First Author Email: lijuan1@ualberta.ca

Co-authors: Jeremy P. Richards, University of Alberta, Edmonton, AB, Canada; Robert A Creaser, University of Alberta, Edmonton, AB, Canada; Andy Dufrane, University of Alberta, Edmonton, AB, Canada; Peter B Larson, Washington State Univ, Pullman, WA

Abstract Body: Morrison is a calc-alkaline porphyry Cu-Au-Mo deposit in the northern Babine Lake area of British Columbia. Mineralization is genetically and spatially related to Eocene plagioclase-hornblende-biotite porphyry intrusions, which intruded into the Upper Jurassic Ashman Formation of the Bowser Group sedimentary rocks. The plagioclase-hornblende-biotite porphyry intrusions yielded a U-Pb age of 52.21 ± 0.37 Ma. The mineralization can be divided into 3 stages: (1) vein-type and disseminated chalcopyrite and minor bornite (associated with potassic alteration); (2) vein-type molybdenite (associated with weak potassic alteration); (3) polymetallic sulfide-carbonate veins (dolomite ± quartz-sphalerite-galena-arsenopyrite-chalcopyrite; related to sericite-carbonate alteration). Re-Os dating of molybdenite from stage 2 yielded ages of 53.55 ± 0.22 and 52.69 ± 0.22 Ma. One of the ages (52.69 ± 0.22 Ma) overlaps within error the age of the plagioclase-hornblende-biotite porphyry and suggests a genetic relationship. Gold is associated with copper mineralization, whereas molybdenite mainly occurs at the edge of copper mineralization zone. Stage 1 vein fluids are higher temperature (Th = 400° to 524°C) and saline. (39.8 to 47.8 wt.% NaCl equiv.). Stage 1 disseminated chalcopyrite-pyrite mixtures have $\delta^{34}S_{CDT}$ compositions of -0.2 and 0.8‰, and calculated $\delta^{18}O_{fluid}$ values from vein quartz range from 5.1 to 7.9‰. These data suggest that the early Cu-Au mineralizing fluids were likely of magmatic origin. Stage 2 is associated with cooler and slightly less saline fluids (Th = 320° to 408°C; salinities = 37.0 to 43.1 wt.% NaCl equiv.). Molybdenite and pyrite from stage 2 veins have $\delta^{34}S_{CDT}$ values of -2.1 to -1.2‰ respectively, and calculated quartz $\delta^{18}O_{fluid}$ values range from 0.9 to 4.6‰, possibly indicating increased groundwater involvement. Fluid inclusions in stage 3 veins have homogenization temperatures of 163° to 218°C and salinities of 3.1 to 3.9 wt.% NaCl equiv. $\delta^{34}S_{CDT}$ compositions of sphalerite and pyrite from these veins range from -7.1 to -5.6‰, and the calculated maximum $\delta^{18}O_{fluid}$ values derived vein quartz range from -16.8 to -6.0‰. These data suggest that stage 3 is associated with a cool and dilute fluid, likely dominantly of meteoric water origin.

Title: Using Remote Sensing and GIS to Better Understand a Copper Porphyry Deposit (Peru)

Presenter/First Author: Niyomi Khalid, Western University, London, ON

Presenter/First Author Email: niyomi.khalid@gmail.com

Co-authors: Micha Pazner, Western University, London, ON, Canada

Abstract Body: This study concerns a copper porphyry which was recently discovered in Central Peru. The overall copper reserves are unknown and cannot be estimated from field inspection alone. The primary objective is to develop new Remote Sensing (RS) and GIS techniques. The second objective is to use these new techniques, along with existing methods, to map and interpret mineral, lithological and structural features.

The two primary RS data types used are medium-resolution ASTER data and high resolution Worldview-2 (WV-2) data. ASTER is a multispectral sensor, which has a broadband coverage (14 bands). ASTER's 14 bands are divided into three wavelength subsystems, with three bands in Visible and Near Infrared (VNIR), six in Short-Wave Infrared (SWIR) and five in the

Thermal Infrared (TIR) portion of the Electro-magnetic spectrum. ASTER's SWIR has sufficient spectral resolution to be used for lithological mapping and hydrothermal alteration mineral exploration associated with porphyry copper. WV-2 is a multispectral satellite with a high spatial resolution of 1.84m.

The study area is about 2x2km situated in a Cu-Mo porphyry belt in central Peru with a semi-arid climate and has considerable relief. The porphyry is approximately 50 million years old and the Pre-Andes orogeny, in which it is found, originated approximately 30 million years ago. The mineralized Cu-Mo porphyry system is dacitic in composition and intruded into the Cretaceous volcanics and the granodiorites of the Coastal Batholith. Most of the porphyry is phyllic altered and strongly leached with hematite/ferric capping and Cu-oxide occurrences.

Various RS-GIS techniques are used to aid in understanding the movement of copper in this deposit. These techniques include False Color Composites (FCC), band ratios, PCA for alteration minerals, and digital image classifiers for lithology. A Sobel edge fetection filter was implemented in MATlab for lineament mapping. A weighted omnidirectional shaded relief filter model was implemented in ArcGIS for structural mapping. ASTER and WV-2 are utilized in conjunction with SRTM DEM data. Results indicate ASTER is applicable to alteration minerals and lithology mapping, while WV-2 is effective in structural mapping.

Title: The Key Controls on Making Rare Earth-Rich Carbonatites

Presenter/First Author: Frances Wall, University of Exeter, Penryn,

Presenter/First Author Email: wall.sweeney@googlemail.com

Co-authors: Sam Broom-Fendley, University of Exeter, Penryn TR10 9FE, United Kingdom; Vicky Do Cabo, , , ; Emma Dowman, , , ; Dora Kavecsanszki, , , ; Ed Loye, University of Exeter, Penryn TR10 9FE, United Kingdom; Kate Moore, University of Exeter, Penryn TR10 9FE, United Kingdom

Published Material: Gathers together and analyses results from PhD and MSc theses, which are being prepared for various separate publications and have been presented as conference papers

Abstract Body: Deposits related to carbonatites are still the most important resource for rare earth elements (REE). Levels of light rare earths (La, Ce, Pr, Nd, Sm) can reach >10 wt% in some carbonatites, e.g. in the carbonatite mines at Mountain Pass, USA and Mount Weld, Australia, and although enrichment in the higher atomic number 'heavy' REE is rare, it does occur, and the deposit under exploration at Lofdal, Namibia is an example.

Results from our studies at Songwe, Chilwa Island and Kangankunde, Malawi, at Lofdal, Namibia; Mountain Pass and Mount Weld help towards a better understanding of the key controls needed to produce high enough levels of REE, in large enough quantities, to be of economic interest.

Carbonatites originate from small degree partial melts in the mantle. The most important control on production of large REE-rich carbonatites may be geodynamic environment or a changing mantle through geological time. Whatever the source, it is hard to envisage creating a REE-rich carbonatite without fractionation of magma during the journey into the upper crust. Apatite is the most important single mineral control on fractionation of REE in carbonatite magmas.

Many REE-rich carbonatites form in transition environments and show pegmatoid textures. All have evidence of substantial fluid activity, including fluid metasomatic aureoles around the carbonatite, explosion breccias and subsolidus fluid activity within the carbonatite intrusions. REE-bearing mineralizing fluids follow earlier fenite fluids out into the metasomatic aureole. Mantle source is the ultimate control on the heavy REE-enriched carbonatite at Lofdal but hydrothermal processes are key to precipitation of the ore minerals.

Subsequent alteration can provide further upgrading, for example the concentration of insoluble components during weathering at Mount Weld and the wholesale reworking of probable earlier carbonatite dykes during metamorphic and metasomatic alteration at Bayan Obo, China.

Title: Rare earth deposits associated with carbonatites: little-known stats and facts every explorationist should know

Presenter/First Author: Anton Chakhmouradian, University of Manitoba, Winnipeg, MB

Presenter/First Author Email: chakhmou@cc.umanitoba.ca

Co-authors: Ekaterina Reguir, University of Manitoba, Winnipeg, MB, Canada; Jindrich Kynicky, , , ; Cheng Xu, , ,

Abstract Body: There are three principal types of rare-earth deposits associated with carbonatites, listed in order of decreasing historical importance: (1) primary magmatic, (2) supergene, and (3) hydrothermal-metasomatic. Primary magmatic deposits have been of historic significance, but are gradually giving way to supergene sources containing higher grades and a relatively larger proportion of heavy REE. Primary REE deposits are scarce for reasons that we are just beginning to understand and place in a global geodynamic context. Phosphorus cycling through mantle sources of carbonatitic melts and early apatite fractionation from these melts appear to figure prominently in REE metallogeny. For purely subjective reasons, igneous provinces that should have been at the forefront of REE exploration activities, have been largely neglected. Hydrothermal reworking of carbonatites has a significant effect on their REE budget, and is generally conducive to the development of high-grade, but localized mineralization. Development of hydrothermal-metasomatic deposits is hampered by their typically small size and mineralogical factors, such as elevated contents of REE-Ca(± Sr, Ba) carbonates. Supergene deposits in (reduced) laterites have very favorable economic parameters, but pose greater metallurgical challenges. Contrary to the popular opinion, carbonatite-hosted projects can compete with other bedrock deposit types in the critical REE market.

Title: Hydrothermal transport, deposition, and fractionation of REE: Experimental data and thermodynamic calculations

Presenter/First Author: Artaches A Migdissov, Los Alamos National Laboratory, Los Alamos, NM

Presenter/First Author Email: artas65@gmail.com

Co-authors: Anthony E. Williams-Jones, McGill University, Montreal, QC, Canada; Alexander Timofeev, McGill University, Montreal, QC, Canada

Abstract Body: Evidence collected from natural systems suggests that hydrothermal transport and deposition often play a key role in concentrating the REE to economically exploitable levels. Understanding the chemical mechanisms responsible for the aqueous mobilization/deposition of the REE at elevated temperature is, thus, crucial for developing predictive models of REE ore formation. The stability of the aqueous complexes which the REE form with various ligands at elevated temperature is the key factor controlling the concentration and mobilization of REE in hydrothermal systems. An additional control is imposed by the solubility of the minerals which bind and cause precipitation of the metals of interest.

Over the past two decades, a substantial body of experimental data has been collected on the stability of REE species in aqueous fluids at high temperature. These data suggest that the speciation of the REE in hydrothermal solutions up to 300ºC is significantly different from that predicted by the theoretical models, which are still widely employed to evaluate REE mobility in nature. Moreover, in contrast to an earlier belief, these data demonstrate a pronounced dependence of the stability of some species on the atomic number of the REE, an effect that can cause REE fractionation in some hydrothermal processes.

In this contribution, we report the results of thermodynamic calculations re-evaluating the mechanisms responsible for the hydrothermal transport and deposition of the REE, based on the latest experimental data. We also evaluate the fractionation effects that can be observed during leaching/deposition in various natural environments.

Title: The Sullivan Island Carbonatite Complex and Its Relationship to Late Alkalic Magmatism in the Central Metasedimentary Belt boundary tectonic zone, Grenville Orogen, Southeastern Ontario

Presenter/First Author: Robert Michael Easton, Ontario Geological Survey, Sudbury, ON

Presenter/First Author Email: mike.easton@ontario.ca

Abstract Body: The little studied Sullivan Island carbonatite complex is exposed in and along the Ottawa River 90 km northwest of Ottawa, and is hosted in deformed upper amphibolite facies gneisses of the boundary zone (CMBbtz) that separates the Central Metasedimentary and Central Gneiss belts of the Grenville Orogen. The complex consists of fenitized country rock and a breccia composed of a matrix of calcitic silicocarbonatite (~20% SiO_2) rich in strontium (5955 ppm) and a variety of variably fenitized country-rock fragments. REE-bearing phases in the complex are predominantly fluorapatite and allanite, with the latter forming large crystals. Small grains (<20µ) of synchsite, bastnasite and barian-strontianite are also present. Abundant scapolite within the silicocarbonatite may indicate the presence of Cl- and F-rich fluids. Radioactive mineralization in the complex is limited, but, 2 U-Th airborne gamma-ray spectrometric highs, 1 assayed at 927 ppm U and 2717 ppm Th by scintillometer, occur immediately south of the complex along the north-trending Ross fault, which may have controlled emplacement of the complex.

An unpublished U-Pb zircon age of circa 1050 Ma, obtained in the early 1980s from the siliciocarbonate, is likely an emplacement age, as it is consistent with the presence of zircon grains in the silicocarbonatite matrix, and with a minimum age for the complex based on a cross-cutting mafic dike of the 590 Ma Grenville dike swarm. Furthermore, volumetrically significant alkaline magmatism occurred along the length of the CMBbtz in Ontario between 1055 and 1030 Ma, resulting in the emplacement of nepheline syenite and syenite intrusions and calcite-diopside±scapolite±apatite vein dikes (pseudocarbonatites of Mitchell 2005), and the development of REE-bearing metasomatized marbles characterized by pink-orange calcite. Thus, the Sullivan Island carbonatite complex is likely related to this Grenvillian alkaline magmatic event, and its location in the younger Ottawa-Bonnechere graben may be simply fortuitous.

Title: The Solubility and Speciation of Tantalum in Fluoride-Bearing Aqueous Solutions

Presenter/First Author: Alexander Timofeev, McGill University, Montreal, QC

Presenter/First Author Email: alexander.timofeev@mail.mcgill.ca

Co-authors: Artaches A Migdissov, Los Alamos National Laboratory, Los Alamos, NM; Anthony E. Williams-Jones, McGill University, Montreal, QC, Canada

Abstract Body: Recent investigations (in press) have demonstrated that niobium is mobile in aqueous fluids at elevated temperature, and that this mobility increases with higher fluoride activity. There are, however, no data on the solubility and speciation in aqueous solutions of its geochemical “twin”, tantalum. Such data would permit assessment of the relative mobility of niobium and tantalum in hydrothermal fluids and their fractionation in various geologic environments. As with niobium, hard acid-soft base (HSAB) considerations suggest that fluoride is the ligand most likely to form stable complexes which will facilitate the development of significant concentrations of tantalum in hydrothermal fluids. Results of previous experiments by Zaraisky et al. (2008) conducted with columbite-(Mn) in fluoride-bearing solutions at elevated temperature and pressure suggest that tantalum is an order of magnitude less soluble than niobium, but no thermodynamic data or equilibrium constants were derived from these experiments.

In this study, we determined the solubility of tantalum oxide in aqueous solutions at elevated temperature (100-250 °C), variable fluoride activity (~10^{-5}-10^{0} mF), and variable pH (2.0 and 2.8). Our experiments involved determining the solubility of tantalum oxide in F-bearing aqueous solutions at temperatures up to 250 °C and vapour-saturated water pressure. The experiments were performed using the autoclave solubility method and employed a technique involving teflon tubes, which was developed previously for determining the solubility of REE fluorides in F-bearing solutions.

Preliminary results indicate that the speciation and solubility of tantalum are dependent on the activity of fluoride in the aqueous solution. At low fluoride activity (~ $<10^{-2.5}$ mF), niobium solubility is low, whereas at higher fluoride activity (~ $>10^{-2.5}$ mF), the solubility of tantalum increases by multiple orders of magnitude. However, at an equivalent fluoride activity the solubility of tantalum is more than an order of magnitude less than that of its twin, niobium. The rapid increase in tantalum solubility at higher fluoride activity is similar to that observed for Nb, and suggests that tantalum may dissolve as a hydroxide or hydroxyl-fluoride species in our experiments.

Title: Y and HREE Mineralization in the MAW Zone, Athabasca Basin: Petrography and Fluid Inclusion Studies

Presenter/First Author: Morteza Rabiei, University of Regina, Regina,

Presenter/First Author Email: Rabeiemorteza@gmail.com

Co-authors: Guoxiang Chi, University of Regina, Department of Geology, Regina, SK, Canada, Regina, SK, Canada; Charles Normand, Saskatchewan Ministry of the Economy, Saskatchewan Geological Survey, Regina, SK, Canada

Abstract Body: The MAW Zone REE deposit represents one of the largest heavy REE and Y concentrations inside the Athabasca Basin in northern Saskatchewan. The deposit is located in the southern part of the basin between the Key Lake and McArthur River unconformity-related uranium deposits. The spatial association of this deposit with unconformity-related uranium deposits and faults that parallel a basement high (“quartzite ridge”) led geologists to consider a genetic relationship between each.

Petrographic examination of the host sandstone shows that it has been subjected to silicic, argillic, and dravitic alteration, and is cut by abundant fractures filled with dravite and drusy quartz. Also present in the altered sandstones are minor amounts of zircon, clays, iron oxides, and galena. Xenotime as the ore mineral is generally scarce in the samples examined, but is locally abundant in brown patches in the sandstones. Petrographic studies suggest that mineralization took place after significant compaction of the sandstones. The drusy quartz contains liquid-rich biphase inclusions, vapour-dominated inclusions with various vapour percentages, and daughter-mineral–bearing inclusions. The coexistence of these fluid inclusions suggests a boiling hydrothermal fluid system and heterogeneous trapping of fluid inclusions. Homogenization temperatures of the liquid-dominated biphase inclusions range from 71° to 138^{o}C, and the ice-melting temperatures range from -10.4° to -27.1^{o}C, corresponding to salinities from 14.4 to 24.9 wt.% NaCl equivalent. The ice-melting temperature and salinity data are comparable to those reported for unconformity-type uranium deposits present in the same general area, but the homogenization temperatures are relatively low. The potential genetic relationship between the REE mineralization and the unconformity-type uranium deposits needs to be further constrained from geochronological and stable isotopic studies.

Title: In situ U-Pb geochronology, Hf and Sm-Nd isotopic characteristics of zircon, titanite, apatite and monazite from the Hoidas Lake REE mineralization, northern Saskatchewan, Canada

Presenter/First Author: Krisztina Pandur, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: lewendula@gmail.com

Co-authors: Kevin Michael Ansdell, University of Saskatchewan, Saskatoon, SK, Canada; Christopher RM McFarlane, University of New Brunswick, Fredericton, NB, Canada; John M. Hanchar, Memorial University of Newfoundland, St John's, NL, Canada; Charlie T. Harper, , ,

Abstract Body: The diopside-allanite veins and apatite breccia veins of the Hoidas Lake rare earth element (REE) deposit were emplaced along the Hoidas-Nisikkatch Fault, an inferred subsidiary of the regional Black Bay Fault, and cross-cut the strongly deformed Archaean and Paleoproterozoic granitoid gneisses of the Rae Province. We report on the results of laser-ablation ICP-MS U-Pb geochronology of zircon and titanite from the diopside-allanite veins and green apatite and monazite from the apatite breccia veins, Hf isotopic data of zircon and Sm-Nd isotopic compositions of titanite, apatite and monazite, in an attempt to constrain the age of the REE mineralization, and to provide implications on its magmatic source.

Geological relationships and in situ U-Pb data indicates that the REE veins formed during and after peak metamorphism, which occurred at ca. 1.9 Ga. However, there are zircon crystals in the diopside-allanite veins with concordant U-Pb ages of ~2350 Ma which are interpreted to be inherited from granitoids that formed during the Arrowsmith Orogeny. Zircon rims with concordant U-Pb ages around 1906 Ma are inferred to represent zircon growth during the emplacement of the REE veins, based on textural features and the difference in Hf isotopic composition of rims vs. cores (εHf(t) of approximately -5 vs. 30, respectively). Titanite and monazite yielded concordant U-Pb ages ranging from ca. 1931 to 1825 Ma, whereas green apatite defined a discordant array with an upper intercept of ~1814 Ma. The calculated εNd(t) values of titanite, green apatite and monazite (-15.3 to -10.9) are comparable to εNd(t) values reported for the Martin Group alkali basalts in the Beaverlodge Domain and the Christopher Island Formation in the Baker Lake Basin, both of which also yielded similar U-Pb ages, suggesting that these alkali units originated from a similar source, most probably an ancient and compositionally complex lithospheric mantle reservoir.

Title: Airborne Geophysics for Rare Earth Element Exploration

Presenter/First Author: Olivier Ayotte, Organization Not Listed, Montréal, QC

Presenter/First Author Email: olivier_ayotte@yahoo.com

Co-authors: Olivier Nadeau, Organization Not Listed, Washington, DC; Timothée Fortin LaMothe, , ,

Abstract Body: Abstract:

The Lake Leroux REE project is localized in the upper Gatineau region, Quebec Canada, 265 km NW of Montreal and 100 km N of Mont-Laurier.

Geological setting: The calc-silicate rocks of the Grenville Group are in contact with

Pre-Grenville granitic gneisses. The contact zone is cut by dikes of REE rich pegmatites.

Mineralogy synthesis: Magmatic rock, layered and probably metamorphosed , not magnetic, radioactive. Name: Syenite charnockitique, the mineralization is associated with hydrothermal alteration of pyroxene. The pyroxene are altered in a matrix of quartz and potassium feldspar.

On the outskirts, pyroxene contains thorium. At heart, it is altered in allanite (REE). The altered pyroxene in allanite is then cut by britholite veinlets. Hydrothermal mineralization in britholite and allanite (traces). Traces of hydrothermal zircon. Potassium Feldspar 70%, Quartz 15%, Pyroxene (thorium) (15%)

Geophysical Surveys: An Airborne Geophysical Survey covering 500 Line Kilometers of Aeromagnetic Gradiometer and Spectrometric was flown.

The Survey results indicate an N-S trending magnetic anomaly with a distinct break in the trench south of the central point. Samples taken from the edge of the discontinuity show elevated amounts of mineralization. To date ground fellow-up has uncovered more than 188 ground spectrometric anomalies. Richest samples were collected around the Hi/Low Magnetic Contrast, and high spectrometric counts area (Total Counts 500 cps and over).

Geochemistry: Samples shows up to 1, 6% TREO and up to 18% H+M+Y/TREO. More than 45 samples were analyzed by (ICP, ME-MS81) and 60 by XRF.

Ore Characterization : Bulk Samples (100 kg each) from 3 sites, will be analyzed by: " electron microprobe " to get a rough estimate of minerals present, " size- by- size" to get the basic levels for each size fraction based on ICP-MS and ICP-MP analyses , and possibly" QEMSCAN " to get an accurate estimate of minerals.

Title: Gold Mineralization at the Renabie Mine: The Importance of an Early Hydrothermal Vein Anisotropy on Shear Zone Localization

Presenter/First Author: Jordan McDivitt, Laurentian University, Sudbury,

Presenter/First Author Email: jmcdivitt@gmail.com

Co-authors: Bruno Lafrance, MERC, The Goodman School of Mines, Laurentian University, Sudbury, ON, Canada; Daniel Kontak, Mineral Exploration Research Centre, Sudbury, ON, Canada

Abstract Body: Gold mineralization in metamorphic terranes records the structural focussing of hydrothermal fluids of either magmatic or metamorphic affinity. The term “orogenic” emphasizes quartz-carbonate veins that are syn- to post-peak regional metamorphism in timing. Detailed outcrop-scale mapping and sampling at the former Renabie mine (~1.1 Moz Au) within the Wawa subprovince of Ontario suggests that the shear zone-hosted, sericite-banded quartz veins predate deformation. These gold bearing-banded veins are enriched in Ag, Bi, Mo, Pb and Te, and are hosted by ca. 2741 granitoids of the Wawa terrane directly marginal to volcanic units of the Michipicoten greenstone belt. Three deformation events (D_1-D_3) account for the observed vein geometries along the main east-striking mineralized structure. The early sericite-banded quartz veins occupy the centers of east-east southeast trending, reverse-sinistral D_2 shear zones. Although there is a spatial association between the banded veins and D_2 shear zones, the veins are overprinted by F_1 and F_2 folds, suggesting that they were emplaced early with respect to both deformation events. Gold-bearing pyrite veins were generated late relative to the D_2 event possibly during D_3 reactivation of the shear zones as dextral transcurrent fault zones. The intimate spatial association between the sericite-banded veins and D_2 shear zones suggests that the veins acted as a pre-existing anisotropy, which facilitated the initiation and propagation of the shear zones that then acted as conduits for the migration of hydrothermal fluids. The results of this study have implications for genetic models regarding gold deposits in metamorphic terranes by illustrating that the presence of early veins and altered domains, mineralized or barren, can subsequently focus strain and localize later vein generation. Thus, the Renabie mine exemplifies how composite veins can form during multiple events in a shear-zone hosted gold deposit.

Title: Unravelling the Archean to Proterozoic History at the Meliadine Gold District, Nunavut, Canada

Presenter/First Author: Christopher Lawley, Natural Resources of Canada, Ottawa, ON

Presenter/First Author Email: clawley@nrcan.gc.ca

Co-authors: Vicky McNicoll, Geological Survey of Canada, Ottawa, ON, Canada; Robert A Creaser, University of Alberta, Edmonton, AB, Canada; Benoît Dubé, Geological Survey of Canada, Québec, Canada; Patrick Mercier-Langevin, , , ; Sally Jane Pehrsson, Geological Survey of Canada Ottawa, Ottawa, Canada

Published Material: Part of these findings (Re-Os ages and U-Pb monazite ages) were presented at 'Geology Matters' (November 2014, Halifax) and the Yellowknife Geoscience Forum (November 2014, Yellowknife). Some of these findings (Re-Os ages and U-Pb monazite ages) comprise part of a manuscript submitted to Economic Geology. However, new U-Pb dettrital zircons have not previously been reported.

Abstract Body: The Meliadine gold district comprises a combination of orogenic greenstone- and BIF-hosted gold mineralization. The largest gold deposits (e.g., Tiriganiaq) occur north of the NW-trending Pyke Fault and/or along its E-trending splays. New U-Pb detrital zircon ages suggest that greenschist to amphibolite facies turbiditic and mafic volcanic host rocks were deposited ≤2.66 Ga, in agreement with the inferred age of the Rankin Inlet greenstone belt at ca. 2.66 Ga. However, a polymictic conglomerate south of the Pyke Fault was deposited ≤2.50 Ga and confirms that the Rankin Inlet greenstone belt comprises intercalated Archean to Paleoproterozoic supracrustal successions.

Gold in the district is paragenetically late and occurs at arsenopyrite grain boundaries, fracture fills, and/or as clusters of gold inclusions associated with variably recrystallized arsenopyrite domains and hosted within hydrothermally altered and veined BIF. These micro-textures suggest that sulphide recrystallization liberated gold that was remobilized, at least locally, into low-strain microtextural sites along with other precious- and base-metals during a late fluid-assisted event(s). We propose that remobilization was concomitant with the growth of hydrothermal xenotime and monazite (1.86–1.85 Ga), which post-date arsenopyrite and occur together with gold. New Re-Os arsenopyrite model ages range from 2.3–1.8 Ga, whereas replicate analyses of the two most Re-rich and homogeneous arsenopyrite samples yield Re-Os model ages at ca. 2.27 and 1.90 Ga. We speculate that gold at the Meliadine gold district was initially introduced at 2.27 Ga and/or 1.90 Ga along with arsenopyrite and was subsequently remobilized, coupled with arsenopyrite recrystallization, during the Trans-Hudson orogeny at 1.86–1.85 Ga.

Title: *Key parameters controlling the genesis of the BIF-hosted Meadowbank gold deposit, Churchill Province, Nunavut*

Presenter/First Author: Vivien Janvier, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Québec,

Presenter/First Author Email: vivien.janvier@ete.inrs.ca

Co-authors: Sébastien Castonguay, Geological Survey of Canada, Québec, Canada; Patrick Mercier-Langevin, Geological Survey of Canada, Québec, Canada; Benoît Dubé, Geological Survey of Canada, Québec, Canada; Michel Malo, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, Canada; Vicky McNicoll, Geological Survey of Canada, Ottawa, ON, Canada; Robert A Creaser, University of Alberta, Edmonton, AB, Canada; Benoît de Chavigny, , , ; Olivier Côté Mantha, Agnico Eagle Mines ltd, Val d'Or, QC, Canada; Sally Jane Pehrsson, Geological Survey of Canada Ottawa, Ottawa, Canada

Abstract Body: *The Meadowbank gold deposit is hosted in banded iron formations (BIF) of the ca. 2711-2710 Ma Pipedream-Third Portage volcanic sequence of the Woodburn Lake Group. This sequence comprises* several similar BIFs of which only one contains economical gold mineralization (Central BIF). Host rocks consist of greenschist to amphibolite grade intermediate to felsic volcaniclastic rocks, mafic and ultramafic rocks, quartzite and BIFs. Notwithstanding cryptic and strongly overprinted Archean tectonism, four phases of Proterozoic deformation have been regionally documented. In the Meadowbank deposit area, several generations of structures are recognized: 1) isoclinal F_1 folds and D_1 faults overprinted by 2) south-trending isoclinal F_{2a} folds and associated D_2 fault zones that cut ore zones. Late D_2 deformation consists of north-trending gentle F_{2b} folds, 3) open to closed SW-plunging F_3 folds, and 4) south-verging shallowly-inclined, open to tight, chevron-style F_4 folds. The bulk of the gold, *associated with pyrrhotite ± pyrite, is hosted in BIF. Gold-rich quartz-pyrrhotite-pyrite veins are present in volcaniclastic rocks intercalated with the BIF.* Grunerite and chlorite are common in mineralized BIFs, whereas muscovite, chlorite and pyrite dominate in volcaniclastic rocks. Biotite, Fe-Mg amphibole and garnet occur in higher metamorphic grade rocks to the south. Crosscutting relationships suggest that the gold was introduced along D_1 faults and was likely remobilized during D_2, especially along sheared contacts and F_{2a} fold limbs. Deposit- and regional-scale field work coupled with new U-Pb ID-TIMS zircon crystallization ages and lithogeochemistry indicate that the Meadowbank deposit is located at or near the boundary between two distinct lithological assemblages (2710 Ma and 2717 Ma) separated by plausibly long-lived fault zones that potentially have controlled gold deposition and distribution, a specific structural setting that is unique to the mineralized Central BIF.

Title: Key geological parameters of the BIF-hosted Musselwhite gold deposit, Superior Province, northwestern Ontario and implications for exploration.

Presenter/First Author: William Oswald, INRS-ETE, Quebec, QC

Presenter/First Author Email: william.oswald@ete.inrs.ca

Co-authors: Sébastien Castonguay, Geological Survey of Canada, Québec, Canada; Benoît Dubé, Geological Survey of Canada, Québec, Canada; Vicky McNicoll, Geological Survey of Canada, Ottawa, ON, Canada; John Biczok, Goldcorp, Thunder Bay, ON, Canada; Patrick Mercier-Langevin, Geological Survey of Canada, Québec, Canada; Michel Malo, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, Canada

Published Material: GAC-MAC talk in May 2013 in Fredericton; SOFW during fall 2014; GSC Current Research submitted and currently undergoing edition.

Abstract Body: Musselwhite is a world-class syn-deformation Au deposit hosted by amphibolite facies Algoma-type banded iron formation (BIF) comprised in the Mesoarchean North Caribou greenstone belt, Superior Province. The deposit is located just 2 km west of a major tectonic boundary with the ca. 2857 Ma Schade Lake gneissic complex. Detailed underground and surface mapping provides critical insights on the deposit- and regional-scale geological and structural settings of Au mineralization. The bulk of the Musselwhite ore is hosted in silicate-rich BIF and occurs as stratabound pyrrhotite replacements and associated silica flooding with local discordant qz±po veins. The ore zones are associated with D_2 high strain zones concentrated along hinges and strongly attenuated fold limbs of tight F_2 folds. The layered anisotropy induced by competent BIF and surrounding mafic and ultramafic volcanic rocks has clearly influenced the rheological response to D_2 deformation at all scales, and hence played an important role in Au-bearing fluids flow and ore formation and distribution. A polygenic conglomerate was discovered in the upper part of the stratigraphy. New U-Pb ages of ca. 2665 Ma on late-M_2 monazite provide a minimum timing constraint for the regional D_2 metamorphic/deformation event to which most of Au mineralisation is associated at Musselwhite.

Reappraisal of stratigraphic relationships supported by U-Pb geochronology indicates that the mine stratigraphy is inverted, part of the overturned limb of a kilometre-scale F_1 syncline, in agreement with multiple occurrences of mesoscopic refolded F_1 folds. Previously unrecognized regional F_1 folding, which is strongly overprinted by the dominant D_2 deformation, has undoubtedly influenced the distribution and geometry of the BIF units hosting the bulk of Au mineralisation and provides new vectors for exploration at regional scale. The importance of a major fault and the presence of conglomerate in the upper stratigraphic sequence provide guidelines for exploration throughout the greenstone belt, especially when combined with tightly folded silicate-rich BIF horizons in altered anisotropic succession.

Title: Hydrothermal Chromium Mobility in the MacLellan Au-Ag Deposit: Implications for Petrogenetic Interpretation

Presenter/First Author: Evan Carman George Hastie, Laurentian University, Sudbury,

Presenter/First Author Email: ehastie@laurentian.ca

Co-authors: Joel E Gagnon, University of Windsor, Windsor, ON, Canada; Iain M. Samson, University of Windsor, Windsor, ON, Canada

Abstract Body: The MacLellan Au-Ag deposit is located approximately 7 km NE of Lynn Lake, Manitoba and is hosted by a sequence of mafic metavolcanic rocks that comprise part of the northern section of the Lynn Lake greenstone belt. Outcrop mapping, core logging, and petrographic analysis in combination with mineral and whole rock chemical analysis indicate that the host rock sequence was dominated by porphyritic metabasalt (now amphibole-plagioclase schist) with a tholeiitic composition prior to Au-Ag mineralization-related deformation and alteration. The amphibole-plagioclase schist has been subsequently affected by: 1) biotite ± quartz alteration during a syn-D_2 hydrothermal

event, and 2) chlorite + carbonate ± amphibole ± quartz alteration (with and without biotitic bands) during a syn-D_4 hydrothermal event. This second alteration style, which affects rocks for strike lengths of 100s of metres, is accompanied by significant increases in the abundances of Mg, Ni, and Cr relative to unaltered amphibole-plagioclase schist. Although mineralogical evidence of alteration was identified previously, its association with hydrothermal enrichment of Mg, Ni and Cr was not. Rocks identified in this study as deformed and altered amphibole-plagioclase schist (i.e., tholeiitic metabasalt) have been previously classified as 'high Mg-Ni-Cr basalts' or 'picrites', however, their association with hydrothermal alteration makes these magmatic classifications inappropriate. Evidence of mobility of elements routinely considered to be immobile in hydrothermal systems (i.e., Ni and Cr) and the resulting impact on identification of igneous protoliths has implications for greenstone belts in general where mafic to ultramafic metavolcanic rocks have been identified based on classification schemes that use Mg, Ni and Cr. This is particularly relevant to rocks that exhibit relatively high loss on ignition, evidence of shearing, and lack of equivalent, relatively unaltered rocks.

Title: Gold mineralization in the Belleterre mineral district, Pontiac Subprovince, Québec — relationships to deformation events and lamprophyre intrusions

Presenter/First Author: Mahamed Koïta, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Québec,

Presenter/First Author Email: mahamed.koita@ete.inrs.ca

Co-authors: Marc Richer-Laflèche, Institut national de la recherche scientifique, Québec, QC, Canada; Lyal B. Harris, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec, QC, Canada; Michel Jebrak, UQAM, Montreal, QC, Canada

Abstract Body: Lode gold in Belleterre Group volcano-sedimentary rocks 150 km S of Rouyn-Noranda in the Pontiac Subprovince of the Superior craton is known since the 1930s; the former Belleterre mine produced > 960,000 oz of gold at an average grade of 13.7 g/t. The area still harbours a promising gold potential. Numerous calcalkaline lamprophyre dikes, granodiorite and QFP intrusions cut through volcanic rocks and are present in most gold showings. Lamprophyre dikes are separated into (1) chlorite (after biotite), (2) hornblende-biotite and (3) biotite generations. Most lamprophyres predate lode-gold, although some host gold.

The first deformation phase (D1) produced regional structures and a penetrative cleavage (S1) oriented E-W in the southern part of the belt, progressively becoming N-S northward. The second deformation phase (D2) is characterized by a crenulation cleavage coplanar with the Belleterre anticline axial plane and shear zones. Some tonalite, granodiorite, monzonite and monzodiorite bodies intruded in D2. Conjugate faults formed in a third (D3) event. Mineralization comprises: (1) early lode gold that predates D1; (2) late-D1 veins up to 700 m long, varying from 10cm to 3m thick infilling faults and tensile fractures; (3) contemporary syn-D2 lode gold in very narrow shear veins, and veins in felsic intrusions. Fault-fill veins, controlled by syn-volcanic faults along basalt-gabbro contacts which focused hydrothermal fluids, display a multiphase paragenesis enriched in Py, Po, Sp, Ga, Cp ± quartz, ankerite, calcite, electrum and gold (associated with sulfides). Pyrite is the main sulfide mineral in some veins while pyrrhotite dominates in others, despite the greenschist facies metamorphism. The first episode of mineralization is characterized by disseminated pyrite containing sub-microscopic gold. The second episode consists of gold remobilized during peak metamorphism (continuing during retrograde metamorphism) and free gold with pyrrhotite, galena, and bismuth.

Title: Syn-Orogenic, Intrusion-Related Gold Mineralisation Associated with an Archean Compressional Fault in the Bachelor Mine, Desmaraisville, Abitibi, Canada.

Presenter/First Author: Sacha Marier Boston, University of Quebec at Montreal UQAM, Montreal,

Presenter/First Author Email: marier_boston.sacha@courrier.uqam.ca

Co-authors: Alain Tremblay, GEOTOP, Montréal, QC, Canada; Jérémie Lemarchand, , ,

Abstract Body: Located in the northeastern part of the Archean Abitibi greenstone belt (AGB), the orogenic gold mineralisation of the Bachelor mine is hosted by the 2730-2720 Ma Obatogamau Formation. The source of gold mineralisation is presumably related to the 2650-2680 Ma syenite of the O'Brien pluton, a late syn-orogenic intrusion of the AGB. This contribution presents our preliminary field observation and structural interpretation based on underground and surface geological mapping of the Bachelor mine.

The Desmaraisville area is located within the Lamark-Wedding structural corridor, a major NE-SW trending structure of the AGB. Two main structures host the mineralization in the Bachelor mine: (1) the "Main Structure", and (2) the "Wac (i.e. Waconichi) Structures". The "Main Structure" is approximately East-West trending (N105) and is sub-vertical or dips steeply to the south. It is host to a massive core of K feldspar-hematite-silica-pyrite (K-Hm-Si-Py) bounded by a dense stockwork of veins locally showing late-stage brecciation that is marked by abundant quartz-rich matrix. The "Wac structures" are frequently underlined by mylonitic shear zones, sometime brecciated, that are characterized by alternating bands of sericite-pyrite-silica (Ser-Py-Si) and K-Hm-Si-Py tectonic layers. Sericite seems to be a late phase of the mineral assemblage, sometimes overprinting the Hm-K rich layers. The "Wac Structures" trend N075 and dip approximately 60º to the southeast. Fault lineations and shear-sense indicators suggest a right-lateral reverse movement. Our preliminary observations suggest that the "Main" and "Wac" structures formed an anastomosed network of fractures relate to the auriferous hydrothermal fluids circulation. The junction of the "Main" and "Wac" structures corresponds furthermore to important mineralised pockets and constitutes high potential ore shoots. Note that the "Wac Structures" are strongly refracted within the "Main Structure" which significantly affects the ore zone geometry. These structures probably also represented preferential weakness planes that have been used for the upward migration of the O'Brien syenite into the Archean crust.

Title: A Mineralogical, Geochemical and Geochronological Study of Marathon Gold Corporation's Valentine Lake Gold Camp; Central Dunnage Zone, Newfoundland

Presenter/First Author: Monica Anne Barrington, Memorial University of Newfoundland, St. John's, NL

Presenter/First Author Email: barringtonmonica@gmail.com

Co-authors: Graham D Layne, Memorial University of Newfoundland, St John's, NF, Canada; Greg Dunning, Memorial University of Newfoundland, St John's, NF, Canada; Sherry M Dunsworth, , ,

Published Material: Some minor aspects (deposit location, QTP vein styles and host lithologies) outlined in the abstract have previously been presented (posters) by the author's during the Student Mineral Colloquium at PDAC 2014, and during the 2014 GAC Conference in New Brunswick. These same aspects have also been reported in publications and technical reports released by Marathon Gold Corp, at least annually, since 2011.

Abstract Body: Marathon Gold Corporation's Valentine Lake Gold Camp is located in the Exploits Subzone of the Dunnage Terrane of the Newfoundland Appalachians, approximately 20 km east of the main Iapetan suture - the Red Indian Line (RIL). The property contains numerous auriferous zones within a northeast-southwest trending mineralized corridor, largely hosted within Neoproterozoic (563 Ma) trondhjemite and associated phases of the Valentine Lake Intrusive Suite (VLIS). Gold mineralization occurs primarily within quartz-tourmaline-pyrite (QTP) veins, vein stockworks and adjacent selvedges. Minor gold also occurs within QTP networks containing varying amounts of carbonate, muscovite, chlorite, apatite and rutile - as well as in late base metal-rich quartz veins, and in en echelon quartz-carbonate-chlorite predominated veins and tension gashes. All vein networks reside in close proximity to a 30 km regionally extensive, brittle-ductile shear zone, which defines the eastern contact of the VLIS with a Silurian fault-scarp sequence, the Rogerson Lake Conglomerate (RLC). A suite of heterogeneously deformed basaltic and gabbroic dykes, variably transposed toward the penetrative regional foliation, also traverse the property. Detailed ore petrography has identified pre-native gold precious metal-telluride and post-native gold base metal-telluride assemblages in all QTP vein networks. Locally, an additional late base metal assemblage, associated with silicification and pyrite recrystallization, may pre-date a second generation of gold mineralization. Ore petrography, U-Pb geochronology, trace element analysis of native gold, and sulphur isotopic analysis of pyrite are being combined to constrain the timing and nature of gold mineralization at Valentine Lake and to recognize any correlation between mineralization and distinct events during the Salinic and/or Acadian orogenies.

Title: *Mineralogical and Geochemical Vectors for Ore Targeting: the Footprint of the Canadian Malartic Gold Deposit, Québec*

Presenter/First Author: Nicolas Gaillard, McGill University, Montréal, QC

Presenter/First Author Email: nikos24700@hotmail.fr

Co-authors: Anthony E. Williams-Jones, McGill University, Montreal, QC, Canada; Stefano Salvi, , , ; James R Clark, , , ; Philip Lypaczewski, , , ; Stephane Perrouty, Western University, London, ON, Canada

Published Material: Preliminary results regarding mineral chemistry were presented at the Keystone SEG conference. Last results greatly improve the understanding of the Canadian Malartic footprint by providing new mineral tools (white mica chemistry) for ore targeting. We also investigated the substitution mechanisms involved in the compositional variations of micas. Last, we provide new whole-rock geochemical data which give us insights on the signature of the Canadian Malartic Gold deposit (investigation of mass changes relative to distance to the ore zones), as well as new parameters to investigate the physico-chemical changes going away from the deposit.

Abstract Body: Canadian Malartic represents an important example of a large-tonnage, low-grade gold deposit in the southern Superior Province. It is located in the Pontiac Subprovince, in contact with, and immediately south of the east-west trending Cadillac-Larder Lake fault zone, marking the contact with the Abitibi Subprovince. Most gold deposits in the Abitibi Greenstone Belt are of orogenic type and are typically associated with quartz-carbonate veins and albite-carbonate alteration. Canadian Malartic contrasts with these deposits in that the gold is disseminated in potassically altered (pyrite-K-feldspar-biotite-calcite) quartz monzodiorite porphyries and adjacent clastic metasedimentary rocks. Mineralization is associated with quartz-biotite-carbonate-microcline±pyrite veinlets with potassic (biotite, K-feldspar) and pyritic alteration haloes, and is distributed as elongated, lens-shaped orebodies, strongly controlled by faults and lithological contacts. Hydrothermal alteration in clastic metasediments was accompanied by mass gains in S, LOI and K, consistent with the mineralogical characteristics of the alteration assemblage. Gold mineralization in metagreywacke is associated with substantial mass gains in Ag-Te-Bi-Mo-Pb-W. These observations can be used to trace the extent of the ore deposit footprint and provide vectors towards mineralization. Core-logging, whole-rock geochemistry as well as variation in gold concentrations show that the intensity of hydrothermal alteration decreases sharply away from the deposit. Biotite compositions are a potentially valuable footprinting tool to identify directional vectors toward mineralization, as they show significant increases in fluorine and magnesium concentrations from distal unaltered rocks toward the ore shell. Preliminary results indicate that the visible alteration halo (*e.g.*, pyritisation, carbonation or potassic alteration) does not extend more than 500 meters from the southern limit of the pit.

Title: Role of colloidal transport in the formation of high-grade gold veins at Brucejack, British Columbia

Presenter/First Author: Nicolas Harrichhausen, McGill University, Montreal,

Presenter/First Author Email: nharrichhausen@gmail.com

Co-authors: Christie D Rowe, McGill University, Montreal, QC, Canada; Matthew Tarling, McGill University, Montreal, QC, Canada; Warwick S Board, Pretivm Resources Inc, Vancouver, BC, Canada; Charles James Greig, Pretivm Resources Inc, Vancouver, BC, Canada

Published Material: Some of the field observations will have been presented on a poster at the 2014 Canadian Tectonics Group meeting in Sudbury and in an Oral presentation at the 2015 GEOTOP conference.

Abstract Body: Extraordinary concentrations of gold (up to 40 kg/tonne) occur in quartz-carbonate veins at the Brucejack gold deposit in British Columbia. These veins are part of an extensive mineralized vein stockwork and quartz-sericite-pyrite alteration zone. Unlike nearby lower-grade giant porphyry-style copper-gold deposits, the distribution of grades at Brucejack is highly variable, creating challenges for resource estimation. We propose that a model of structurally controlled, episodic and concentrated gold precipitation might best explain the gold distribution at Brucejack. During rapid fracturing, fluid pressure drops contribute to precipitation of colloidal nanogold (or electrum) and colloidal silica. These colloids may self organize and accumulate locally in structural dilation sites over many cycles of fracturing, eventually reaching extremely high grades. Recrystallization of amorphous silica to quartz destroys any colloidal microstructure and pushes any impurities to grain boundaries. The Brucejack deposit has been deformed post mineralization thus a reference site to compare observations is required. Fresh silica sinter formed in a hydrothermal system associated with active slip on the Fairview Fault, Nevada, contains an amorphous silica phase with 2-3% dispersed gold. Field observations at Brucejack of the structure of veins and faults within the deposit-hosting stock work, as well as microprobe and optical microscopy observations of selected quartz textures, will be presented and compared to preliminary observations from our recent fieldwork at the Fairview Fault. By comparing these two deposits, we hope to determine whether colloidal transport played a role in gold deposition at Brucejack.

GOLD EXPLORATION AT SOUTH EASTERN DESERT, EGYPT USING REMOTE SENSING TECHNIQUES

[1] **Salem M. Salem**

[2] **Nehal M Soliman**

[1&2]National Authority for Remote Sensing and Space Sciences (NARSS), Cairo, Egypt.

ABSTRACT

The processing of ASTER images band ratios 7/6*4/6 and (7+9/8) supported by field geology, mineralogical and geochemical analyses enabled detection of two alteration zones as targets for gold exploration at Al Faw- Eqat belt (a case study in the south eastern desert). Representative samples were collected from the detected areas, north of Gabal Eqat (area1) and north of Gabal Al Faw (area 2) for geochemical analyses to assess the gold and associated metals. The result of Atomic absorption and ICP analyses recorded Au content up to 9.8 g/t in the quartz veins and 7.8 g/t in the altered volcanics in area1 and 14.0 g/t in the quartz veins and 6.8 g/t in the altered volcanics in area2.

Al Faw- Eqat belt is made up of metamorphic and magmatic late Proterozoic rock assemblages. The metamorphic suite consists of ophiolitic ultramafics thrusted over the metavolcanosedimentary (mvs) schist of intermediate to basic composition. It is highly tectonized sheared metavolcanics and ultramafic rocks extended in the NW/SE trend. The magmatic suite comprises syn- to late-tectonic calc-alkaline granites of less deformed tonalite and monzogranites which were intruded by post-tectonic potassic calc-alkaline granite form Gabal Eqat body sending sheets, plugs, apophasis and quartz veins in the surrounded mvs leaving marked of alterations promised localities for mineralization.

Title: Structural geology and timing of deformation at the Gibraltar copper-molybdenum porphyry deposit, Cariboo Region, British Columbia

Presenter/First Author: Lori Kennedy, University of British Columbia, Vancouver, BC

Presenter/First Author Email: lkennedy@eos.ubc.ca

Co-authors: Nader Mostaghimi, , , ; Janet Gabites, , , ; Richard M Friedman, University of British Columbia, Vancouver, BC, Canada

Published Material: presented at the GSA in Vancouver 2014

Abstract Body: The Gibraltar copper-molybdenum mine, located northwest of Williams Lake, is hosted in the Late Triassic Granite Mountain batholith. The main ore zone, hosted within the Mine Series phase tonalite has been structurally dismembered and questions still exist regarding the relationship between pluton emplacement, mineralization (215 ± 1.0 – 210 ± 0.9 Ma; Harding, 2012) and deformation.

The oldest structures on the property include a gently southwest dipping foliation (S_1), that is locally subparallel to mineralized sheeted veins, and large mylonitic high strain zones with a top to the north or northeast sense of displacement. Discrete, imbricate south-southwest dipping thrust faults are interpreted as kinematically linked to the large high strain zones. North-striking dextral-normal faults, with well-developed cataclasites, cross-cut S_1 fabrics and thrust faults and likely formed at shallower crustal levels. Shallowly southeast-plunging lineations, including intersections, fold axes, and boudin necks, affect all fabrics and represent the last stage of deformation: cause of this late-stage flattening resulting in boudinage and crenulations is not yet resolved.

We present structural cross sections through the Granite Lake operational pit to illustrate the effect of deformation on ore distribution. There is generally a positive correlation between areas of intense alteration and mineralization and deformation and this is highlighted on the cross sections.

U-Pb (zircon; TIMS) taken from the Granite Lake pit provides an age of crystallization of the Mine phase tonalite. $^{40}Ar/^{39}Ar$ cooling ages obtained from muscovite that defines deformation fabrics (e.g. S_1, thrust faults, SE-plunging lineations) show a range of Eocene ages for deformation (~54-34 Ma). We interpret that some of the Ar-Ar cooling ages represent resetting during Eocene deformation.

Title: Oxidation state and Cu content of arc magmas: implications for metallogeny

Presenter/First Author: Jeremy P. Richards, University of Alberta, Edmonton, AB

Presenter/First Author Email: Jeremy.Richards@UAlberta.ca

Published Material: Richards, J.P., The oxidation state, and sulfur and Cu contents of arc magmas: Implications for metallogeny: Lithos, *in press*.

Abstract Body: Published Fe_2O_3/FeO ratios and Cu contents of fresh volcanic and intrusive rocks from Phanerozoic arcs indicate that, on average, they are slightly more oxidized ($\Delta FMQ \approx +1 \pm 1$) than other magmas derived from depleted upper mantle (e.g., MORB; $\Delta FMQ = -1$ to 0), but contain similar Cu contents (median values of ~50–100 ppm) across their compositional ranges from mafic to intermediate rocks. Magmatic Cu content does not correlate with oxidation state, and median values decrease gently with fractionation, suggesting mildly compatible behaviour during partial melting and fractionation in the presence of minor amounts of condensed sulfide phases. It has previously been shown that normal andesitic arc magmas containing ~50 ppm Cu can readily form large porphyry deposits (by late-stage partitioning of Cu into an exsolved hydrothermal fluid phase upon emplacement at shallow crustal levels). There is therefore no evidence for, and no need to invoke, the existence of

unusually Cu-rich magmas to form typical arc-related porphyry Cu deposits.

There is also no evidence or need for the precipitation of large volumes of sulfides in lower crustal cumulate zones during arc magma fractionation (except where lower crustal rocks are unusually reduced, as perhaps in Japan). If such sulfides did exsolve from arc magmas in volume, they would be expected to strongly deplete the magma in Cu and other chalcophile and siderophile metals, and would thus significantly reduce the potential to form later porphyry-type deposits. On the other hand, precipitation of small amounts of sulfide phases is likely, and their incorporation into lower crustal amphibole-rich arc cumulate sequences may provide a fertile source rock for later re-melting events under lower total sulfur fugacity conditions (i.e., after the flux of S from the subduction zone has ceased). Such trace residual sulfides can be expected to be enriched in Cu, Au, and PGE, and may explain the Au-rich (and rarely PGE-enriched) character of some post-subduction porphyry and related epithermal deposits.

Title: Three-Dimensional Electrical Conductivity Models of the Morrison Porphyry-Cu Deposit, British Columbia

Presenter/First Author: Benjamin Lee, University of Alberta, Edmonton, AB

Presenter/First Author Email: blee3@ualberta.ca

Co-authors: Juliane Huebert, University of Alberta, Edmonton, AB, Canada; Bahman Abbassi, University of Quebec Abitibi-Témiscamingue UQAT, Rouyn-Noranda, QC, Canada; Lijuan Liu, USTC University of Science and Technology of China, Hefei, China; Martyn Jonathan Unsworth, University of Alberta, Edmonton, AB, Canada; Jeremy P. Richards, University of Alberta, Edmonton, AB, Canada; li Zhen Cheng, University of Quebec Abitibi-Témiscamingue UQAT, Rouyn-Noranda, QC, Canada; Doug Oldenburg, The University of British Columbia, Vancouver, BC, Canada

Published Material: These findings add to abstracts submitted to:AGU Meeting, San Francisco 2013GAC-MAC Joint Meeting, Fredericton 2014

Abstract Body: Electromagnetic (EM) methods can detect metallic sulfide-bearing ore bodies, including porphyry deposits with disseminated mineralization, based on their electrical conductivity contrasts relative to the surrounding host rock. The airborne ZTEM (Z-Axis Tipper Electromagnetic) method uses natural low frequency EM signals in the range 30-720 Hz to determine conductivity from the surface to a depth of 2 km. ZTEM measures vertical and horizontal magnetic fields and is effective at determining relative lateral changes in conductivity. However, electric field measurements are required to obtain an absolute value of the subsurface conductivity. The magnetotelluric (MT) method measures both electric and magnetic field data in the range 0.001-1000 Hz to determine conductivity at even greater depths than the ZTEM technique. However, MT surveys require ground contact to measure electric fields and as a consequence are slower and more expensive to deploy. The spatially dense and higher frequency ZTEM data and the lower frequency MT data complement each other to reduce the non-uniqueness of the three-dimensional inversion. Since both methods derive the tipper from measurements of the vertical and horizontal magnetic fields, both datasets can be inverted simultaneously to create electrical conductivity models.

We present a case study from the Morrison deposit, a Cu-Au porphyry system located in the Babine Lake region of British Columbia. The deposit is related to Eocene biotite feldspar porphyry (BFP) stock that intruded into Middle-Late Jurassic sedimentary rocks. Alteration and mineralization zoning at Morrison are clearly observed, and centered on a central BFP stock. The proximal potassic zone is associated with disseminated chalcopyrite and minor bornite, and is an electrically resistive feature in the 3-D model. A surrounding conductive region is consistent with the observed distal chlorite-carbonate alteration, and associated with pyrite enrichment outside the potassic core. This complicated structure requires densely sampled ZTEM data and lower frequency MT data in order to constrain the inversion model. We show that inverting a combination of ZTEM and MT data utilizes the advantages of each technique to create a more comprehensive three-dimensional conductivity model of the porphyry Cu-Au ore body.

Title: A study of the Cu-Ni-Fe-S mineralogy of footwall veins at the McCreedy East mine, Sudbury, ON: The formation of millerite and origin of splays from trunk veins

Presenter/First Author: Paul Wawrzonkowski, Laurentian University, Sudbury, ON

Presenter/First Author Email: pwawrzonkowski@laurentian.ca

Abstract Body: Footwall Cu-Ni-Fe-S ores in the Sudbury basin are considered to have been derived from Fe-Ni-S contact ores which underwent fractionation or post-formational remobilization, exploiting existing structures within the footwall. A study of these ores, which are composed of chalcopyrite (Ccp), bornite (Bn), millerite (Mlr), pentlandite (Pn), was conducted using samples from the McCreedy East mine. The ores are located in trunk veins, which are up to 5 m wide, dominated by Ccp and Pn, and splay veins, which are smaller (<1 m wide) offshoots from the main trunk veins. The research was conducted to better understand how mineralogy varies with depth, the relationship between the main trunk veins and the splays and to develop a model explaining the origin and evolution of the splays. SEM-EDS studies indicate that pn in splays is more Ni-rich, with Ni:Fe ratio of ~2. Mlr exhibits up to 1 wt. % (Fe+Co), which is homogeneously distributed. It commonly exhibits twin lamellae, possibly associated with a local increase in *P*. As NiS undergoes a α – β transition below 379 °C, with a concomitant increase in *V*, this could explain the observed twinning. Chemical analyses (SEM-EDS) indicate near ideal stoichiometry for both Ccp and Bn, with Bn showing up to 1.5 wt. % Ag. The Bn also has inclusions of Ag and AgTe. Ccp and Bn appear to have crystallized nearly simultaneously and no other Fe-S mineral (Py, Po) is found. Secondary covellite develops along fractures and grain boundaries in bn. Platinum-group-minerals (merenskyite, michenerite, moncheite) are found as inclusions in Pn and Mlr. We interpret the splays to be Cu+Ni+PGE-enriched products, possibly resulting fractionation products of the earlier-formed trunk veins. The presence of extensive twinning in the Mlr suggests emplacement at T>379°C. The mineralogical assemblage of the splays suggests formation at fS_2 ~-8 to -4 log units and fO_2 -32 to -28. Strong similarities exist between it and the bornite zone at the Kidd Creek mine.

Title: Resource Potential for Industrial Limestone on Southampton Island, Nunavut

Presenter/First Author: Shunxin Zhang, Organization Not Listed, Iqaluit,

Presenter/First Author Email: Shunxin.Zhang@NRCan-RNCan.gc.ca

Abstract Body: Quicklime (CaO) is a product of thermal decomposition of limestone, which has many uses in the mining industry. With the projected growth of the mining industry in the Kivalliq Region of Nunavut alone,

4 000 000, 4 700 000 and 4 000 000–10 000 000 kg of quicklime would be required annually at the Meadowbank gold mine and the proposed Kiggavik uranium and Meliadine gold mines, respectively.

Southampton Island is strategically located within barging distance of the mining projects in the Kivalliq Region, and about 2/3 of the island is covered by Upper Ordovician and Lower Silurian limestone. In view of 1) recent and projected growth of the mining industry in the region, 2) demands for quicklime, 3) reducing transportation costs, and 4) providing significant opportunities for economic development and local employment in Nunavut, Canada-Nunavut Geoscience Office has conducted a research project to test the purity of limestone on Southampton Island.

In 2009, the project stratigraphically focused on the Upper Ordovician Bad Cache Rapids and Churchill River groups, and geographically on the area close to the community of Coral Harbor. Overall, these limestones predominantly demonstrate chemical-industrial purity values in the "low purity" range (52.4–47.6% CaO).

In 2013 and 2014, the project stratigraphically moved up section to the Lower Silurian Ekwan River Formation, and geographically to the southwestern portion of Southampton Island. The area between Manico Point and Nalugalaavik Point, about 320 km^2, has been explored, and detailed sampling for whole rock analysis (X-ray fluorescence) was carried on along several creeks in the area. The majority of the geochemical data suggest that high-calcium limestone (>54.3% CaO) occurs in the Ekwan River Formation on the southwestern part of the island. The newly discovered "high-purity" limestone on Southampton Island should provide a valuable resource for Nunavut, and especially for its Kivalliq Region.

Abstract Body: Inuit stone sculpture from the Arctic is highly regarded around the world as an icon of Canada. An ongoing collaborative reconnaissance project between the Government of Nunavut, Department of Economic Development and Transportation, and the Canada-Nunavut Geoscience Office has documented new and existing carving stone resources as part of the Nunavut Carving Stone Deposit Evaluation Program (NCSDEP).

Community consultations and guidance to sites by over 50 carvers have verified 70 poorly known traditional carving stone deposits. Including government mapping discoveries brought forward, 84 carving stone sites of various sizes were evaluated in the vicinity of 22 out of 25 communities in Nunavut. All sites have been characterized by stone quality, tonnage and composition. Non-talcose "artisan serpentinite" and "artisan marble" with Mohs hardness of 2 – 2.5 are the territorial-wide carving stones of choice.

Major artisan serpentinite deposits are associated with mafic-ultramafic rocks of the Archean Prince Albert Group, a 1000-km long supracrustal succession in eastern Nunavut. Elsewhere, artisan marble deposits are found where broadly distributed mafic-ultramafic magmatic events intrude fine-grained Proterozoic carbonate rocks. A 1200-km long domain of Neoproterozoic Franklin Magmatic Event sills and dikes formed skarn marble deposits locally from Coronation Gulf to Baffin Island.

The NCSDEP is interested in developing new collaborative partnerships with academia to advance the understanding of carving stone genesis in Nunavut. Suites of rock samples are available for the study of crustal fluid migration, regional metamorphism, mantle signatures, age-dating, asbestiform minerals in altered ultramafic rocks and skarn mineral alteration in carbonate rocks. Scientific evaluation of carving stone deposits should provide new insights into geological processes across Nunavut and add considerable value to the already impressive works of art created here.

Title: Contribution to the geologic study of the zone the South to Imiter center oriental Anti-Atlas

Presenter/First Author: Nouaman EL Aouad, Cadi Ayyad University, Marrakech,

Presenter/First Author Email: nouaman.geomine@gmail.com

Abstract Body: Imiter deposit located in Jbel Saghro was exploited since the antiquity. It is a part of the Anti Atlas mountains, in the South of Morocco. The mineralized axes are known in the middle neoprotorzoic black metapelites, which contains magmatic injections as dykes at its bottom and intermediate part.
The zone of study located in the central South of the zone of the deposit. the aims of our study are i) detailled mapping of the zone ii) structural and metallogenic studies iii) exploration of western extension of the mineralized corridors.
The technics of mapping used in this project are: i) digital mapping based on satellite pictures and the images of Google Earth; ii) mapping of detail (method of karkours) of ground

While basing itself on the digital map; iii) petrographic study of the injections magmatic; vi) litho geochemistry of mineralized axes.

The South of the central zone of the Imiter field presents a high metallogenic potential. It contains the extension of the structure with carbonates which is affected by dextral fault and becames rich on oxides in its western part. The effect of the granitic intrusion of Taouzzakt is registered well by the metamorphism of greenschist facies in metapelite and dykes in the Southwest of the zone. This study pointed out tectonic gradient with flexible tectonic located toward the North of the zone.

Nearby the intrusion we noticed post-schisteuse folding oriented N70 °E. This gradient led under the

influence of the intrusion's temperature. Far from the intrusion the temperature is weak and resulted of faultings of direction NW, N20°E. On the other hand in the South, close up to the intrusion, the temperature is relatively high gave folded structures. Besides the silicification of sandstones nearby the intrusion, hydrothermal alteration and circulation has been observed.
The microscopic analysis of the thin sections of the magmatic injections and associated mineralized faults samples showed three types : i) ultrabasic injections with olivine and pyroxene far from the mineralized axes; ii) intermediates dykes nearby sulphides mineralized axes; iii) acids dykes associated to the mineralized axes.

Title: Geology of the Hardaban Zn-Pb deposit in Xinjiang, NW China, and its comparison to the Tekeli Zn-Pb deposit, Kazakhstan

Presenter/First Author: Yaxiaer Yalikun, University of Windsor, Windsor,

Presenter/First Author Email: yaxar@uwindsor.ca

Co-authors: Chunji Xue, China University of Geosciences (Beijing), Beijing, China; David T A Symons, University of Windsor, Windsor, ON, Canada

Abstract Body: The recently discovered Hardaban deposit is located in the Precambrian strata of northern Xinjiang. It shows many similarities to the Tekeli deposit and has the potential to be a large SEDEX deposit. The Hardaban deposit is located in the northwestern margin of the Kazakhstan-Yili plate, which is sandwiched between the Siberian and Tarim cratons in the western Tianshan Mountains. Its strata are divided into a lower series of clastic rocks, a middle series of clastic-bearing carbonate, and an upper series of clastic rocks. Acidic intrusives occur mostly as large batholiths and alkaline intrusives occur as rather small and rarely exposed stocks. The attitude of the orebodies are conformable with the northeastward-trending host rocks. The orebodies are dark-gray to black and fissile with dolomitic clay and sulphide layering. The ores contain more than 25 different minerals but are mainly galena, sphalerite and pyrite. Tekeli is a large stratabound Pb-Zn deposit in the northeastern Tianshan area of Kazakhstan and is part of the Tekeli-Yili massif. The deposit is hosted in the deformed Tekeli suite of alternating coals, clays, siliceous-clayey shales and limestone horizons. Deformed sheets, sills and dikes of gabbro, basalt and diabase intrude the sediments. Overall the Hardaban and Tekeli lead-zinc deposits are very similar in depositional and tectonic environment and in geological and ore characteristics, implying a similar stratabound ore genesis. Presumably, the Tekeli lead-zinc metallogenic belt extends eastward into the Sailimu micro-block as part of the Hardaban Group.

Title: Characterization of selenium-rich minerals from the Sagar property, Labrador Trough, northern Quebec

Presenter/First Author: Raven Sharma, University of Manitoba, Winnipeg,

Presenter/First Author Email: raven.k.sharma@gmail.com

Co-authors: Mostafa Fayek, University of Manitoba, Winnipeg, MB, Canada; Quentin Yarie, Honey Badger Exploration Inc., Toronoto, ON, Canada; Craig Scherba, Honey Badger Exploration Inc., Toronto, ON, Canada

Abstract Body: The Sagar property, located within the Romanet Horst in the central part of the Labrador Trough, northern Quebec, Canada is a host to a number of mineral showings. Although numerous companies have explored the Sagar property, the genetic history of mineralization is poorly understood. The Sagar property has anomalous amounts of uranium, gold, copper, lead and zinc which have been interpreted to be part of an IOCG system. More recently, anomalous nickel, cobalt and selenium have been reported at the Viking showing, but the source of these elements is unknown. The objective of this research is to characterize the minerals from sample MXF-13-46 collected from the Viking showing and to determine if the mineralization at Sagar is consistent with an IOCG system. MXF-13-46 is composed of selenide minerals (40%) in a hematite matrix (60%). The selenide minerals characterizing the Viking showing include, penorseite $(Ni,Co,Cu)Se_2$, molybdemnite ($PbSeO_3$), umangite (Cu_3Se_2), and wilkmanite (Ni_3Se_2). Selenide minerals are less common in ore deposits than sulfide and telluride minerals despite the greater crustal abundance of selenium in comparison to tellurium. The abundance of selenide minerals comprising the Viking showing appear to have formed from lower-temperature hydrothermal fluids (<300°C), replacing selenium rich minerals that are stable at higher temperatures (>300°C), and the presence of a hematite matrix suggest that the Viking showing is part of a shallow, low temperature IOCG system.

Title: Granite-hosted W Mineralization in the Dajishan W-Ta-Nb Deposit, Nanling Range, Southeastern China

Presenter/First Author: Mingqian Wu, China University of Geosciences Beijing, Windsor,

Presenter/First Author Email: aria.wu1990@gmail.com

Co-authors: Iain M. Samson, University of Windsor, Windsor, ON, Canada; Dehui Zhang, , ,

Abstract Body: The Nanling Range, SE China, is one of the world's important Ta-Nb-W-Sn-Be metallogenic belts. Vein W, granite-hosted Ta-Nb and an unusual style of disseminated granite-hosted W mineralization are present in the Dajishan deposit. The W mineralization (wolframite and lesser scheelite) is developed as ore pods that are randomly distributed through the No. 69 muscovite albite granite (the 101 deposit). The 101 deposit is also the host to disseminated Ta-Nb mineralization. The genesis of this type of mineralization and its relationship with both granite-hosted Ta-Nb and vein W mineralization are enigmatic. At Dajishan, most micas in the ore pods are euhedral-subhedral lath-shaped crystals and have a Fe-rich phengite core and a Fe-poor phengite or lepidolite rim, whereas most micas in other portions of the No. 69 granite tend to be anhedral, radial aggregates of trilithionite crystals, and lack any evidence of compositional zoning. Wolframite crystals in the ore pods are all hübnerite, but two textural subtypes are present: one occurs as interstitial crystals without mineral inclusions, the other also occurs as interstitial crystals, but contains numerous mica and albite inclusions. All these crystals were developed in contact with micas and inherited some mica textures. Micas in the veins have similar composition to the cores of micas in the ore pods, but no compositional zoning was observed. Wolframite-group minerals in the veins show no obvious compositional differences from those in the ore pods. These data indicate that disseminated wolframite in the ore pods most likely formed, at least partly, through replacement of mica during interaction of the granite with W- and Li-bearing fluids, rather than from direct crystallization from late-stage granitic melts.

Abstract Body: Heavy mineral deposits along the coastal belt and fluvial river bars of Bangladesh constitute a potential national asset. Economically exploitable heavy mineral deposits have already been discovered in the deltaic coastal zone of Bangladesh within the unconsolidated Holocene sediments. This study was undertaken to determine the occurrence, qualitative and quantitative analysis of heavy mineral suite of Kawar Char, located along the coastal belt of the Bay of Bengal, South-West Bangladesh. More than 100 surface samples and hand auger samples up to a depth of 10 ft in a grid pattern were collected to study the heavy minerals. Grain size analysis, bromoform separation and microscopic study of the non-magnetic samples reveal the presence of significant quantities of Zircon, Rutile, Garnet, Magnetite, Ilmenite etc. An attempt has been made to prepare lithological model and geological cross section of the studied area based on the mineralised zones. The study covers about 7.00 Km^2 of the area confirming a highly prospective zone (>15% heavy mineral content) of 1.00 km^2 located at the central part of the study area. The average depth of mineralised sand is about 5 ft. At present sedimentation in the island is active and field study suggests that, the prospective zone for mineralisation is increasing with the progressive sedimentation. This is the first approach to field visit the area and confirming the heavy mineral availability. Detailed work in Kawar Char Island may help to get the greater extent of mineralized sands along the coastal belt of South-West Bangladesh.

Title: Cryptic Structural Controls on Metallogeny Patterns as Revealed by the Distribution of Heavy Minerals in Stream Sediments from the Flat River Area, Mackenzie Mountains, NWT.

Presenter/First Author: Hendrik Falck, Northwest Territories Geoscience Office, Yellowknife, NT

Presenter/First Author Email: Hendrik_falck@gov.nt.ca

Co-authors: Edith Martel, Northwest Territories Geoscience Office, Yellowknife, Canada; Stephen Day, , , ; Kelly Pierce, , ,

Published Material: Geochemical Data to be pubished as a NWT Open Report.Interpretation and geological discusion is unpublished.

Abstract Body: In 2014, a silt, water, and bulk stream sediment survey was conducted along the western Mackenzie Mountains by the Northwest Territories Geoscience Office and the Geological Survey of Canada, collecting material and observations from 190 sites. Regional stream sediment surveys have been carried out over much of the Canadian Cordillera using the National Geochemical Reconnaissance (NGR) methodology including a grab sample of silt-sized stream sediment, and a corresponding water sample, at a target sample density of one sample per 13 km^2. The methodology used also includes the collection of a coarser-grained and volumetrically-larger samples at one sample per 26 km^2 for heavy indicator minerals, which are picked for kimberlite indicator mineral grains, magmatic massive sulphide indicator minerals, and gold grains.

The results for the most recent survey demonstrate the Flat River region's anomalously high metal potential. For some commodities, such as tungsten and lead-zinc, this elevated endowment is well known and represented by two world-class deposits, Cantung and Howards Pass, respectively. However for other elements, intriguingly anomalous samples contain suites of minerals including gold, cassiterite and sapphire grains that are inconsistent with the known showing types, suggesting that further exploration for different mineralization styles is required in this area.

Even for the known mineralization, the geology of this region remains poorly understood. Structural controls, such as faults, have been suggested (Goodfellow + Jonasson, 1987; Hart + Lewis, 2006) as a mechanism for focusing economic mineralization but rarely have the faults been identified, nor has the history of those faults been defined to substantiate the hypothesis. Reconnaissance mapping and geophysical surveys along the March Fault have supported the interpretation of the fault as a long-lived crustal-scale structure, which played an important role in controlling the mineralization in the region.

First Author Student?: No

Co-authors: Anthony DeToni, INRS, QUébec, QC, Canada; Jean-François Montreuil, INRS, QUébec, QC, Canada; Julien Wahl, , , ; Carl Guilmette, Université Laval, Québec, QC, Canada; Mathieu Champagne, , , ; Sébastien Dourlet, , , ; Anne Chabot Bergeron, , ,

Abstract Body: Iron oxide alkali-alteration (IOAA) ore systems create the largest metasomatic (hydrothermal alteration) systems known within the continental crust. The metasomatic processes culminate into:

1) iron, vanadium and specialised-metal ores within iron oxide±apatite (IOA or Kiruna-type) deposits,

2) base-, precious-, specialised- and nuclear-metal ores or by-products within magnetite-, magnetite-hematite- and hematite-group IOCG deposits, and

3) polymetallic ores within certain skarns and albitite-hosted uranium deposits.

Each of these deposit types is a consequence of the systemic development of metasomatic facies across the upper crust as its geotherms rise abnormally during regional-scale ascent of highly saline high-temperature fluid columns. From depth-to surface, fluids strongly react with and transform intensely and pervasively precursor rocks over about 30x10x10 km to form a series of alteration facies with their own, newly acquired, bulk- rock and mineral composition, mineral assemblages, grain sizes, textures and even structures. In addition, veins, stockworks and breccias abound and fills are most commonly associated with extensive alteration haloes. Alteration can replace, cross cut, be transitional to, juxtaposed upon, superimposed upon precursor rocks or earlier alteration types. In the process, some units may 'disappear' from their stratigraphic sequence, being totally altered. Identifying and mapping these alterations are fundamental to modern geomapping for energy and minerals and for future exploration and deposit discovery as each alteration type vectors to its own deposit type and metal association.

This contribution illustrates the megascopic geological attributes of these metasomatic systems. Then it highlights the mapping protocols, nomenclature and field database codification system for mapping across the IOAA systems of the Labrador Trough (Québec) as part of the Geomapping for Energy and Minerals (GEM2) program in collaboration with its partner the Ministère des Ressources naturelles du Québec.

Title: The Capricorn Distal Footprints Project: an Orogen-Scale Approach to Mineral Systems

Presenter/First Author: Mark A Pearce, CSIRO Earth Science and Resource Engineering Perth, Kensington, WA

Presenter/First Author Email: mark.pearce@csiro.au

Co-authors: Robert Hough, CSIRO (CESRE), Perth, WA, Australia; Samuel C Spinks, , , ; Robert Thorne, , , ; Alistair White, CSIRO Mineral Resources Flagship, Perth, Australia; Alan Yusen Ley-Cooper, CSIRO, Perth, WA, Australia; Pavel Golodoniuc, , , ; David Gray, , , ; Timothy J Munday, CSIRO Earth Science Resource Engineering, Kensington, WA, Australia

Abstract Body: Exploration through cover is currently the biggest challenge facing the Australian minerals industry. With ~80% of the continent being covered by weathered material, much of Australia's mineral wealth still remains to be found. The Capricorn Distal Footprints project is a AU$17M collaboration between industry, the Geological Survey of Western Australia, academia and CSIRO to address this issue by examining the geophysical and geological footprints of ore deposits at multiple scales across the Capricorn Orogen in Western Australia.

The Capricorn Orogen is located between the Yilgarn and Pilbara Cratons, two of Australia's most prolific metallogenic provinces. Despite several gold and base metal discoveries, the Capricorn still remains largely underexplored. This project comprises six modules aimed at understanding the metallogenic evolution of the orogen and provide exploration models to aid future discoveries: (1) mineral systems evolution, (2) cover characterisation, (3) mineral hosts as distal footprints, (4) hydrogeochemistry, (5) geochemical mapping and lithospheric evolution, (6) 3D digital model and data integration. These themes combine regional geophysical interpretation (airborne electromagnetic, magnetics and gravity with magnetotellurics and passive seismic), to look at lithospheric architecture and its links to the geophysical expression of mineral systems, with hydrogeochemical, regolith, and resistate mineral studies around known deposits to gain insight into the key indicators of mineralisation, not just within a few hundred metres of the deposits but much further afield. This work is complemented by detailed microstructural and fault-scale analysis of comparable mineralised and barren fault zones to understand controls on the formation of, and signatures of mineral deposits across >10 orders of magnitude.

Title: Whole Rock Geochemical Signatures and REE Mineralogy of the Nechalacho Rare-Earth Element Deposit, NWT

Presenter/First Author: Justin Hoyle, University of Windsor, Windsor,

Presenter/First Author Email: hoylej@uwindsor.ca

Co-authors: Iain M. Samson, University of Windsor, Windsor, ON, Canada

Abstract Body: The Nechalacho rare-metal (REE, Y, Nb, Ta, Zr) deposit, located in the Northwest Territories, is hosted by an altered layered nepheline syenite. Three distinct whole-rock geochemical signatures are evident. Two of these signatures have high P, of which, one has high heavy REE (HREE) (type 1) and one has low HREE, but high light REE (LREE) (type 2). The third signature has low P and high HREE, LREE and Zr (type 3). The type 1 and 2 signatures were found to represent abundant xenotime ((Y, HREE)PO_4) and monazite ($LREEPO_4$), respectively. The type 3 signature represents zircon and a variety of non-phosphate REE minerals, such as allanite, fergusonite ((Y, REE)NbO_4), or bastnäsite ($REECO_3F$). The results support the hypothesis that the ore mineralogy can largely be predicted from whole rock geochemistry. Phosphates are an important reservoir for the LREE at Nechalacho. Two main textural types of monazite have been recognized; one that is rod shaped and another that is blocky. Xenotime also occurs in various habits, such as rods and anhedral patches. The deposit is divided into Upper and Basal zones, the Basal Zone having a higher HREE/LREE ratio than the Upper Zone. It has been proposed that the LREE were transported from the Basal Zone to the Upper Zone by hydrothermal fluids and precipitated there as LREE minerals. Williams-Jones et al. (2012, *Elements*, v. 8, p. 355-360) predicted that a series of pulses of aqueous fluid transporting REE and P, passing through a nepheline syenite would precipitate monazite crystals that were progressively more depleted in HREE (relative to the starting fluid) with increasing distance from the source (height in the system). Preliminary LA-ICP-MS data for monazite does not support this model because the concentrations of HREE in monazite increase upwards in the intrusive body, which suggests, along with the textural variability of the phosphates, that the genesis of the LREE mineralization is more complex than the proposed models imply.

Title: The Saint-Honoré carbonatite REE zone, Québec, Canada: Combined magmatic and hydrothermal processes.

Presenter/First Author: Alexandre Néron, University of Quebec at Chicoutimi UQAC, Chicoutimi, QC

Presenter/First Author Email: neron.alex@gmail.com

Co-authors: L Paul Bedard, University of Quebec at Chicoutimi UQAC, Chicoutimi, QC, Canada; Damien Gaboury, University of Quebec at Chicoutimi UQAC, Chicoutimi, QC, Canada; Guillaume Matton, , , ; Steve Thivierge, , ,

Published Material: 12th Biennial SGA meeting - Sunday 11th through Saturday 17th august 2014

Abstract Body: A new model is proposed for the genesis of rare earth element (REE) mineralization at the Saint-Honoré alkaline complex. The originality of the proposed model is to combine both magmatic and hydrothermal crystallization of REE-bearing minerals. Actually, most of the REE mineralization models in carbonatites are based on a late stage hydrothermal activity, where REE are leached from primary minerals such as dolomite and apatite and subsequently deposited in late stage units. Such a model is in agreement with observations of the upper Fe-carbonatite REE mineralisation of Saint-Honoré alkaline complex. It shows characteristic textures of hydrothermal mineralization: polycrystalline clusters hosting bastnaesite crystallized radially from carbonate or barite crystals, the presence of halite and silicification within strongly brecciated units. However, in the deeper part of the Fe-carbonatite (below 1000 meters), bastnaesite inclusions in primary barite suggest an early magmatic crystallization of REE minerals before hydrothermal leaching. It is interpreted that hydrothermal activity was weaker in the deeper part (Cl-depleated, a progressive decrease with depth of secondary fluid inclusion trapped in carbonates, brecciation is significantly less intense), hence preserving the magmatic textures. This magmatic crystallisation of rare earth minerals could be an important factor in generating high volume world-class REE deposits. An example of magmatic world-class deposit is Mountain Pass in California where idiomorphic bastnaesite crystals were described. Furthermore, crystallization of primary barite could be an important exploration guide for REE in carbonatites because its presence seems to reflect favourable conditions to crystalize primary REE minerals.

Title: The Genesis of Heavy REE Mineralisation in the Lofdal Carbonatite Complex, Namibia

Presenter/First Author: Rowan Wollenberg, McGill University, Montreal, QC

Presenter/First Author Email: rowan.wollenberg@mail.mcgill.ca

Co-authors: Anthony E. Williams-Jones, McGill University, Montreal, QC, Canada; Sarah Bodeving, , , ; Scott Swinden, , ,

Abstract Body: The rare earth element (REE) mineralisation in the 765 Ma Lofdal Carbonatite Complex, Namibia, is highly unusual. Whereas carbonatite-associated REE deposits are typically enriched in the light REE, Lofdal hosts an indicated mineral resource of 2.88 Mt total REE oxides at a cut-off grade of 0.1%, of which 76.3% are heavy REEs (HREE). This makes it one of the most HREE-enriched economic or potentially economic deposits in the World. Although the REE were initially assumed to be hosted by carbonatite dykes, textural relationships observed in the field, drill core and microscopically indicate that the REE mineralisation (xenotime-(Y)) is hosted by albitised rocks that formed along planar structures, and that these rocks were subsequently carbonated by hydrothermal fluids. This interpretation is supported by $\delta^{18}O$ and $\delta^{13}C$ values that are consistent with a hydrothermal rather than magmatic origin for the carbonate minerals. The paragenesis is albitisation followed by two generations of xenotime-(Y), overprinted by carbonate (calcite or dolomite). The carbonate-forming fluids may locally have remobilised the REE, but if this were the case, the remobilisation was minor. The first and most common mode of occurrence of xenotime-(Y) is in veinlets of biotite ± calcite ± pyrite that cut the albitite. A small proportion of xenotime-(Y) occurs in discontinuous veinlets (lenses) of apatite. A model is proposed in which early fluids released from a carbonatite magma rose along faults in the basement, albitising (fenitising) gneisses and later fluids fractured the albitites and deposited xenotime-(Y) with biotite, and locally apatite. The carbonating fluid is also likely to have originated from the carbonatite but we do not rule out the possibility that it was a formational water or a mixture of magmatic and formational water.

Title: IOCG-Type And Affiliated Deposits In The Romanet Horst, Labrador Through, Canada: Insights From Geochemical Fingerprint Of High Temperature Albitization

Presenter/First Author: Xin Yu DONG, University of Ottawa, Ottawa,

Presenter/First Author Email: dongxinyu0903@hotmail.com

Co-authors: Olivier Nadeau, Organization Not Listed, Washington, DC; Louise Corriveau, Natural Resources Canada, QUébec, QC, Canada

Abstract Body: Because of their large sizes, simple metallurgy, diversified resources and high grades, Iron-Oxide-Copper-Gold-type (IOCG-type) and affiliated deposits can produce extremely profitable mines. Over a century of geological mapping and exploration work in the Romanet Horst, Labrador Through, Canada, currently suggests a high potential for such deposits. Hydrothermal alteration and brecciation is widespread and commonly associated with Fe-Cu-Au-Ag-U mineralization. In the present research, we focus on primitive high temperature albitization and its geochemical fingerprint. We compare and contrast the albitization and associated mineralization in the Romanet Horst Area with that in the Great Bear IOCG Magmatic Zone. The objective is to characterize the fluids associated with the primitive, high temperature sodic alteration, to establish links, if any, between these fluids and mafic feeder magmas, and to distinguish the albitization which is associated with mineralization from that which is not. It is our hope that the albitization fingerprint will become an exploration vector for IOCG-type and affiliated deposits.

Title: Mineralogical and Geochemical Constraints on the Mobilization and Mineralization of Rare Earth Elements in the Lala Fe-Cu-(Mo, REE) Deposit, SW China

Presenter/First Author: Wei Terry Chen, University of Hong Kong, Hong Kong,

Presenter/First Author Email: chenweifly1@163.com

Co-authors: Mei-Fu Zhou, University of Hong Kong, Hong Kong, China

Published Material: these findings are submitted to a scientific journal, currently under review.

Abstract Body: The Lala Fe-Cu-(Mo, REE) deposit in Sichuan province, SW China, has a paragenetic sequence of Stage I of pre-ore Na-alteration, Stage II of magnetite and minor apatite, and Stage III of Cu-(Mo) sulfides and rare earth element (REE) minerals. REE minerals are monazite, parisite and bastnäsite with minor xenotime. They are generally associated with biotite, muscovite and calcite of Stage III, accompanying with K-Ca-carbonate alteration. In places where magnetite and apatite of Stage II are overprinted by minerals of Stage III, the apatite grains are commonly embayed or eroded, and contain abundant monazite inclusions with minor bastnäsite, calcite and sulfide minerals. These monazite-bearing apatite grains are similar to the metasomatized apatite reported in experiments, and thus are suggested to have formed from the Stage II apatite via a dissolution-precipitation process during of the Stage III fluids. Such a fluid metasomatism has mobilized and leached REEs from the primary Stage II apatite. For country rocks altered by the Stage III fluids (i.e. K-Ca-carbonate alteration), mass balance analysis indicates that up to 70% of their light REEs are also mobilized and leached out during alteration, and thus the country rocks are inferred to be important sources for REE mineralization in the Lala deposit.

Together with mineral assemblages of Stages II and III and previous fluid inclusion data, compositions of amphibole and biotite demonstrate that Stage III fluids have higher K, CO_2 (or HCO_3^- and CO_3^{2-})and HF/HCl fugacity but lower salinity and Na activity than Stage II fluids. We suggest that elevated K and CO_2 in Stage III fluids or associated K-carbonate alteration are possibly important for REE mobilization. The mobilized REEs from country rocks were inferred to be transported as chlorite-complexing before depositing as REE minerals at certain levels. Deposition of REE minerals was likely triggered by mixing with relatively low temperature, F-rich, and oxidized basinal brines and/or local interaction with carbonate hosts. We propose that the common association of REEs with Cu mineralization in many IOCG deposits are possibly ascribed to the specific nature of K-CO_2-rich Cu mineralizing fluids.

Title: REE mineralization in Sin Quyen Fe-Cu-REE-U-Au deposit, Northwest Vietnam

Presenter/First Author: Li Xiaochun, The Independent, Hong Kong,

Presenter/First Author Email: njulxc@163.com

Co-authors: Mei-Fu Zhou, University of Hong Kong, Hong Kong, China

Abstract Body: The Sin Quyen Fe-Cu-REE-U-Au deposit is localized in the Phan Xi Pang zone, northern Vietnam. Orebodies are hosted in the two-mica schist of the Proterozoic Sin Quyen Group, and consist mainly of massive and banded replacement ores. The paragenetic sequence of this deposit mainly includes sodic alteration (Stage I), Fe-REE-U mineralization associated with calc-alteration (Stage II), and Cu-Au mineralization associated with potassic alteration (Stage III). This sequence is similar to those of many IOCG deposits elsewhere.

The Sin Quyen deposit contain about 0.37 Mt (metal) LREE. REE minerals are dominated by allanite, with lesser amounts of monazite, chevkinite, aeschynite, REE-rich apatite, and REE-rich epidote. Among these minerals, monazite and chevkinite were formed in pre-ore sodic alteration stage; whereas allanite, REE-rich apatite, REE-rich epidote and aeschynite were formed in the Fe-REE-U mineralization stage. It is notable monazite has been variably replaced by apatite-allanite-epidote coronas, and chevkinite has been replaced by allanite and aeschynite. During these replacement reactions, REE and other trace elements, including Nb, Ti, P and U, display complex mobility.

LA-ICP-MS dating on monazite grains have yielded an U-Pb age of 812±10 Ma, which is broadly consist with the zircon U-Pb ages of regional felsic and sub-alkaline intrusions. In addition, bulk-ores have similar chondrite normalized REE patterns with those magmatic intrusions. These facts suggests that the REE mineralization may have a genetic relationship with regional felsic or sub-alkaline magmatism. The extensive occurrence of Cl-rich hornblende and biotite, combined with the scarcity of F or CO_2-rich minerals in this deposit, indicates that the fluids were rich in Cl but depleted in F and CO_2. Thus, REE may be transported dominantly as chloride complex. The presence of this Cl-rich ore-forming fluid has produced a distinctive style of REE mineralization in IOCG system.

Abstract Body: We aim to test the hypothesis that sulphide minerals such as pentlandite (Pn) are capable of preferentially uptaking platinum-group-elements (PGE) and playing a critical role in PGE mineralization. Our goal is to combine synchrotron X-ray absorption (XAFS) as well as Electron-energy loss spectroscopy (EELS) experiments along with electronic structure calculations to probe Pn crystallization processes that bear relevance to not only the formation of magmatic PGE deposits, but also models of planetary accretion and evolution.

Current models suggest that immiscible sulphide liquids form during the evolution of magmatic PGE deposits. As the immiscible liquid cools, sulphide minerals crystallize. One of the most economically important minerals in magmatic PGE deposits is Pn. Experimental observations show that palladium (Pd) preferentially partitions in Pn, whereas platinum (Pt) is incorporated into other phases. The contrasting behaviour between Pt and Pd is enigmatic, considering their apparently similar geochemical affinities. More recently, some authors have suggested the presence of PGE nanoclusters in the Pn lattice and the potential of Pn for hosting PGEs has come into question.

Pn occurs mostly as a ternary Fe-Ni phase, although abnormaly Fe-rich Pn has been reported to occur in meteorites. It is well known that the stabilities of solids depends largely on their configurational entropies and our modeling will take this into consideration using Special Quasirandom Structures (SQS) as implemented in a novel algorithm. This SQS approach will allow us to determine the optimal distribution of the Fe and Ni atoms by matching a specified set of correlations (or cluster functions) between neighboring atoms to the corresponding correlations of the perfectly disordered state. The optimal ordering of the Fe and Ni atoms will be determined over a wide range of Fe/Ni values, and their relative stabilities will be evaluated quantitatively. Subsequently, PGE (i.e., Pd and Pt) will be incorporated in the disordered lattices of Pn calculated from the SQS approach. Once the optimal ordering of the atoms has been determined, the electronic structures of Pn will be investigated and the ionic degrees of freedom will relax by solving the Kohn-Sham equations within the spin-polarized-generalized-gradient approximation.

Title: The Relationship between Structural and Chemical Complexity of Boron Minerals with Geological Time

Presenter/First Author: Edward S Grew, Univ Maine, Orono, ME

Presenter/First Author Email: esgrew@maine.edu

Co-authors: Sergey V Krivovichev, , St Petersburg, Russia; Robert M Hazen, Carnegie Inst, Washington, DC

Abstract Body: Boron minerals are among the most structurally and chemically complex naturally occurring inorganic compounds. Of the 280 B minerals approved by the IMA, there are 250 species with known structures for which the age of the earliest reported occurrence in the geologic record has been reported. The earliest B minerals are 3550 Ma metamorphic tourmalines in the Isua supracrustal belt (Greenland), but many ephemeral species are restricted to Holocene deposits. We have analyzed structural complexity with the program package TOPOS using complexity parameters that provide Shannon information content per atom and per unit cell [Min. Mag. 77 (2013) 275-326]. The average contents per atom and per unit cell are 3.92 and 338 bits, respectively (compare 3.23 and 228 bits, respectively, for all minerals). Qingsongite, cubic BN (2 bits), is the simplest.

There are 16 B minerals with information content per unit cell > 1000 bits. The structural complexity of rogermitchellite, $Na_6(Sr,Na)_{12}Ba_2Zr_{13}Si_{39}(B,Si)_6O_{123}(OH)_{12}\cdot9H_2O$ (2321 bits) and byzantievite, $Ba_5(Ca,REE,Y)_{22}(Ti,Nb)_{18}(SiO_4)_4(PO_4,SiO_4)_4(BO_3)_9O_{22}[(OH),F]_{43}\cdot1.5H_2O$ (1574 bits) results from chemical complexity based on the number of essential chemical constituents. However, chemically simpler hydrated Ca borates, e.g., ginorite, $Ca_2B_{14}O_{20}(OH)_6\cdot5H_2O$ (1506 bits), ruitenbergite, $Ca_9B_{26}O_{34}(OH)_{24}Cl_4\cdot13H_2O$ (1492 bits), alfredstelznerite, $Ca_4B_{16}O_{16}(OH)_{24}\cdot19H_2O$ (1359 bits), are also structurally complex, which we attribute to the interplay of borate polyanions and hydrogen bonding networks. The earliest complex borates are takéuchiite (1179 bits) and blatterite (1656 bits), which are reported uniquely from 1825 Ma deposits at Långban and Nordmark (Sweden).

Plots of information contents per atom and per unit cell versus the earliest reported occurrences of B minerals in the geologic record reveal a broad increase in complexity, but this trend could result from preservation bias due to the ephemerality of many hydrated borates.

Title: Reassessment of the Parameterization of the Bond-Valence Model: Results and Applications

Presenter/First Author: Olivier C. Gagné, University of Manitoba, Winnipeg, MB

Presenter/First Author Email: olivier.c.gagne@gmail.com

Co-authors: Frank C Hawthorne, University of Manitoba, Winnipeg, MB, Canada

Published Material: This is a culmination of my Ph.D. work. Small parts have been reported at: ACA 2013, Honolulu, HI (oral); IUCr 2014, Montreal, Qc (poster); IMA 2014, Johannesburg, South Africa (oral). The majority of the presentation is new material. A paper covering the presentation material is ready for submission.

Abstract Body: We have recently completed a bond-length dispersion analysis for atoms bonded to oxygen that has led to the collection of 188,797 bond distances from 33,543 coordination polyhedra originating from ~9650 unique crystal structure refinements. We use this data to evaluate 237 published pairs of bond-valence parameters for atoms bonded to oxygen. The range of deviations from the valence-sum rule as well as the average fit obtained from these parameters leads us to conclude that the parameterization of the bond-valence model is not satisfactory; we thus investigate for (1) new equations that can describe the relation between bond length and bond strength, and (2) the best way of deriving the bond-valence parameters of these equations. Following the determination of (1) and (2), we derive 137 new pairs of bond-valence parameters for ions bonded to oxygen using a new method of derivation, the GRG-RMSD (Generalized Reduced Gradient Root-Mean-Square-Deviation) method. We usually find small but consistent improvements in fit for all ions compared to the best published parameters, although some less common ions show a striking improvement; the RMSD from the valence-sum rule for $^{[4]}P^{3+}$ changes from 0.946 to 0.243 v.u., Re^{7+} from 1.000 to 0.276 v.u, Np^{6+} changes from 1.209 to 0.078 v.u, etc. Agreement for the anion bond-valence sums is also improved. Moreover, we find a positive correlation between coordination number and bond-valence sum for most multiple-coordination numbers-cations, where low coordination number configurations give low bond-valence sums and vice-versa. We also find a positive correlation between RMSD and mean bond-length for groups of ions with a similar crystal-chemical behaviour. This new parameterization adds a crucial level of confidence to the bond-valence method for use in bonding analysis and modeling. To that effect, we use the results of the bond-length survey to assign a range of bond-valences that ions can adopt, which we use to predict the full range of site occupancy of crystal structures.

Title: The Effect of Growth Rate on Uranium Partitioning Between Calcite and Fluid

Presenter/First Author: Jeremy M Weremeichik, Mississippi State University, Mississippi City, MS

Presenter/First Author Email: jmw868@msstate.edu

Co-authors: Bruno Thien, Paul Scherrer Institute, Villingen, Switzerland; Aleksey Sadekov, University of Cambridge, Cambridge, United Kingdom; Rinat I Gabitov, Mississippi State University, Mississippi State, MS

Abstract Body: Elemental to calcium ratios in calcium carbonate minerals are being used to study environmental conditions at which crystallization occurred. In particular, foraminiferal U/Ca has been proposed as proxy for determining seawater carbonate ion concentration (CO_3^{2-}) (e.g. Russel et al., 2004). However the kinetic effect of U/Ca incorporation into calcite has been the subject of investigations but is not well understood (e.g. Ni et al., 2007). Therefore, this work is focused on the evaluation of growth rate and its effect on uranium partitioning between calcite and fluid.

The calcites produced during this study were crystallized isothermally from $NH_4Cl-CaCl_2$ doped with uranium by diffusion of CO_2 from ammonium carbonate source. This method yielded growth of large crystals (>1 mm in size) without stirring of the fluid. Growth rate of calcite (crystal extension rate) was monitored by sequentially spiking calcite-precipitating fluids with rare earth element (REE) dopants. The U/Ca was analyzed with SIMS at spots matching those where REE were determined using CAMECA ims 1270 ion microprobe at UCLA (USA). Elemental analyses of the fluids were performed using Thermo Element XR, ICP-MS at the University of Cambridge (UK).

Partition coefficients $K^U=(U/Ca)_{calcite}/(U/Ca)_{fluid}$ increases with increasing of growth rate (V). K^U increases by a factor of two when V increases from 0.01 to 0.14 nm/s and remained near constant at faster rates. Numerical simulations using the growth entrapment model (GEM) (Watson, 2004) and unified uptake kinetics model (UUKM) (Thien et al., 2014) explain the observed K^U-V trend.

Title: Characterization of Interfacial Processes in Soils with High Resolution Transmission Electron Microscopy and Focused Ion Beam Technology

Presenter/First Author: Michael Schindler, Laurentian University, Sudbury, ON

Presenter/First Author Email: mschindler@laurentian.ca

Co-authors: Michael F Hochella, Virginia Tech, Blacksburg, VA

Published Material: Some of results were shown last year at the Goldschmidt conference but without any conclusions. A paper has been submitted to the journal "Geology"

Abstract Body: High resolution transmission electron microscopy (HRTEM) and focused ion beam (FIB) technology are used to characterize mineral surface coatings in upper soil horizons. The combination of both techniques allows deciphering past abiotic and biotic soil processes and thus the reading of environmental records preserved on the nanoscale. Key to the preservation of a rarely observed mineralogy and chemistry in the surface coatings are limited diffusion of elements in Fe-hydroxide coatings in combination with silicification events of nano- to micrometer size confined pore and interface spaces. The most intriguing features include petrified cocci in proximity to a structural analogue of green rust, pockets of jarosite encapsulated by amorphous silica and chains of biogenic magnetite. The observations in this study indicate that chemical processes in confined pore and interface spaces are often in disequilibrium with the bulk soil and that, Fe-silica-bearing coatings are excellent tracking tools for the evolution of the chemistry of soils and sediments.

Title: Metals partitioning in soils by SEM-EDS-SDD mapping of the elements distribution: Applications for geochemical exploration and environmental sciences

Presenter/First Author: Valerie Lecomte, University of Sherbrooke, Chicoutimi,

Presenter/First Author Email: vlecomte@iosgeo.com

Co-authors: Réjean Réjean, Geoscientists IOS Services Inc, Saguenay, QC, Canada; Hubert Cabana, , ,

Abstract Body: Soils are composed of a mixture of components that play roles in metals binding: humic substances, oxides, carbonates, charcoal, detritals *etc*. Deportation of trace metals between these components is still not well documented and expected to depend on variety of environmental factors. Conventional analysis methods, such as partial or sequential extractions, provide information on metals abundance related to specific components, but are likely not as selective as indicated. The current objective is to determine the metal's binding sites in anomalous soils at the microscopic scale, mostly using scanning electron microscopy (SEM) with a backscattered electron detector (BSE) and last generation energy dispersive spectrometer (EDS-SDD). The experiment was carried out on a collection of soils from sites known to show various natural or anthropogenic metal enrichments. The mapping of chemical elements distribution allowed locating different metals phases and precipitation sites, even if metals were in trace amount. High magnification imaging and microanalyses were performed to characterize the nature of the chemical signal (organic matter, oxides, clays, residual minerals, *etc*.). Results show, for example, that copper in humic soil dominantly precipitates on organic matter up to a saturation point, where it start precipitation as distinct authigenic sulfides, and in a lesser extent to accumulates in iron and manganese oxides. Each metal has its own distinctive behavior. For the mineral exploration industry, knowledge of the metals partitioning and dispersion mode shall improve the deconvolution of the signal in order to locate their source and discriminate true from false anomaly. In regard of environmental sciences, a better comprehension of the metals binding sites will help to anticipate the associated risk and it shall provide important information to design the appropriate decontamination or remediation methods.

Title: *In situ* characterization of gold in arsenopyrite combining large area SEM imaging and nano-scale HRTEM studies: an example from the Dome Mine, Timmins, Ontario

Presenter/First Author: Dirk Schumann, Fibics Inc, Ottawa, ON

Presenter/First Author Email: dirkschumann11@gmail.com

Co-authors: Jessica Maarit Stromberg, University of Western Ontario, London, ON, Canada; Alexandre Laquerre, Fibics Incorporated, Ottawa, ON, Canada; Dave Mayer, Fibics Incorporated, Ottawa, ON, Canada; Mike W Phaneuf, Fibics Inc, Ottawa, ON, Canada; Hojatollah Vali, McGill University, Montreal, QC, Canada; Neil Banerjee, Western University, London (Ontario), ON, Canada

Abstract Body: The *in situ* characterization of minerals associated with ore zones and geochemical anomalies is a novel tool that can increase exploration and extraction efficiency. The knowledge of how gold occurs within sulphide minerals (e.g., in the lattice or as nano-particles) is of great importance to mining companies in order to define effective extraction methods. Bulk rock and microprobe analyses alone lack the spatial resolution and sensitivity necessary to accomplish the required level of characterization. We present a suite of advanced SEM, FIB and TEM techniques that can be applied sequentially and quickly.

A sample from the Dome Mine in Timmins, Ontario was analyzed using large area SEM imaging, TEM specimen preparation, and high-resolution TEM (HRTEM) characterization. The primary gold hosting mineral at the Dome Mine is pyrite that contains free gold as inclusions, fracture filling, and along grain boundaries as well as "invisible" gold in arsenopyrite. Of special focus for this study was the gold associated with the arsenopyrite.

The samples were imaged in a Zeiss Sigma HDVP SEM using the large area imaging module Atlas 5. Overview mosaics with the BSE signals were acquired at a resolution of 100 nm/pixel. Areas of interest for TEM specimen preparation were additionally imaged at 15 nm/pixel. The image

mosaics were combined with µXRF elemental maps and FIB foils were extracted. HRTEM analyses of the extracted FIB sections reveal areas with complex zonation patterns in the arsenian-pyrite. Zones with irregular copper-rich inclusions alternate with zones of As-rich bands (50 to 400 nm in width). EDX line scans across arsenopyrite inclusions revealed the presence of Au bound to the crystal lattice of the arsenopyrite crystals.

The applied sequence of techniques enabled a quick and systematic characterization of gold mineralizations from a micro to the nanometer scale in a reasonable time.

Title: The Process of Serpentinization in Beni Bousera Massif (Internal Rif, Morocco)

Presenter: Amina Wafik, DLGR Laboratory (Unit associated to CNRST, URAC 43), Marrakech,

Presenter Email: wafik@ucam.ma

First Author: Zaineb Hajjar, Cadi Ayyad University, Marrakech,

First Author Email: zaineb.hajjar@edu.uca.ma

First Author Student?: No

Co-authors: Abderrahim Essaifi, Faculté des Sciences Semlalia, Université Cadi Ayyad, Marrakech, Morocco; Marc Constantin, Laval University, Quebec, QC, Canada

Abstract Body: The Beni Bousera massif is part of the Sebtide units in the internal Rif (Morocco). It is mainly composed by mantle peridotites surrounded by crustal metamorphic series (kinzigites, micaschists, schists). Intensity of ductile deformation in the peridotites allows recognizing from bottom to top: 1) coarse grained porphyroclastic to granular spinel peridotites including spinel pyroxenites layers; 2) spinel porphyroclastic peridotites with layers of garnet pyroxenites; 3) garnet and spinel mylonites.

Serpentinization is superimposed on the ductile deformation. Following the exhumation, fluid circulations induced serpentinization of the peridotites. Serpentinization is concentrated at the top of the peridotites, along the mylonitized zone, and decreases towards the bottom of the massif. It is manifested by the formation of mesh texture and hourglass texture in foliation plans in the high serpentinized peridotites to brecciaed texture in low serpentinized peridotites. Pyroxene is still intact marked by few serpentine veins. This differential serpentinization reflects a low silica activity.

The study of the Raman shifts indicates that, in the low wavenumber region, four main peaks (near 230, 390, 690 and 1100 cm^{-1}) characterize the spectra of lizardite and chrysotile. The differences between chrysotile and lizardite spectra could be clearly identified by sharpness of the Raman lines. In particular, a single band at 1100 cm^{-1} is observed at chrysotile whereas several convoluted bands are observed between 1060 and 1100 cm^{-1} at lizardite. Therefore the serpentine showed a brecciaed texture in the bottom of the massif and the mesh texture, hourglass texture and vein texture in the top of the massif correspond to lizardite type, whereas the serpentine filling the fracture is a chrysotile.

Regarding the tectono-metamorphic evolution of Beni Bousera massif we can relate the serpentinization phenomenon to the thermal event between 19 to 14 Ma as defined by Zircon and Apatite Fission Track.

Title: Optimising Analyses of Geological Material with an Analytical Scanning Electron Microscope

Presenter/First Author: Miguel Larose, Polytechnique Montreal, Montreal, QC

Presenter/First Author Email: larose.miguel@gmail.com

Co-authors: Felix Gervais, École Polytechnique, Montreal, QC, Canada; Gilles L'Espérance, Polytechnique Montreal, Professeur titulaire, Génie des matériaux, Centre for Characterization and Microscopy of Materials (CM)2 - Director, Montreal, QC, Canada

Abstract Body: The need to determine the precise composition of geological material is ever growing and the data widely used in multiple fields such as geochemistry and metamorphic petrology. Although routinely used, electron microscopes analyses are not always optimized nor is the surface of the sample perfectly prepared.

This study presents advances in scanning electron microscopy (SEM) coupled with an EDS (SiLi) detector on thin-sections of amphiboilte-facies pelitic schists and garnet grains therein. The purpose is to optimize the various operating parameters, such as probe current, accelerating voltage, working distance, live acquisition time and concentrations of major and trace elements within the sample. We present examples of optimized analyses and their limits for several applications including: 1) characterization of polished surface condition using secondary electron imaging; 2) zoning profile for major elements in garnet; 3) x-ray maps for major elements in garnet. In order to verify the possibility of quantification with this optimized method, our results are then compared to those obtained for the same samples using the electron microprobe, the customary instrument for such analyses. This methodology will further be used to optimize data acquisition for a new analytical SEM coupled with both WDS and EDS (SDD) detectors, acquired by the Centre for Characterization and Microscopy of Materials $(CM)^2$ of Polytechnique Montreal.

Title: Strain-Enhanced Diffusion in Feldspar: A Strain Speedometer?

Presenter/First Author: Naomi Barshi, McGill University, Montreal, QC

Presenter/First Author Email: naomibarshi@gmail.com

Co-authors: Vincent van Hinsberg, McGill University, Montreal, QC, Canada; Christie D Rowe, McGill University, Montreal, QC, Canada

Published Material: Portions of this project were presented at the Structural Geology and Tectonics Forum in June 2014, Golden, CO, and at the Geotop Student Conferences in 2014 and 2015. None of these findings are under review and have not been recently accepted by any journal.

Abstract Body: Rocks in Earth's crust deform over many different timescales. The rate at which they deform (strain rate) cannot be directly measured in the rock record with present tools. Strain rate can be constrained in specific cases of dateable features such as syn-kinematic mineral growth or intrusions, but a generally applicable tool has not yet been developed. Previous studies on tourmaline show deformation-enhanced element mobility that could, in theory, be used to calculate the duration of deformation. Unfortunately, the required diffusion parameters are lacking for tourmaline and it is not a rock-forming mineral, rendering it unusable as a tool to infer bulk rock strain rate. Feldspars dominate the rheology of Earth's crust, diffusion parameters are known across a range of pressure-temperature conditions, and feldspars can grow with compositional zoning. Compositional zoning serves as a physical, and potentially chemical, strain marker. I combined strain measurements along a 500-meter-long strain gradient transect with element mobilities measured as a function of strain in zoned plagioclase phenocrysts. Major, minor, and trace element analyses on electron microprobe and laser ablation inductively coupled plasma mass spectrometry provide the necessary resolution for precise diffusion modeling at the low strains observed. Thermobarometry indicates that conditions of feldspar formation were 700 ± 30ºC and 190 ± 30 MPa, with no indication of later fluid overprint during deformation. Any divergent element mobilities in zoned plagioclase phenocrysts from this study are most likely a result of strain, and because fluids did not significantly mobilize elements, modeling changes in element mobilities can be used to yield an estimated duration of deformation. These results will be combined to inform a paleo-strain speedometer for the middle crust.

Title: Deformation, Phyllonitization and Associated Element Mobilization of Granitoid Rocks.

Presenter/First Author: Anette Utgården Granseth, Norwegian University of Science and Technology, Trondheim,

Presenter/First Author Email: anettegranseth@gmail.com

Co-authors: Bjorn Eske Sorensen, Norwegian University of Science and Technology, Trondheim, Norway; Trond Slagstad, Geological Survey of Norway, Trondheim, Norway; Nolwenn Coint, Norges Geologiski Undersoekels, Trondheim, Norway

Published Material: Presented as a poster with preliminary results at the Winter Conference 2015 in Stavanger, Norway. Hosted by the Geological Society of Norway.

Abstract Body: This study investigates the mobilization of the major and trace elements related to deformation and associated phyllonitization of the Fagervika granitoid. East of Trondheim, Norway lays the area of Bymarka, that is a part of an ophiolite complex that is dominated by greenstones and several felsic intrusives, including the Fagervika granitoid that is the largest. The granitoid extends approximately 7 km inland, from the shore of Trondheimsfjorden and southwards towards Skjelbreia Lake where it fingers out. Extensive detail mapping of the Fagervika granitoid in the area around Gråkallen reveals an area with varying degrees of deformation and associated phyllonitization, including occurrences of sulphide-bearing hydrothermal quartz in association with the deformation zones. Two types of deformation zones were recognized. 1. Millimetre to centimetre mica- and epidote-rich zones with dynamically recrystallized quartz. 2. Decimetre to meter wide zones with quartz, muscovite, little or no feldspar, except a few albite porphyroblasts and varying degrees of deformation, from protomylonite to mylonite. The least deformed samples have a magmatic texture, but the feldspars shows weak sericitization and saussuritization. With increasing degree of deformation, the feldspars disappear and muscovite appears, revealed by the loss of Na, Ca and Eu and gain of K. There is also a relationship between the relative amount of recrystallized quartz to clast ratio and the amount of trace element mobilization. Comparisons of the least and most deformed samples are shown by examining mineral assemblages and textures, along with quantitative geochemical and mineralogical data. Isocon diagrams and quantitative Rietveld will be used to infer which major and trace elements and minerals that have been mobilized during deformation. The next step will be to compare the geochemical data to microscopic investigations, and SEM, microprobe and laser data will be used to accurately determine the mineral chemistry of the different mineral phases. By using principles of geochemistry, the goal is to understand the element mobility path of the different elements and minerals in the granitoid during deformation.

URL: http://www.cbc.ca/news/canada/sudbury/scientist-unlocking-secrets-from-sudbury-s-black-rocks-1.1158083

Abstract Body: This study implements the use of High Resolution Transmission Electron Microscopy (HRTEM) and Focused Ion Beam (FIB) techniques for the investigation of nano-sized particulate matter and secondary mineral phases in black-rock coatings. These coatings occur in the vicinity of the smelter centres in Sudbury, Trail and Rouyn-Noranda, Canada, and are products of past emissions of sulphur dioxide (creating sulphuric acid) and particulate matter. HRTEM studies indicate the presence of emitted particulates and aerosols that became trapped in a viscous amorphous silica gel during coating formation. The identification of these phases gives insight on nano-sized particulate matter that is commonly undetected when examining soils and lake sediments. The HRTEM studies also show that the silica-rich coatings (a) suppress the transformation of secondary phases such as Fe-hydroxides and Fe-sulfates (e.g. jarosite minerals) towards thermodynamically stable phases such as goethite and hematite, and (b) limit the equilibration between pore spaces occupied by nano-sized particulate matter, secondary Fe-Cu-sulfates and jarosite group minerals, and trapped phyllosilicates such as clays and chlorite. The preservation and disequilibria of mineral phases in these silica coatings give insight into past environmental conditions during coating formation and the nature of past and present nano-sized particulate matter emitted by smelters.

Title: Structural accommodation of K at dravitic tourmaline's *X*-site: insight from Raman spectroscopy and single crystal X-ray diffraction

Presenter/First Author: Eleanor Jane Berryman, Technical University Berlin, Potsdam,

Presenter/First Author Email: berryman.eleanor@gmail.com

Co-authors: Bernd Wunder, Helmholtz-Zentrum Potsdam GFZ, Potsdam, Germany; Andreas Ertl, Universität Wien, Vienna, Austria; Monika Koch-Mueller, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam, Germany; Wilhelm Heinrich, , , ; Gerhard Franz, Technische Universität Berlin, Berlin, Germany

Published Material: The Raman spectra were presented at the IMA conference in Johannesberg, September 2014.

Abstract Body: Potassium incorporation in dravite increases with pressure, temperature, and its relative concentration in the crystallizing fluid, leading to K-dominant tourmaline (maruyamaite [$K(Mg_2Al)Al_6Si_6O_{18}(BO_3)_3(OH)_3O$]) forming at high-grade conditions given a K-rich fluid. The question remains of how the large K^+ ion influences tourmaline's crystal structure, particularly in comparison to the more common end-member, dravite [$NaMg_3Al_6Si_6O_{18}(BO_3)_3(OH)_3(OH)$]. In addition, most Raman spectroscopic studies have been conducted on natural tourmaline, which are solid solutions of multiple end-members. The presence of many site substitutions in these tourmaline leads to complicated Raman spectra, hindering unambiguous band assignments.

To understand how tourmaline accommodates the K^+ ion, we characterized synthetic maruyamaite by electron microprobe, single crystal and powder XRD, Raman and IR absorption spectroscopy. Our synthetic tourmalines have a constrained composition and correspondingly simpler Raman spectra allowing us to unambiguously assign the O-H stretching bands to specific site compositions. The incorporation of K in dravitic tourmaline expands the unit cell volume from a value of 1570 Å^3 for our dravite to 1588 Å^3 for our maruyamaite. In detail, the *X*-site polyhedra of the latter expand, with average <*X*-O> distances of 2.737(12) Å (cf. ~2.69 Å for dravite). The other coordination polyhedra are similar in size to dravite. Comparison of the Raman spectra of dravite and maruyamaite reveals K's effect on the local bonding environment. The Raman band assigned to the occupied *X*-site shifts from 3750 (dravite; ^{X}Na) to 3769 cm^{-1} (maruyamaite; ^{X}K), reflecting the shortening of the O-H bond in the *X*-site-neighbouring *W*(*O1)* site. In addition, the presence of vacancies at the X-site is common to all synthesized tourmaline, as indicated by a band at 3618 – 3622 cm^{-1}. The lower frequency of this band indicates that vacancies are associated with a lengthening of the O-H bond at the *W*(*O1*) site.

The investigation of Raman spectra of well-characterized synthetic tourmaline allows unambiguous band assignment. Moreover, the occurrence and relative positions of these bands combined with single crystal XRD provides insightful information about the effect of composition on tourmaline's crystal structure.

Abstract Body: Trace elements composition in gangue fluorite - generally its patterns and ratios -has been widely used to determine the source of solutes in hydrothermal fluid when studying the genesis of hydrothermal ore deposits. This is under the assumption that the trace element composition of fluorite is representative of the hydrothermal fluid from which the fluorite precipitated. However, the trace element compositions of minerals are strongly affected by the partitioning behavior of these elements. Therefore, in order to obtain information on the trace element

composition of the hydrothermal fluid that no longer exists from fluorite, it is crucial to know the partition coefficients of the elements of interest between fluorite and fluid. It is well known that partition coefficients vary with physicochemical conditions, which can be predicted with Lattice-Strain model (see Blundy & Wood 1994). We are performing fluorite-fluid partitioning experiments to obtain a basic set of partition coefficients as a starting point to build a model using Lattice-Strain Theory, to extrapolate coefficients for any set of physicochemical conditions. We have successfully synthesized fluorite, verified by X-ray diffraction analysis, in aqueous solutions doped with trace elements at typical hydrothermal temperatures from 60 °C to 250 °C. Analysis of the trace elements concentration in synthesized fluorite and residual fluid from the 60 °C experiment using ICP-MS technique gave us the first set of partition coefficients, which are in general agreement with the data obtained by van Hinsberg (2010) using a different experimental approach. Once this model is built, natural fluorite crystals sampled in ore deposit will be analyzed for trace element content, and relevant partition coefficients will be applied to reconstruct the trace elemental composition of the ore-forming fluid.

Title: Effects of Viewing Geometry, Aggregation State, and Particle Size on Reflectance Spectra of the Murchison CM2 Chondrite

Presenter/First Author: Valerie B Pietrasz, California Institute of Technology, Pasadena, CA

Presenter/First Author Email: valerie.pietrasz@gmail.com

Co-authors: Matthew R Izawa, University of Western Ontario, London, ON, Canada; Paul Mann, University of Winnipeg, Winnipeg, MB, Canada; Edward Cloutis, University of Winnipeg, Winnipeg, MB, Canada; Kim Tait, Royal Ontario Museum, , Canada; Tanja Shäfer, , , ; Kurt Mengel, TU Clausthal, Clausthal-Zellerfeld, Germany; Andreas Nathues, Max Planck Institute for Solar System Research, Katlenburg-Lindau, Germany; Michael Shäfer, , , ; Guneshwar Thangjam, , , ; Martin Hoffmann, , ,

Abstract Body: Several current missions will investigate 'dark' asteroids, whose spectra have weak or no distinct spectral features. Many non-compositional effects can influence reflectance spectra, complicating the analysis of such data from remote surfaces. Using a sample of Murchison CM2 chondrite, a series of absolute reflectance (across a 0.3µm–2.5µm range) spectra was collected, varying a range of these non-compositional parameters. In situ spectra of three samples with both saw-cut and fusion-crusted faces were taken; sub-samples of these slabs were then powdered to <150µm to investigate spectral homogeneity within a sample. To explore the effects of grain size, a series of measurements was taken in which the same sample was measured at progressively smaller grain sizes (1000, 500, 250, 150, 90, and 45µm). Mixtures of coarse (0.5-1mm) particles combined with varying amounts of <45µm fine particles taken from the same sample as well as homogeneous samples prepared with different powder-packing (regular, fluffy, and packed) techniques were measured to examine surface texture effects. Lastly, spectra of one <90µm sample were taken at different phase angles to better account for the wide variations in viewing geometry that are possible from spacecraft encounters. Intra-sample heterogeneity, while spectrally detectable, is relatively limited and generally within the range of variations exhibited by duplicate measurements of the same sample after repacking. Decreasing grain size causes a decrease in spectral contrast and increased visible spectral slope. Fine-grained particles appear to exert a disproportionately strong influence on spectral properties relative to their volume. Phase angle effects include increased visible slope with increasing phase angle, a trend that may reverse at very high phase angles (>~100°). Overall, it should be possible to make reasonable compositional interpretations of carbonaceous chondrite spectra and constrain some physical properties (e.g., grain size). The full spectral resolution data collected may also inform the interpretation of hyperspectral data returned from Ceres, Bennu, and other dark carbonaceous chondrite-like surfaces.

Title: The position of Anthropogenic Activities on Atlantic and Indian Oceans in Africa

Presenter/First Author: Babagana Abubakar, Seabed, Lagos,

Presenter/First Author Email: babaganabubakar2002@yahoo.com

Published Material: Africa is the second largest and most populated continent after Asia. Geographically it is located between the Atlantic and Indian Oceans. Most of the Africa's most populated and industrialized cities are located along the coast of the continent facing the Atlantic and Indian Oceans, example of such cities include Casablanca, Dakar, Accra, Lagos, Luanda and Cape town all facing the Atlantic Ocean and cities like East London, Durban, Maputo, Dar-es-salaam and Mogadishu are all facing the Indian Ocean. As a result of the geographical locations of African Coastal Cities plus increase in their population, industries, sea port operations, petroleum exploration activities, trafficking of toxic wastes and improper waste management culture lead to the incessant increase in the pollution of the two oceans. NATURE OF POLLUTION OF THE ATLANTIC OCEAN i. The petroleum exploration activities going on along the coast of "Gulf of Guinea" region in countries such as Equatorial Guinea, Sao Tome and Principe, Gabon, Nigeria, Angola and others continuously causes oil spillages in the process of drilling, bunkering and discharging of petroleum products in the Atlantic Ocean.

Abstract Body: Africa is the second largest and most populated continent after Asia. Geographically it is located between the Atlantic and Indian Oceans. Most of the Africa's most populated and industrialized cities are located along the coast of the continent facing the Atlantic and Indian Oceans, example of such cities include Casablanca, Dakar, Accra, Lagos, Luanda and Cape town all facing the Atlantic Ocean and cities like East London, Durban, Maputo, Dar-es-salaam and Mogadishu are all facing the Indian Ocean. As a result of the geographical locations of African Coastal Cities plus increase in their population, industries, sea port operations, petroleum exploration activities, trafficking of toxic wastes and improper waste management culture lead to the incessant increase in the pollution of the two oceans.

NATURE OF POLLUTION OF THE ATLANTIC OCEAN

i. The petroleum exploration activities going on along the coast of "Gulf of Guinea" region in countries such as Equatorial Guinea, Sao Tome and Principe, Gabon, Nigeria, Angola and others continuously causes oil spillages in the process of drilling, bunkering and discharging of petroleum products in the Atlantic Ocean.

ii. The incessant degreasing of the Sea Ports "Quay Aprons" along the Coastal cities of Lagos, Duala, Libreville, Luanda, Cape Town etc are continuously polluting the Atlantic Ocean with chemicals which is affecting negatively the Ocean marine biodiversity of the Atlantic Ocean in general.

iii. Local wastes generated from the houses located in the coastal cities are always finding their ways directly or indirectly into the Atlantic Ocean. In fact this explains why plastic containers are always deposited by the Ocean along the African beautiful coastal beaches.
iv) Gas flaring activities in the gulf of guinea region is another source of pollution and even source of canalizing the ongoing climate change across the globe in the region. Because a report released by the renown non-governmental organization on environmental pollution the Netherlands

based Climate Justice Programme under the aegis of "friends of the Earth" indicated that the coastal region of Nigeria along accounts for 16 percent of the world's total flare.

Title: Evaluation of Satellite SST Data Using in situ Skin SST Measurements

Presenter/First Author: Lei Guan, Ocean University of China, Qingdao,

Presenter/First Author Email: leiguan@ouc.edu.cn

Co-authors: Liqin Qu, , , ; Kailin Zhang, , ,

Published Material: Presented at PORSEC-2014.

Abstract Body: Sea Surface temperature (SST) is an essential indicator for climate change. High accuracy and stability of the satellite SST products are required for long-term climate data records of global SST. It is important to routinely collect in situ SST measurements for the evaluation and improvement of the quality of satellite SST products. The infrared SST autonomous radiometer (ISAR), made by the University of Southampton, has been deployed on the research vessel Dong Fang Hong II of Ocean University of China since September 2009. The ISAR designed with an accuracy of 0.1 K was calibrated at National Physical Laboratory, UK, in June 2009, through the Committee on Earth Observation Satellites (CEOS) comparison of Infrared radiometry in support of satellite calibration and validation for measuring SST for studies of climate change. The R/V Dong Fang Hong II operates mainly in the China Seas including Bohai Sea, the Yellow Sea, the East China Sea and the South China Sea, for about 300 days per year. The skin SST measurements were collected during 33 cruises in the China Seas from 2009 to 2013. The satellite SST products are compared with shipboard measurements of skin SST. The results will be presented and discussed.

Title: Internal Waves Induced the Increase of Nutrients and Chlorophyll-a Concentrations in the Dongsha Atoll Continental Shelf

Presenter/First Author: Jia-Jang Hung, Natl Sun Yat Sen Univ, Kaohsiung,

Presenter/First Author Email: hungjj@mail.nsysu.edu.tw

Co-authors: S.-H. Peng, , , ; Y.-H. Wang, , ,

Abstract Body: Many studies have already reported that the internal waves were generated frequently in the Luzon Strait and propagated westward to reach or break down on the Dongsha Atoll continental shelf. We have conducted several cruises to measure hydrological (T, S, D) and biogeochemical (nutrients, Chl-a) conditions from two transects covering the slope, shelf break and shelf zones of Dongsha Atoll in the northern South China Sea (SCS). We found that the surface water off Dongsha Atoll was generally depleted with nutrients and its DIN/DIP ratio was quite low and similar to the typical ratio of surface water in the northern SCS. However, the concentrations of nutrients, Chl-a and particulate organic carbon (POC) were enhanced after internal waves (IW) induced upwelling and lifted cold and nutrient rich water to the surface. Meanwhile, the DIN/DIP ratio in the euphotic zone was significantly elevated and approached to that in the aphotic zone after a distinct event of internal waves. Such features can be seen in both eastern transect (M1-M6) and northeastern transect (NM1-NM4) particularly on the shallow zones near the Atoll. The effects of a down-welling (W2 Station) event on biogeochemical distributions can be evaluated through a short time-series observation of T, DO and nutrients at 50 m during the passage of IW. A 30-hour sequential observation shows that the upwelled IW can transport nutrients into surface layer and down-welled IW can transport DOC and POC into subsurface layer and affect carbon budget significantly. In addition, the moored station (IW Station) shows simultaneous changes of T and Chl-a at 40, 100 and 150m, indicating a significant effect of IW on T and phytoplankton biomass. The POC derived from the enhanced nutrients in surface did not likely accumulate on shelf sediments (<50 m), which may imply a transport of Chl-a and POC toward north-western regions. Preliminary data also show that the area was likely a sink of atmospheric CO_2 along the eastern transect (M1-M6).

Title: Impact on the Circulation in the Sumjin River Estuary under summer monsoon condition

Presenter/First Author: Young Jae Ro, Chungnam National University, Daegu,

Presenter/First Author Email: royoungj@cnu.ac.kr

Published Material: Partial result were published in the Journal of Korean Coastal and Ocean Engineering Society.

Abstract Body: The Sumjin/Kangjin Estuarine System (hereafter, SKY) is one of most complex and the lastly remained natural system whose river runoff is drained into the South Sea of Korean Peninsula and is interconnected among Sumjin River, Kangjin Bay and Kwangyang Bay through very narrow channel. During the monsoon season, River runoff is around 300 to 500 % of normal condition. River runoff is dominant forcing for the estuarine circulation system in addition to tidal forcing with 4.5 meter range. Among many features, we have reproduced the tidal and residual current system with skill scores > 90 %. Very strong tidal current is reproduced with speed exceeding 3.5 m/s in the Noryang Channel and 2.5 m/s in the Changson Channel. Residual current shows very complex pattern with local eddy motions with radius around 2~3 km with clockwise and counterclockwise rotations.

In the Yeosu Channel where the longitudinal length is around 30 km, and cross-channel width around 5~8 km, the tidal current speed exdeeded 2.0 m/s during monsoon season. It also shows the asymmetry of current and salinity field due to deflection effect by the Coriolis Force.

Title: Seasonal and Inter-Annual Variations of Remotely Sensed Biogeochemical Parameters in Northern Gulf of Mexico and Their Correlations to the Size of Hypoxia

Presenter/First Author: Jinchun Yuan, Elizabeth City State Universit, Elizabeth City, NC

Presenter/First Author Email: jyuan@mail.ecsu.edu

Abstract Body: With the development of algorithms for many biogeochemical parameters in surface water, satellite remote sensing has become a useful tool for the study of marine ecosystems. The hypoxia (O_2 < 2 mol L^{-1}) in the northern Gulf of Mexico has been measured annually in summer for about three decades with shipboard methods. A systematic

study of other biogeochemical parameters and their relation with dissolved oxygen and systematic monitoring of the hypoxia size are essential for understanding hypoxia development and for evaluating the effectiveness of the proposed conservation remedies. Here, we report a study of seasonal and inter-annual variations of remotely-sensed area-weight-mean of sea surface chlorophyll a (*chl a*), colored dissolved organic matter (CDOM) index, particulate organic carbon (POC), particulate inorganic carbon (PIC), and attenuation coefficient at 490 nm (K_{490}) of the northern Gulf of Mexico. Area-weight-mean of *chl a*, CDOM index, POC, PIC, and K_{490} were derived from SeaWiFS data from September 1997 to December 2010. Each one of these biogeochemical parameters showed a strong seasonal cycle with a peak in the Spring and a valley in Autumn. In addition, a strong linear correlation between hypoxia size in bottom waters and area-weighted-mean of *chl a*, POC, and K_{490} in surface waters were observed. These correlations offer an alternative method for estimating hypoxia size from remote sensing data.

Title: SEASONAL VARIABILITY OF CARBONATE SYSTEM CHARACTERISTICS IN A CORAL REEF ECOSYSTEM, SOUTHERN TAIWAN

Presenter/First Author: Pei-Jie Meng, National Museum of Marine Biology and Aquarium of Taiwan, Pingtung,

Presenter/First Author Email: pjmeng0926@gmail.com

Co-authors: Chung-Chi Chen, NTNU National Taiwan Normal University, Taipei, Taiwan

Abstract Body: The objective of this study is to explore the seasonal variability of carbonate system parameters and to identify the factors affecting the pCO_2 in surface water of a coral reef ecosystem. The total alkalinity (TA), pH and calculated partial pressure of CO_2 (pCO_2) were measured in the water column from a total of 17 stations in the Nanwan Bay, southern Taiwan. The results of the study show that spring and winter hydrographical characteristics and vertical mixing of water column was different from the other seasons and therefore contributing to the discrepancy of data collected as correlation of temperature, salinity, carbonate system parameters for summer and autumn. The control factors of the pCO_2 in surface water during seasonal changes lead to the following conclusion. The non-temperature related effect during spring is greater than temperature related effects. The reverse is true for summer while both temperate and non-temperature related effects more or less offset each other in autumn. One point to note, non-temperature related effects are made up of not only the effect of biological but also vertical mixing of water column and the exchange of gases in the Nanwan Bay. According to calculations, the seasonal data of pCO_2 in surface water is namely 393.7, 406.3, 399.2 and 366.9 µatm, respectively. The seasonal sea-air differences in Δ*p*CO2 were -3.3, 14.3, 7.2 and -29.1 µatm, respectively. These data indicate that the Nanwan coral reef region is the source of CO_2 in the atmosphere during summer and autumn. The calculation an average sea gases flux of CO_2 is -0.98 $gCm^{-2}year^{-1}$ and the annual absorption of gases is -29.3t. In addition to seasonal variability and fluctuations in temperature, the results suggest that vertical mixing of water column, intermittent upwelling of water and the biological effect also account for the changes in the pCO_2 of the water column in this coral reef ecosystem.

Title: Flooding Effects on Organic Carbon Consumption in the East China Sea

Presenter/First Author: Chung-Chi Chen, NTNU National Taiwan Normal University, Taipei,

Presenter/First Author Email: ccchen@ntnu.edu.tw

Abstract Body: A central motivation for this study was to reveal how flood effects on plankton community respiration (CR) in the East China Sea (ECS). In 2010, a devastating flood occurred in July in the Changjiang River; with mean monthly discharge of 60,527 $m^3 s^{-1}$. To compare, data was examined in July of 2009, when the riverine flow was low (mean monthly values = 33,955 $m^3 s^{-1}$). During flood, a tremendous amount of freshwater was delivered into the ECS, and low sea surface salinity (≤ 31 psu) covered almost two third of this continental shelf. High nitrate concentration in the ECS was also measured during the flood, and it was significantly higher than that of 2009 non-flood with mean ± SD values of 6.2 ± 9.8 and 2.0 ± 5.3 µM, respectively. Although primary production in the surface water was high in 2010 flood with mean ± SD value of 62.1 ± 33.8 mg C $m^{-3} d^{-1}$. Surprisingly, the mean value of Chl *a* was only slightly higher in 2010 than that of 2009, and bacterial biomass was even lower in 2010 compared to that of 2009. The CR was however still higher in 2010 than that of 2009, with mean (± SD) values of 105.6 (± 66.7) and 73.2 (± 76.9) mg C $m^{-3} d^{-1}$, respectively. To further explore, the difference (i.e., 2010 – 2009) of variables at the same station between two sampling periods were compared. Values of difference in CR was positively and negatively linearly regressed with that of differences in Chl *a* and fCO_2 (all $p \leqq 0.001$), respectively. These results imply that the flooding effect on higher CR during 2010 might be more attributed to phytoplankton. It also infers that the huge amount of fCO_2 absorption during 2010 flood was relative to strength of plankton activity, especially phytoplankton. These results all suggest that the devastating flood has significant effect on organic carbon consumption in the ECS. This impact might be even more pronounced when extreme rainfall events and flood magnitude have increasing dramatically throughout the world in last few decades.

Title: The Acidification Coupled with Eutrophication of the Coastal Waters of Bolinao, Pangasinan, Philippines

Presenter/First Author: Mary Chris Tentia Lagumen, Marine Science Institute, University of the Philippines, Quezon City,

Presenter/First Author Email: marychristentia@gmail.com

Abstract Body: Ocean acidification is becoming a global concern due to its potential effects on marine resources. In coastal areas, an emerging problem is ocean acidification due to eutrophication resulting from human activities. The coastal water of Bolinao, Pangasinan, Philippines has become eutrophic due to increased nutrient loading from unconsumed fish feeds in fish cages. Mariculture is a big industry in Bolinao. In over a decade, the area has experienced decreased oxygen levels leading to hypoxia, fish kills, and algal blooms. The decomposition of organic matter from unconsumed fish feeds results not only to high nutrient buildup but also increased CO_2 and acidity in the area. Nutrients (ammonia, nitrate, nitrite, phosphate and silicate), total alkalinity (TA), dissolved inorganic carbon (DIC), pH, dissolved oxygen (DO), aragonite saturation state (Ω_{arg}) and partial pressure of carbon dioxide (pCO_2) were measured to determine the combined effect of acidification and eutrophication in Bolinao. Monitoring results have shown an increase in nutrients by 30% to 70% in over a decade. Total alkalinity (TA) data have a good correlation with salinity showing lower TA values in less saline waters. High DIC values were obtained from shallow stations with depth less than 5 meters. pH exhibited a clear seasonal cycle showing low pH values during the start and toward the end of the year while it increased from April to August. Lowest pH values were obtained from high residence time areas compared to areas which are near the opening of the channel. The eutrophic and acidified coastal waters of Bolinao are already affecting the seagrass and coral reef ecosystems in the area.

Title: Assessing the impact of tides and winds on the circulation of the Gulf of La Spezia with high-resolution, three-dimensional simulations

Presenter/First Author: Lina Porciello, CNR Institute for Marine Science, Lerici,

Presenter/First Author Email: lina.porciello@sp.ismar.cnr.it

Co-authors: Marcello G. Magaldi, Johns Hopkins University, 34th and North Charles Streets, Baltimore, MD 21218, MD; Annalisa Griffa, ISMAR-CNR, U.O.S. of Pozzuolo di Lerici, Forte Santa Teresa, 19036, Lerici (SP), Italy; Massimiliano Barbolini, , , ; Francesco Ferro, , , ; Mireno Borghini, , ,

Published Material: EGU2015 VIENNA. The results are not under review or published yet.

Abstract Body: The Gulf of La Spezia (Ligurian Sea, Northwestern Mediterranean) is characterized by a complex geometry and extends along a Southeast-Northwest axis with maximum width and length of 9 and 13 km, respectively. Water exchanges between the inner and outer parts of the Gulf are limited to two openings of a breakwater. The Gulf is site of intense harbor activities and subject to significant urban and industrial discharges from the town of La Spezia.

Despite its importance, the three-dimensional circulation of the Gulf of La Spezia is not well established. Recent observational efforts suggest a mean circulation scheme, which is not fully in agreement with the hypothesized three-dimensional baroclinic response to wind forcing. Previous numerical studies are either bi-dimensional or neglect the complexity of the Gulf using idealized geometries.

In this study, the three-dimensional open-source DELFT3D model is setup to assess the dynamics and the circulation patterns in the Gulf. A high-resolution horizontal grid (nominal spacing of about 50 m) is employed to fully resolve the complex real geometry of the region. Different simulations are run by varying the idealized forcing conditions. The first simulation aims at assessing the role of the semidiurnal tidal signal observed in the outer portion of the Gulf and with a sinusoidal oscillation with a period of 12 h and 25 min and a sea-level amplitude of 15 cm. In the second simulation, another oscillation of 70 min and amplitude of 5 cm is superimposed to the tidal signal to mimic the local seiche. A third simulation considers the addition of idealized sea breeze effects.

All simulations start at rest and with typical observed hydrographic initial conditions. The initial temperature (salinity) linearly decreases (increases) in the vertical. No-slip conditions are applied at all material boundaries and a Chezy coefficient of C=50 is used for the bottom frictional term. Horizontal viscosity and diffusivity are both set to a 0.05 m^2/s while a “k-Ɛ” turbulent closure scheme is used in the vertical.

Results and differences in the runs are quantified in terms of velocity at the two openings of the breakwater, residence times, erosion of the initial stratification as a measure of mixing. Realism of the different scenarios is validated against the observations taken in the area.

Title: Paleotempestology of Chezzetcook Inlet, Nova Scotia

Presenter/First Author: Frank Oliva, University of Ottawa, Ottawa, ON

Presenter/First Author Email: foliva@uottawa.ca

Co-authors: Andre E Viau, University of Ottawa, Ottawa, ON, Canada; Matthew C. Peros, Bishop's University, Sherbrooke, QC, Canada

Abstract Body: A multi-proxy approach framework is presented to reconstruct the paleotempestology in Chezzetcook Inlet, Nova Scotia on the eastern Canadian seaboard. This study aims at identifying high storm activity periods, intensity and frequency of past tropical storms by using fossil remains, such as shells and foraminifera deposited on land or in fresh water basins from past storm surges. Sediment cores extracted from coastal lakes and marshes were chosen based on several criteria, such as elevation, distance from the Atlantic Ocean and the material composition of barriers. Several laboratory analyses are conducted on the sediment cores, for example x-ray, magnetic susceptibility, loss-on-ignition and grain-size. Future work will also include the study of other proxies including exploring the geochemistry of the past storms. Oxygen and carbon from individual tree rings will be extracted to establish storms' unique isotopic signatures and to validate sediment core findings.

Title: Turbulence in the Summertime Pycnocline

Presenter/First Author: Iossif Lozovatsky, University of Notre Dame, South Bend, IN

Presenter/First Author Email: i.lozovatsky@nd.edu

Co-authors: Jae-Hak Lee, KORDI Korea Ocean Research and Development Institute, Ansan, South Korea; Harindra Joseph Fernando, University of Notre Dame, Notre Dame, IN

Abstract Body: Microstructure measurements in the East China Sea allowed examination of turbulence influenced by summertime stratification in shallow (52 to 62 m depth) tidal basin, using 134 CTD and the dissipation rate profiles obtained during a 25-hour drift over a slightly slopping bottom. Turbulence in the pycnocline was highly intermittent, with spatially alternating layers of low (~ 10^{-9}) and enhanced (~ 10^{-7}) W/kg dissipation rate. An analysis of temporal variability of ε, eddy diffusivity K_N and squared buoyancy frequency N^2. Near the upper boundary of the pycnocline, majority of the dissipation and diffusivity extrema coincide with the extrema of buoyancy frequency, showing positive and negative (min-max) correlations. A negative correlation was mainly found in weakly stratified layers of the pycnocline and in a stratified upper portion of the BBL. The dependence of the dissipation on the normalized squared buoyancy frequency was very strong (the “-3” power) in a relatively narrow range of weak stratification when turbulence not only dissipated but also produced mixing that reduces the local buoyancy (density) gradient.

Analysis of the cumulative distribution functions (CDF) of the logarithm of the dissipation rate in the test area showed that the empirical CDFs can be successfully approximated by the generalized extreme value distribution for the areas of sharp pycnocline as well as less stratified transitional layers between the pycnocline and BBL and between the pycnocline and surface layer. This suggests that the generation and dissipation of turbulence in the summer pycnocline of ECS and adjacent startified layers can be considered as a result of extreme events such as random internal-wave breaking and sporadic instabilities. This turbulence occurred under light winds, being influenced by tidal currents in the BBL and internal waves in the pycnocline.

Title: PASSIVE ADVECTION AND REDISTRIBUTION OF HEAT IN WARMING OCEAN BASINS

Presenter/First Author: Oluwayemi Anne Garuba, George Mason University Fairfax, Fairfax, VA

Presenter/First Author Email: ogaruba@masonlive.gmu.edu

Co-authors: Barry A Klinger, George Mason University Fairfax, Fairfax, VA

Abstract Body: An important parameter for the climate response to increased greenhouse gases or other radiative forcing is the speed at which heat anomalies propagate downward in the ocean. Ocean heat uptake occurs through passive advection/diffusion of surface heat anomalies and through the redistribution of existing temperature gradients due to circulation changes. Atlantic meridional overturning circulation (AMOC) weakens in a warming climate and this should slow the downward heat advection (compared to a case in which the circulation is unchanged). However, weakening AMOC also causes a deep warming through the redistributive effect, thus increasing the downward rate of heat propagation compared to unchanging circulation. Total heat uptake depends on the combined effect of these two mechanisms.

Passive tracers in a control and perturbed CO2-quadrupling experiments are used to investigate the relative effect of passive advection and redistribution. The spatial pattern and mechanisms of warming are examined. One feature of global warming appears to be the deeper heat penetration in the Atlantic than in the Indo-Pacific oceans. Even though our experiments display deep injection of a passive tracer in the deep-water formation region of the North Atlantic, most of the difference in speed of heat penetration is due to the redistribution term rather than this North Atlantic sinking. With further experiments we isolate the effect of weakening overturning on the heat uptake associated with passive advection. The separate effects of wind and salinity changes in changing circulation and the resulting effect on redistribution in the individual basins are also investigated.

Title: Temperature and salinity effects as a climate change impact on flowering of the seagrass *H. stipulacea* along the coast of Tanzania

Presenter/First Author: Moses Joel Shimba, University of Dar es Salaam, Dar es Salaam,

Presenter/First Author Email: shimbamoses@yahoo.com

Abstract Body: Long term data sets on the phenology of Tanzania seagrasses either do not exist or have not been correlated with changing climate. The present investigation attempts to assess the influence of ocean physical parameters (temperature and salinity) on flowering of seagrass (*H. stipulacea*) as the means of determining and predicting the effect of climate change on sexual reproduction of marine plants. Flowers have not been reported for tropical seagrass *Halophila stipulacea* along the coast of Tanzania, Indo-Pacific, but after transplanting from Kunduchi intertidal mudflats to experimental cultures, flowers were observed. Staminate and pistillate flowers were produced at the temperature-salinity interactions of 24-28 °C/38-42 ‰ and 28-32°C/38-42 ‰ under 12 hr photoperiod (582 Lux) after twelve months in culture, but not at low temperature against low and mid salinity interactions at 20-24 °C/30-34 and 20-24 °C/34-38 ‰. A total of 79 flowers were recorded from January to December, 2013; where 54 staminate and 25 pistillate flowers were recorded throughout the experimental culture. Plants cultured at 24-28 °C/38-42 ‰ produced 25 staminate and 11 pistillate flowers, while plants at 28-32 ^{o}C/38-42 ‰ produced 29 staminate and 14 pistillate flowers, while none of the flowers observed in lower ranges of temperature against low and mid salinity interactions**.** It is concluded that temperature and salinity are the primary controlling factors involved in the flowering of *Halophila stipulacea*; and hence climate change is expected to cause a significant effect on seagrasses by affecting their reproductive ecology and physiology.

Title: A Survey of Summer Coccolithophore Stocks and Diversity in the Western Edge of the Barents Sea

Presenter/First Author: Jacques Giraudeau, University of Bordeaux 1, Talence,

Presenter/First Author Email: j.giraudeau@epoc.u-bordeaux1.fr

Co-authors: Ludovic Devaux, Université Bordeaux/CNRS/EPHE, Talence, France; Thierry Garlan, , ,

Abstract Body: The Barents Sea, a shallow Arctic marginal sea, is particularly vulnerable to large-scale hydro-climatic changes associated with the polar amplification of climate change. Key oceanographical variables in this region are the seasonal development of sea-ice and the location and strength of physico-chemical gradients in the surface and subsurface water layers induced by the convergence of Arctic- and Atlantic-derived water masses. The biomass and taxonomic groups of phytoplankton species thriving in surface waters of the Barents Sea are therefore subjected to a large spatial and temporal variability according to the seasonal dynamics of the Arctic Front and changes in the structure of the upper water column (Signorini and McClain, 2009). Remote sensing imagery (e.g. Smith et al., 2004) confirmed the increasing success of calcifying haptophytes (coccolithophores) in the summer phytoplankton production of the Barents Sea over the last ca. 20 years, as a response to an overall larger contribution of Atlantic waters to surface and sub-surface waters, as well as to enhanced sea-ice melt-induced summer stratification of the photic layer. The present study provides a first thorough description of coccolithophore standing stocks and diversity in the western edge of the Barents Sea from surface and water column samples collected during August-September 2014 along a S-N transect from northern Norway to southern Svalbard, as part of the research cruise MOCOSED 2014 (SHOM - RV *Pourquoi Pas ?*). Census counts are discussed in view of the physical-chemical status of the photic layer as extracted from multisensor vertical casts and remote sensing. We aim here at filling some gaps in our knowledge on hydrological processes influencing the production and diversity of calcareous phytoplankton in polar environments.

Title: Coastal eutrophication and biogeography in northeast United States (Maine to Delaware) estuaries as recorded by dinoflagellate cysts

Presenter/First Author: Andrea Michelle Price, McGill University, Montreal,

Presenter/First Author Email: andrea.price@mail.mcgill.ca

Co-authors: Vera Pospelova, University of Victoria, Victoria, BC, Canada; James S Latimer, , , ; Gail L Chmura, McGill Univ, Montreal, QC, Canada

Abstract Body: We are investigating the use of dinoflagellate cysts (the fossilizable life stage of planktonic dinoflagellates) from sediments as a means to evaluate and monitor levels of cultural eutrophication. Nutrient concentrations in coastal waters do not always reflect the total amount of nutrients entering a water body, as they are rapidly taken up by phytoplankton and aquatic vegetation. One method to estimate nutrient input is nutrient loading models. Coupling nutrient loading models along with biological indicators that act as early warning signs in water quality degradation can be used to quantify the level of nutrient inputs that may be harmful to estuaries. Dinoflagellate cyst assemblages are known to reflect sea-surface conditions and are used in paleoenvironmental reconstructions to provide information on sea-surface temperature, salinity, productivity, and nutrient availability. Although previous studies have noted the impact of eutrophication on assemblages of cyst taxa in sediments, no study has compared empirical values of nutrient loading to cyst assemblages. We have assessed the relationship of cyst assemblages to nitrogen levels estimated from nutrient loading models and examined if this relationship varies with biogeographic province and type of estuary (riverine, lagoon, coastal embayment, and fjord). A total of 61 sediment samples from 23 estuaries collected by the EPA were analyzed. We found nitrogen loading and cysts produced by heterotrophic taxa are positively correlated when estuary type is accounted for. Nitrogen loading is also a statistically significant parameter influencing the spatial distribution of cyst assemblages in the study area, along with sea-surface temperature, tidal range, water residence time, grain size, and biogenic opal. In addition, the cyst signal clearly documents two biogeographic provinces, and supports studies of other marine organisms which delineate the boundary between the Acadian and Virginian provinces at Cape Cod.

Title: Sedimentation in Hinchinbrook Entrance, Alaska, USA: correlations with wave energy on the Gulf of Alaska continental shelf

Presenter/First Author: Nicole Robina Marshall, Virginia Institute of Marine Science, Gloucester Point, VA

Presenter/First Author Email: nrmarshall@vims.edu

Co-authors: Courtney Kay Harris, Virginia Inst Marin Science, Gloucester Point, VA; Steven A Kuehl, College William & Mary, Gloucester Point, VA

Abstract Body: A high-resolution sedimentary sequence from Hinchinbrook Entrance (HE), Alaska is used to determine relationships between sedimentation and environmental factors, such as proxies for wave energy on the Gulf of Alaska continental shelf. The Copper River discharges into the northern Gulf of Alaska predominately during the summer (May to October), with the formation of a surface sediment plume that is largely advected westward into Prince William Sound through HE by the Alaska Coastal Current. During the winter (October to May), storms spawned by the Aleutian Low generate large waves with the potential to resuspend sediments on the shelf. Cores from HE show regular interlaminations of fine and coarse sediment that are interpreted as summer and winter annual deposition, respectively. Yearly layers are divided into measured summers and winters using XRF Sr/Pb as a proxy for grain size. Wave data from the Gulf of Alaska (NOAA NDBC) were transformed into proxies for wave energy, including bottom wave orbital velocities, bed mobility percentages and recurrence intervals for resuspension. The threshold for resuspension on the shelf is 0.19 ms^{-1} based on the mean d_{50} of shelf sediments. Bed mobility, frequency for resuspension, and mean bottom wave orbital velocities are higher in the winters compared to the summers. Thicker winter deposits at HE are present when wave energy on the shelf is higher. Sediments from HE have a cyclical pattern of winter and summer sedimentation, however the deposit thickness is ~6 orders of magnitude greater in the winter of 2001, during which time the average bottom wave orbital velocities along the Gulf of Alaska shelf were highest and the shelf was most mobile compared to any other season on record. The wave energy on the shelf appears to be controlling winter sedimentation into Prince William Sound, providing implications for reconstructing past winter wave energy on the Gulf of Alaska continental shelf beyond historical records.

Title: Comparing Bayesian stable isotope mixing models: Which tools are best for sediments?

Presenter/First Author: David J Morris, University of Virginia, Charlottesville, VA

Presenter/First Author Email: djm7k@virginia.edu

Co-authors: Stephen A Macko, Univ Virginia, Charlottesville, VA

Published Material: I will be using my data that was published by Faux et al. 2011, but using different tools to analyse the data.

Abstract Body: Partitioning of contributions of organic components into a mixture has been a long term goal in organic geochemistry. Using stable isotope mixing based on a Bayesian models have received much attention as a means of coping with multiple sources and uncertainty in isotope ecology (e.g. (Phillips et al., 2014)), enabling the probabilistic determination of the contributions made by each food source to the overall diet of the organism in question. We have applied these techniques to marine sediments for the first time. The sediments of the Chukchi Sea and Beaufort Sea offer an opportunity to utilize these techniques for organic geochemistry. There are at least three likely sources of organic carbon that are contributors to the marine sediments: pelagic phytoplankton, sea ice algae and terrestrial material from rivers and coastal erosion, as well as considerable variation in the marine $d^{13}C$ values. Bayesian mixing models using bulk $d^{13}C$ and $d^{15}N$ data from Shelf and Basin allow for the probabilistic determination of the contributions made by each of the sources to the organic carbon budget, and can be compared with existing source contribution estimates based upon biomarker models (e.g. (Belicka & Harvey, 2009), (Faux et al., 2011)). With a variety of mixing models now available, this study compares results from SIAR, MixSIR and IsotopeR in order to suggest which tool is most appropriate for marine sediments.

Published Material: Physics of Estuaries and Coastal Seas (PECS), Porto de Galinas, Brazil Oct 2014. Not under review nor submitted for publication

Abstract Body: Superstorm Sandy made landfall in northern New Jersey at 2350 hr GMT on 29 October 2012. Serious coastal flooding resulted in significant loss of life and catastrophic property damage (~ $85 billion) for Metropolitan New York (NY), northern New Jersey (NJ) and coastal Long Island (LI). At least 286 people were killed along the path of the storm in seven countries. The track and intensity of the storm were relatively well-predicted a few days in advance by the National Weather Service's (NWS) National Hurricane Center (NHS). Observed flooding during Sandy overran the FEMA estimated 500-year flood risk contour in some coastal locations and resulted in FEMA's prompt removal of their flooding maps immediately after Sandy made landfall. This paper discusses simulations of the surface winds and sea level pressure from an ensemble of WRF-derived runs coupled to a 2D version of ADCIRC (Ocean Circulation Model) and SWAN- simulated wave field and their associated storm surge and coastal setups. By comparing a subset (11 member) of the WRF runs, the question of whether Sandy was a worst-case scenario is discussed.

Title: Ocean Climate Change, Sea Level Increase and Tsunami Hazard Monitored in Real Time over Decades by Sensors on Submarine Telecommunication Cables

Presenter/First Author: Christopher R Barnes, University of Victoria, Victoria, BC

Presenter/First Author Email: crbarnes@uvic.ca

Co-authors: David T Meldrum, , , ; Erica Campilongo, , ,

Published Material: Preliminary data in abstract at AGU Dec 2013; no scientific journal publication submission yet

Abstract Body: Ocean climate change, sea level increase, and tsunami and slope failure hazards represent major factors in environmental change and threats, with profound global and regional socio-economic impacts. Advances in sensor technologies, cabled ocean observatories, and partnerships in submarine telecommunications industry, all combine to promote new Green Cable Systems in providing critical environmental data on regional and global scales. In 2012, three UN agencies, ITU/WMO/UNESCO IOC, established a Joint Task Force that advocates adding environmental sensors to trans-ocean and regional submarine telecommunication cables. JTF is now developing a Wet Demonstrator whereby a commercial grade cable with three repeaters and sensor packages (temperature, pressure, and 3-axis accelerometer), deployed for a year at c. 2000m water-depth, will show installation and operational reliability and data quality. One scenario uses a research cabled ocean observatory with a nearby cable maintenance ship for deployment (e.g. NEPTUNE/Ocean Networks Canada; RSN/Ocean Observatories Initiative or Aloha, US; DONET, Japan; EMSO, Europe), in-kind support, technical staff, and free release of real-time data. Environmental and economic benefits of such a demonstration, ensuring a quantum leap by industry to generate new real-time sensor data every 50-70 km along new and refurbished cable systems across different transects of the world's oceans, would be of profound importance. These advances address global issues affecting societies and future generations, and save vast resources from destruction because of imprecise tsunami hazard warning systems and sea-level change quantification. JTF proposes that for modest cost a new suite of real-time environmental data will be generated over decades to underpin public policy for management, safety, and regulation and for industrial and infrastructure planning.

Title: Short- and Long-Lasting Ocean Circulation Changes Induced by an Extreme High-Latitude Volcanic Eruption

Presenter/First Author: Francesco S.R. Pausata, Stockholm University, Stockholm,

Presenter/First Author Email: francesco.pausata@misu.su.se

Co-authors: Léon Chafik, , Stockholm, Sweden; Rodrigo Caballero, Stockholm University, Stockholm, Sweden; David S Battisti, University of Washington Seattle Campus, Seattle, WA

Abstract Body: Large volcanic eruptions can have major impacts on global climate affecting both atmospheric and ocean circulation through changes in atmospheric chemical composition and optical properties. Since the residence time of volcanic aerosol is around 2-3 years for strong eruptions, it was generally believed that volcanic eruptions produce mainly short-term climate impacts. Therefore, wide attention has been given to the effect of large tropical eruptions on the atmospheric circulation, but only to a lesser extent to the oceanic circulation. Furthermore, high-latitude eruptions have been considered to have an impact only on the Hemisphere where they occur.

In this study, using a coupled ocean-atmosphere-chemistry model, we generate a 20-member ensemble simulation and we examine both short- (1-4 years) and long-term (60 years) effects of an extreme high-latitude eruption. In particular, we focus on systems of crucial importance for the global climate, such as the ocean's meridional overturning circulation and El Niño Southern Oscillation.

We found an El Niño-like response in the 6-8 months after the eruption (similar to the tropical eruptions) and followed by a transition to La Niña-like that peaks 24 months after the eruption. However, the increased likelihood of El Niño phase for a high-latitude eruption has a different explanation compared to tropical eruptions. In the latter case, an El Niño phase may be triggered by reduced surface radiation that smoothens the zonal SST gradient along the equatorial Pacific. While for high-latitude eruptions, changes in atmospheric dynamics in the northern hemisphere trigger a weakening of the trade winds over the western tropical Pacific hence leading to El Niño-like response.

We show for the first time how high-latitude eruptions also lead to long-term effects on ENSO changing both its period and its variability (Fig. 1, left panel). These long-term changes are connected to changes in the strength of the Atlantic Meridional Overturning Circulation induced by the eruption.

Our results show that impacts of high-latitude eruptions may well not be confided to the hemisphere where they occurred but spread globally via atmospheric-oceanic feedbacks (short-term) and via changes in the AMOC and ocean heat content (long-term, Fig. 1, right panel).

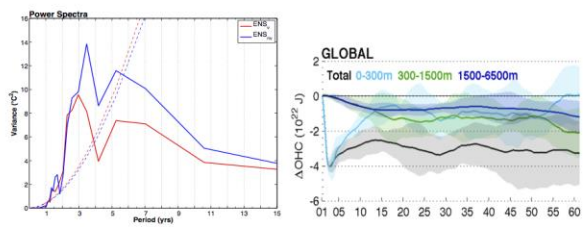

Figure 1: On the left, ENSO power spectrum (solid lines) and the least-squares best fit of a theoretical Markov "Red Noise" spectrum (dotted lines) at 90% confidence level for volcano – ENS_v (red) and no-volcano ensemble mean – ENS_{nv} (blue). On the right, integrated OHC (J) difference between ENS_v and ENS_{nv} from the surface to different indicated depths for the global ocean. The shadings represent the standard deviation of the ensemble difference. Note how the volcanic anomaly persists in the ocean after 60 years (black line).

Title: Surface and Bottom Temperature and Salinity Climatology and Long-Term Changes along the Continental Shelf off the Canadian and U.S. East Coasts.

Presenter/First Author: Benjamin Richaud, Woods Hole Oceanographic Institution, Woods Hole, MA

Presenter/First Author Email: brichaud@whoi.edu

Co-authors: Terrence M Joyce, WHOI, Woods Hole, MA; Young-Oh Kwon, Woods Hole Oceanographic Institution, Woods Hole, MA

Abstract Body: Climatological studies of surface and bottom temperature and salinity have already been presented for different regions along the Canadian and U.S. shelves separately. Here, we merge data sets from the two regions. The first one consists of data from 1910 to 2010, on a large area going from the Scotian Shelf to the Labrador Shelf, the other one goes from Cape Hatteras to the Scotian Shelf, and begins as early as 1864. The resulting data set gives the location, depth and date of stations measuring surface and/or bottom temperature and/or salinity, bottom being defined as less than 10 meters from the bathymetry-given depth. Here, we will focus on the mean seasonal cycle along the shelf and the structure of the mean fields of surface and bottom temperature and salinity and their long-term temporal changes from 1950 to 2010.

Title: The Role of Internal Tides in Patterns of Spatial Variability at Canyons

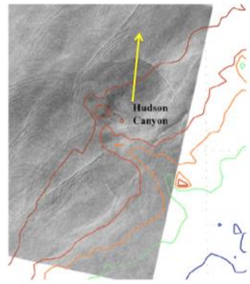
Presenter/First Author: Timothy F Duda, Woods Hole Oceanographic Inst, Woods Hole, MA

Presenter/First Author Email: tduda@whoi.edu

Co-authors: Weifeng Zhang, Woods Hole Oceanographic Insti, Woods Hole, MA; Arthur E Newhall, , , ; Karl Richard Helfrich, WHOI, Woods Hole, MA

Published Material: Some of the internal tide results were reported in a JPO paper* and the AGU Ocean Sci meeting 2014. The hybrid extension of the model is new. * Zhang, W. G., T. F. Duda and I. A. Udovydchenkov, Modeling and analysis of internal tide generation and beamlike onshore propagation in the vicinity of shelfbreak canyons, J. Phys. Oceanogr., 44, 834-849, http://dx.doi.org/10.1175/JPO-D-13-0179.1 , 2014.

Abstract Body: Canyons at the continental slope are places of notable biological activity when compared with adjacent areas. Spatial patterns of activity within canyons have also been noted. Probable contributing factors for the enhancement and the patterns are circulation, seafloor environment, and mixing-induced fluxes. Internal tides (ITs) near canyons have been identified as a probable contributor to mixing and secondary circulations. In addition, IT energy is not evenly distributed at canyons, offering a possible explanation for some of the spatial patterns. A full understanding of IT dynamics at canyons would offer the possibility of building a model framework to better understand differences between canyons, similarities between canyons, and response of canyon systems to seasonal cycles and dynamical episodes such as impinging eddies. Here, details of IT generation near continental slope canyons are presented. Both numerical and theoretical methods are used, and the agreement provides confidence in the results. A multiple-scattering mechanism explains spatial variation of IT generation. A distributed-source mechanism explains patterns of IT energy radiation. The estimated spatial distribution of IT-related mixing around canyons is addressed with a hybrid model of IT-driven nonlinear internal waves. The hybrid model consists of a KdV-family model governing IT evolution that captures the nonhydrostatic dynamics leading to nonlinear internal wave formation. Using the entire collection of models, the implications for spatially variable ecosystem character due to the modeled IT patterns are examined.



The arrow shows internal waves radiating from Hudson Canyon. This synthetic aperture radar satellite image published in *An Atlas of Internal Solitary-like Waves and their Properties* by C. R. Jackson(2004) motivated our work.

Title: Results from the first Topo-Bathymetric lidar surveys of the Chiroptera II sensor: Improved geological mapping and coastal hydrodynamic models

Presenter/First Author: Timothy L Webster, Organization Not Listed, Lawrencetown,

Presenter/First Author Email: tim.webster@nscc.ca

Co-authors: Kevin McGuigan, , , ; Nathan Crowell, , ,

Abstract Body: The Applied Geomatics Research Group (AGRG) within the Nova Scotia Community College (NSCC) acquired a new shallow water airborne topo-bathymetric lidar sensor and flew the first missions in September 2014. The survey areas consisted of several embayments along the Northumberland Strait. The low flow rates associated with the inner bays promote high volumes of sediment cover and bedrock features are rarely exposed. These sediments can be re-suspended in the water column during periods of increased wave activity, thus increasing turbidity and limiting the laser penetration depth. The reflectance of the seabed also effects the laser also effects the maximum depth achieved. The area near Cape John, Nova Scotia where Carboniferous sandstone rocks are exposed provides insights into how the sensor can enhance and extend structural information on geological maps. Traditional topographic lidar reveals a smooth terrestrial landscape with limited outcrop as a result of the deposition of glacial till. The bedrock is exposed along cliffs at the coast where limited bedding and structural measurements can be taken. The first attempt to survey was aborted on Sept. 25 because of high water turbidity levels and poor bathymetric lidar returns. However, after a day of reduced winds it was surveyed on Sept. 26 with penetration to 6 m water depth. The results revealed several previously uncharted features on the seabed including reefs. Other than near-shore sand bars, the offshore currents have scoured the seabed to expose the bedrock revealing bedding planes and fault structures. Details of the strike of the beds offshore reveal new details on the folding and faulting in this area and these new data can be used to update the existing geological map, NSDNR Map ME 1990-014. The circulation of water within sheltered bays is important for aquaculture site selection. The results of a hydrodynamic model using Mike-21 for Little Harbour, NS were compared between input data consisting of the original chart information based on a sparse distribution of soundings and the new lidar derived DEM. The results indicate the improved input elevation data produces a more refined and detailed set of outputs. The model results have not been validated against in-situ water levels or current measurements yet, although that is planned this field season.

Published Material: Part of this presentation was published :Normandeau, A., Lajeunesse, P., St-Onge, G., Bourgault, D., St-Onge Drouin, G., Senneville, S., Bélanger, S., 2014. Morphodynamics in sediment-starved inner-shelf submarine canyons (Lower St. Lawrence Estuary, Eastern Canada). Marine Geology 357, 243-255

Abstract Body: The activity and sedimentary processes in a series of inner-shelf submarine canyons located in the Lower St. Lawrence Estuary was examined using high-resolution multibeam bathymetry, backscatter and seismic data as well as by analyzing a ~9 m-long sediment core. The presence of crescentic bedforms, probably representing cyclic steps that were displaced upslope at the bottom of the canyons between 2007 and 2012 indicates that they are currently active through the remobilization of sediment by gravity flows. However, the shelf and shores of the region are characterized by the absence of sediment. Our results indicate that gravity flows currently eroding the canyon floors do not transport new material downslope coming from the shelf but rather remobilize *in-situ* deglacial sediments within the canyon thalweg. End-member modeling analysis performed on grain-size distributions reveals the presence of quasi-continuous flows within the canyons and the presence of only one turbidite. Based on these results, we suggest that frequent hydrodynamic processes and infrequent slope failures are responsible for sediment remobilization in these canyons, although their role in the upslope migrating crescentic bedforms is still unclear. This presentation provides further evidence that sediment supply is not a prerequisite for the origin and activity of inner-shelf submarine canyons.

Title: Acoustic Imaging of the Transition from Fluvial Suspension to Density Underflow on a Marine Delta Lip

Presenter/First Author: John E Hughes Clarke, University of New Brunswick, Fredericton, NB

Presenter/First Author Email: jhc@omg.unb.ca

Co-authors: Peter J Talling, National Oceanography Centre,, Southampton, Hamps, United Kingdom; Matthieu Cartigny, , ,

Abstract Body: The abrupt delta lip transition from continuous fluvial bedload and suspended load transport to episodic gravity-driven underflows has long been a focus of speculation. Hyperpycnal flows have been observed in lacustrine systems where there is minimal density contrast between the inflow and receiving watermasses. The same mechanism, however, is much harder to achieve given a typical 20-30 kg/m^3 contrast between fresh and salt water.

To directly address this process, repetitive surveys were conducted off the lip of the Homathko delta at 15 minute intervals around low-water when the off-delta sediment flux was most intense. Simultaneous bathymetry from 5 to 80m as well as acoustic volume scattering of the water mass was imaged using 90 and 500 kHz multibeams. A rapidly dipping optical backscatter probe was deployed to relate the volume scattering to suspended load.

The acoustic imaging clearly identified the highest suspended load in the overlying outflowing freshwater. The load never at any time approached the level at which it could result in direct hyperpycnal flow. Rather, the suspended load was seen to drop through the base of the freshwater layer into the underlying saltwater forming a near continuous descending flux. This avoids the need to overcome the bulk of the density contrast. Although the descending plume appeared continuous, the development of seabed surges in this flow was intermittent with only 2 surge flows in a single tidal cycle.

The simultaneous bathymetry indicated that just one of the delta lip chutes was intermittently active with both bulk accretion and deflation as well as upslope migrating bedforms. Beyond the mouth of the chute, however, only one flow was sufficiently powerful to cause bedform migration in the downstream channel. That movement was clearly correlated with the development of a discrete turbidity current flow visible in the water column imaging.

The presence of a near continuous descending plume, but only intermittent surges, suggests that there is an intervening step where the sediment flux builds up on the proximal delta lip, before initiating a subsequent flow. The details of that step remain imperfectly understood.

Title: Understanding Sediment Flux Through Delta-top Channels Using Repetitive Multibeam and Hydrodynamic Modeling

Presenter/First Author: Danar Guruh Pratomo, University of New Brunswick, Fredericton, NB

Presenter/First Author Email: dg.pratomo@unb.ca

Co-authors: John E Hughes Clarke, University of New Brunswick, Fredericton, NB, Canada

Abstract Body: The growth of any delta is controlled by the available sediment flux from the feeder fluvial system. The manner in which that sediment moves through the tidally- influenced estuarine channels on the delta top will influence the mechanism of growth and collapse of the delta lip. This study addresses channelized delta top sediment transport on the Squamish Delta in Howe Sound, BC.

The termination of the Squamish River consists of a single channel that flows between flanking intertidal sand bars and over a mouth bar at the lip of the delta. There is a 3-5m tidal range that strongly modulates the flow in the channel and over the adjacent intertidal sand banks. The channel depth at low water ranges from 0.5 to-2m and thus multibeam surveys can only be carried out at high water. The delta front is growing rapidly with about 1 million m^3 of sediment being input from the river system annually.

In 2011, the delta top channel was surveyed every 3-4 days at high water, over a period of 4 months during which the river discharge waxed and waned and the tides ranged from springs to neaps. In 2012 and again in 2013, the channel was surveyed daily over a week while the tides increased from neap to springs. The multibeam data capture the instantaneous expression of both the long wavelength channel shape as well as the superimposed bedforms distribution (as preserved at high water). While the long wavelength shape changes over a time scale of about a week, it was clear that the individual bedforms could not be correlated from one tide to the next.

Preliminary observations off the delta lip clearly demonstrate that the current speeds on the delta top were strongly modulated by the tide, ranging from almost stationary at high water to in excess of 5 knots at low water. To quantify the bed shear stress associated with this modulation, a 3D hydrodynamic model was built to predict the flow within the river, the delta top, and adjacent fjord over the complete tidal cycle. This clearly shows that the sediment flux is dominated by the low water period when the off-delta flows are strongest. The peak intensity of those flows is in turn modulated by the spring-neap cycle. This matches complementary work using repetitive multibeam off the delta lip that shows that mass wasting on the delta front is highly correlated with the spring tide and low tide periods.

Title: Evidence for Subglacial Meltwater Floods Through the Lake Ontario and Eastern Lake Erie Basins

Presenter/First Author: Michael C F Lewis, Geological Survey of Canada Atlantic, Dartmouth, NS

Presenter/First Author Email: Michael.Lewis@NRCan-RNCan.gc.ca

Co-authors: Brian J Todd, Geological Survey of Canada Atlantic, Dartmouth, NS, Canada

Published Material: Partial results for Lake Ontario and Lake Erie separately were presented in NE Geological Society of America section meeting, 1996, Buffalo NY; Geological Society of America meeting, 1998, Toronto; and International Association of Great Lakes - Great Lakes Conference 1999, Cleveland OH. The complete interpretation of subglacial floods affecting Lake Ontario through eastern Lake Erie with connecting onshore evidence at 13.5 (16.2 cal) ka and ending at the cross-lake Norfolk Moraine is unique to this presentation. These findings and interpretation are not under review elsewhere, and have not been submitted to a scientific journal.

Abstract Body: Lakebed relief in deep water of eastern Lake Ontario, portrayed in conventional hydrographic charts, is dominated by linear WSW-trending ridges. The ridges had been interpreted variously in the early 1990s as Holocene fault scarps, and as streamlined glacial landforms. A multibeam sonar survey confirmed the trend of lakefloor relief, but showed that individual ridge features were not as long or as continuous as previously thought. The features are distinct, long (up to 6 km), narrow (100s m wide), subparallel ridges which stand up to 30 m above the surrounding lakefloor, and closely resemble erosional drumlins. Seismic reflection profiles indicated the ridge material is characterized by incoherent internal reflections and rests on a continuous unfaulted bedrock reflector. A piston core recovered stony, sandy diamicton (till), confirming the glacial origin of the relief-forming drumlins, and showed that they are draped with glaciolacustrine and postglacial lake sediments. The till is absent in places between ridges, suggesting the drumlins were formed by erosion from a former till sheet, and were probably sculpted by erosive subglacial flows of meltwater. Onshore digital elevation models reveal drumlins in the same orientation, suggesting the erosive meltwater flows continued WSW into the northern part of the eastern Lake Erie basin where seismic profiles and a borehole reveal an absence of till, except for thin remnants, and glaciolacustrine sediments resting directly on bedrock. This unconformable sequence terminates westward at the cross-lake Norfolk Moraine. An extensive cover of till remains atop a 45m-high bedrock escarpment in the southern part of the eastern Erie basin suggesting an ice cover was pinned there during the subglacial flows. Constraining chronological data indicate that these subglacial meltwater flows, which were effective agents in shaping lake bathymetry and land topography, occurred about 13.5 (~16.2 cal) ka.

Co-authors: Sukun Cheng, Clarkson University, Potsdam, NY

Abstract Body: Wave scattering by ice floes is critical to accurate prediction of ocean waves in the polar regions. Based on the Green function method, scattering from a single circular ice floe has been obtained in the past. The method consists of solving the elastic motion equations of one regular ice floe and matching the boundary conditions at the interfaces of ice and water. With the results for one ice floe, one can construct the integral kernel in the radiative transfer equation to simulate the wave scattering by an ice field. This approach is accurate but time consuming, hence difficult to implement into large scale operational wave models. We propose a simplified diffusion approximation method to calculate the radiative transfer equation for the wave scattering by randomly distributed ice floes. With this method, there is no need to calculate the integral kernel, but one additional diffusion equation for reflected waves needs to be solved. The diffusion approximation method will largely reduce the computational cost for implementing wave scattering into operational ocean wave model. The results from the diffusion approximation and the former exact method are compared for the evolution of wave directional spectra into an ice cover.

Title: Sensitivity analysis of the viscoelastic wave-in-ice model

Presenter/First Author: Jingkai Li, Clarkson University, Potsdam, NY

Presenter/First Author Email: jli@clarkson.edu

Co-authors: Sumona Mondal, , , ; Hayley H Shen, Clarkson University, Potsdam, NY

Abstract Body: In response to Arctic ice reduction, wave models have begun improving their capabilities for the ice covered waters. To study wave propagation under ice covers, the mechanical behavior of the ice cover needs to be modeled. A viscoelastic model has been proposed, which can reproduce all previous model results under appropriate limiting conditions, hence is a candidate for describing various ice conditions present in the marginal ice zone. Two material parameters contained in the viscoelastic model are the shear modulus and the viscosity which need to be inversely determined from field data. Thus it is necessary to know the sensitivity of the model on its parameters under different field conditions. In this study, the sensitivity analysis is performed using Latin Hypercube sampling and the analysis of variance technique. It provides the information on how significant the parameters and parameters' interactions are to the complex wave number and how the model behaves under different plausible wave and ice cover conditions. Implications of the model behavior to the effectiveness of using an inverse method to predict the model parameters are discussed. These implications are also verified by utilizing field data and a brute force search on the viscoelastic model to

determine the model parameters. The same sensitivity analysis of a simpler viscoelastic model is performed too. Such studies can be helpful in informing the design of field campaigns that aim to characterize and measure these parameters. The method used is general. It may be applied to test other models of wave-in-ice as well as models in other fields.

Title: Characterizing the behavior of gravity wave propagation into a floating or submerged viscous layer

Presenter/First Author: Sukun Cheng, Clarkson University, Potsdam, NY

Presenter/First Author Email: chengs@clarkson.edu

Co-authors: Hayley H Shen, Clarkson University, Potsdam, NY

Abstract Body: Due to the reduction of sea ice cover, wave activities have increased in the Arctic region. There is a need to expand the current global wave models to this partially ice covered region. Ice covers change dynamically in response to the wind, wave, and ocean current forcing. Their mechanical properties also change corresponding to their physical composition. A viscoelastic sheet has been recently proposed to model different types of ice cover. In this model, two parameters are used to reflect both the elastic and viscous properties of a deformable and dissipative ice cover. The mathematical nature of this model, which is based on simple linear waves and a simple linear viscoelastic constitutive law, turns out to be very complicated. There are multiple modes co-existing in the resulting dispersion relation. To help understand the physical meaning of this model, we compare it with studies conducted in wave propagation through a mud floor. This problem has a substantial body of literature. The difference between water wave through an ice cover and through a muddy floor is that one deals with a floating material and the other with a submerged material. The mathematical structure and solution procedures are very close to each other. In this work we report the comparison of these two different problems. We show the differences and similarities between them and investigate if phenomena found in one are also present in the other.

Title: Characteristics and changes of sea-ice floe size distribution in Chukchi and Beaufort Seas in fall 2014

Presenter/First Author: Yu Wang, Clarkson University, Potsdam,

Presenter/First Author Email: ywang@clarkson.edu

Co-authors: Benjamin Holt, NASA Jet Propulsion Laboratory, Pasadena, CA; William Rogers, Naval Research Laboratory, Stennis Space Center, MS; Jim Thomson, University of Washington, Seattle, WA; Hayley H Shen, Clarkson University, Potsdam, NY

Abstract Body: Incoming wave fields impact sea ice floe size distribution, which may further impact sea ice melt rates and ice growth.In the changing Arctic, the presence of surface waves and properties of surface waves are changing due to the increase in open water fetch. We use fine resolution satellite data from MEDEA and LandSAT8, which have resolutions of 1m and 15m, respectively, to determine floe size distribution and floe geometry with image processing techniques during a period in August and September 2014 in the Chukchi Sea and Beaufort Sea. Changes in floe size and floe geometry are examined before, during and after a wave event observed by SWIFT buoys.The cumulative floe size number distribution $N(d)$ is introduced to depict the floe size distribution, where N is the number of floes per unit area that are no smaller than diameter d. The result shows that $N(d)$ follows an approximate power law.To determine the underlying power law without the effect of a truncation error, a modified cumulative floe size distribution is obtained.Changes of the floe size distribution are evaluated before and after wave events.

Title: Impact of multidecadal Atlantic meridional overturning circulation variations on the Southern Ocean

Presenter/First Author: Liping Zhang, Princeton University, Plainsboro, NJ

Presenter/First Author Email: Liping.Zhang@noaa.gov

Co-authors: Thomas L Delworth, NOAA, Boulder, CO

Abstract Body: The impact on the Southern Ocean (SO) of multidecadal variations of the Atlantic Meridional Overturning Circulation (AMOC) is investigated using a suite of simulations with a coupled ocean-atmosphere model. We find that the AMOC can influence the SO via two primary pathways: (a) a slow ocean pathway, and (b) fast atmospheric teleconnections. On multidecadal timescales, a stronger than normal AMOC leads to a weaker than normal column averaged south-north density gradient in the ocean between the North Atlantic and the Southern Ocean. This leads to a weakening of deep convection in the Southern Hemisphere (SH) and the Antarctic bottom water (AABW) cell. The spin down of the AABW cell leads to subsurface warming and surface cooling in the SO. The SO cooling could feedback to the overlying atmosphere, inducing intensified westerly winds and thus a strengthened Deacon cell. The westerly wind response further amplifies the initial SO surface cooling by enhanced latent heat loss and through northward Ekman transport, forming a local positive air-sea feedback. In terms of atmospheric teleconnections, warming of the tropical North Atlantic (TNA) due to a strengthened AMOC can directly trigger propagating atmospheric Rossby wave trains to the SH, inducing a low pressure response over the SO and thereby cooling the near-surface ocean. The TNA warming also contributes to a La Niño-like SST cooling over the tropical Pacific Ocean. This influences the SO via the Pacific South Atlantic teleconnection pattern, thereby inducing low atmospheric pressure and cooling of the upper ocean in the SO over the Amundsen Sea region. The opposite is also true when the AMOC weakens. The strong linkage between the AMOC and SO variability on multidecadal time scale has implications for understanding the causes of the recent SO cooling. Our study here suggests that evaluating the causes of recent SO variability should take into consideration not only local processes but also remote forcing from AMOC variations.

Title: Holocene Mass Movements in a Canadian High Arctic Lake, East Lake, Melville Island

Presenter/First Author: Alexandre Normandeau, Université Laval, Québec, QC

Presenter/First Author Email: alexandre.normandeau.1@ulaval.ca

Co-authors: Gabriel Joyal, , , ; Patrick Lajeunesse, Université Laval, Québec, QC, Canada; Pierre Francus, Inst Nat Recherche Sci, Québec, QC, Canada; Scott F Lamoureux, Queen's University, Kingston, ON, Canada; François Lapointe, Inst Nat Recherche Sci, Québec, QC, Canada

Published Material: The same abstract will be presented at the conference: Submarine Mass Movements and Their Consequences in New Zealand. The results are under consideration for the publication in the conference book.

Abstract Body: East Lake, located at Cape Bounty (Melville Island, Canadian High Arctic), was mapped using a high-resolution swath bathymetric sonar and a 12 kHz sub-bottom profiler, allowing imaging for the first time the widespread occurrence of mass movement deposits (MMDs) in a High Arctic Lake. MMDs are mostly located on steep slopes not influenced by high sedimentation rates. The marine to lacustrine transition in the sediment favours the generation of mass movements where the underlying massive mud appears to act as a slip surface for the overlying varved deposits. Based on acoustic stratigraphy and backscatter intensity data, we have identified at least 2 to 3 events that triggered failures in the lake during the last 2000 years. Based on the proximity of the lake to the Byam-Martin Seismic Zone, the location of the MMDs far from sediment input and the possible correlation between a turbidite layer in a sediment core and a recorded earthquake, seismicity could be responsible for sediment failures in the lake basin.

Title: Geomorphology of seismically-induced mass-movements in lakes of south-central Québec

Presenter/First Author: Annie-Pier Trottier, Laval University, Quebec,

Presenter/First Author Email: annie-pier.trottier.1@ulaval.ca

Co-authors: Patrick Lajeunesse, Université Laval, Québec, QC, Canada; Alexandre Normandeau, Université Laval, Québec, QC, Canada; Antoine Gagnon-Poiré, Université Laval, Québec, QC, Canada

Abstract Body: Although Late-Quaternary sediments in lakes located within or near the Charlevoix-Kamouraska and Western-Québec seismic zones are known to have been intensely remobilized by seismic event since deglaciation, postglacial mass movements in lakes of southern Québec inundated by the Champlain Sea and located more than 70 km from these seismic zones remain poorly documented. Recent high-resolution swath bathymetry and acoustic stratigraphy surveys undertaken in four lacustrine basins of south-central Québec (lakes St-Joseph, Aux-Sables, Mékinac and Maskinongé) revealed the widespread occurrence of mass movement deposits and morphologies associated with postglacial seismic activity. Swath bathymetry data at a resolution of 0.5 to 1 m allows the observation in great detail of various morphologies associated with mass movements, such as failure scarps, lobe-shaped deposits, hummocky surfaces, compression ridges and gullies. Subbottom profiles and sediment core data show many rapidly deposited layers which have been dated to ~1000 years BP in Lake Maskinongé, ~915 years BP in Lake-aux-Sables and ~760 years BP in Lake Saint-Joseph. Our results indicate that at least one seismic event triggered mass movement in these four lakes during the last ca. 1000 years. Further analysis and dating of sediment cores will allow determining whether these mass movement deposits recorded the same regional seismic event or different events related to different seismic zones.

Title: Lacustrine Geomorphology and Sedimentary Processes in the Eastern Arm of Manicouagan Reservoir, Québec

Presenter/First Author: François-Xavier L'Heureux Houde, Université Laval, Québec, QC

Presenter/First Author Email: francois-xavier.lheureux-houde.1@ulaval.ca

Co-authors: Patrick Lajeunesse, Université Laval, Québec, QC, Canada

Abstract Body: High resolution multibeam bathymetric and sub bottom profile data were acquired for the first time in 2014 in former Lake Manicouagan, a 60 km long and 3 km wide fjord-lake located in the eastern half of the Manicouagan crater, that is now submerged under 135 m of water in the Manicouagan hydroelectric reservoir. The acquired multibeam echosounder data allowed the production of a complete and full-bottom coverage bathymetric map of the lake area before its flooding at 5m-pixel resolution. This new data provides an invaluable opportunity to analyse the Late Quaternary evolution of this large and deep lacustrine basin and the geomorphological impacts of the recent rapid and high amplitude rise in lake level. Multibeam data allowed the observation of disintegration moraines, sublacustrine fans, gullies, mass movement deposits and crescent-shaped bedforms as well as preserved river beds, fluvial terraces, deltas and strandlines flooded after the construction of the Manic-5 (Daniel-Johnson) Dam in 1970. The multibeam data is complemented by 3.5 and 12 kHz subbottom profiles and short coring samples. Our data suggest that the flooding of the crater basin generated widespread sediment failures in the deglacial and postglacial sedimentary units along the steep slopes of former fjord-lake Manicouagan. The new bathymetric data also allows identifying Lake Manicouagan as one of the deepest lake of eastern North America, which reached 315 m in depth before its flooding.

Title: Late Quaternary Evolution of Fjord-Lakes Pentecôte, Walker and Pasteur (Québec North-Shore, Eastern Canada)

Presenter/First Author: Antoine Gagnon-Poiré, Université Laval, Québec, QC

Presenter/First Author Email: antoine.gagnon-poire.1@ulaval.ca

Co-authors: Patrick Lajeunesse, Université Laval, Québec, QC, Canada; Pierre Francus, Inst Nat Recherche Sci, Québec, QC, Canada; Guillaume St-Onge, University of Quebec at Rimouski UQAR, Rimouski, QC, Canada

Abstract Body: High-resolution bathymetric data acquired using a multibeam echosounder and an interferometric side-scan sonar in 2011

and 2014 allowed mapping the sublacustrine geomorphology of three fjord-lakes of the Québec-North Shore region (eastern Canada) for the first time. Detailed bathymetric maps with a 1 to 3 m resolution produced during these surveys allowed the observation of deep V-shaped bedrock valleys, morainal banks, deep and circular depressions (kettles?), disintegration moraines, slide scars, mass movement deposits and crescent-shaped bedforms. These lakes, located near Younger Dryas morainic systems, were flooded during the Goldthwait Sea postglacial marine transgression and contain sedimentary archives that recorded paleo-environmental changes that have occurred since the last glaciation. Acoustic sub-bottom profiles acquired using a bi-frequency Chirp echosounder (3.5. & 12 kHz), together with sediment core data, reveal the presence of six sedimentary units: bedrock and/or ice-contact sediments (U1), glaciomarine silts and clays (U2), rhythmically laminated silts and clays, possibly varves (U3), mass movement deposits (U4), fluvial deposits (U5) and organic-rich postglacial sediments that contain series of rapidly deposited layers (U6). This poster unveils the results of these underwater mapping surveys and demonstrates their significant contribution to the understanding of Quaternary geological evolution and sedimentary records of deep formerly glaciated lacustrine basins.

Title: High-resolution near-shore geophysical survey using an Autonomous Underwater Vehicle (AUV) with integrated magnetometer and side-scan sonar

Presenter/First Author: Doug Hrvoic, Marine Magnetics Corp, Markham, ON

Presenter/First Author Email: dh@marinemagnetics.com

Co-authors: Joe I Boyce, McMaster University, Hamilton, ON, Canada

Published Material: less than 25% of content reported in oral presentation at SHA conference 2014

Abstract Body: Autonomous underwater vehicles (AUVs) give many advantages over traditional boat-towed survey methods, including the ability to operate under most sea states, and the ability to collect data at very high spatial resolution, which is a significant benefit for archaeological investigation. Integration of magnetometer sensors on AUVs has been problematic due to the magnetic interference produced by the AUV thrusters and electronics. In this study, we evaluated an AUV-deployed magnetic survey system consisting of an Overhauser magnetometer (Marine Magnetics *Explorer*) mated to a portable AUV (OceanServer *Iver2*). To eliminate magnetic interference from the AUV, the magnetometer was tethered to the AUV with a 5m tow cable, as determined by static and dynamic instrument testing, which indicated no detectable magnetic influence at this distance. The system was evaluated in a survey collected over a shallow water test area in Lake Ontario near Toronto, Canada and compared directly with the results of a conventional boat-towed magnetic survey. The AUV magnetic data have equivalent long-wavelength accuracy to the boat-towed data as determined by tie-line error analysis. The AUV data were shown to have less high frequency noise, and were able to identify a number of small ferromagnetic targets that were undetected in the boat-towed magnetic data.

Title: Landform-sediment assemblages in a fjord and cross-shelf trough system: Scott Inlet and Trough (NE Baffin Island, Canada)

Presenter/First Author: Etienne Brouard, Laval University, Quebec City, QC

Presenter/First Author Email: etienne.brouard.1@ulaval.ca

Co-authors: Patrick Lajeunesse, Université Laval, Québec, QC, Canada

Published Material: The results were presented in the Artic Change 2014 meeting. They are not under review neither in any journal.

Abstract Body: Multibeam echosounder, subbottom profiler and sediment core data acquired since 2003 by the CCGC Amundsen together with seismic records and core samples from the Geological Survey of Canada allow the reconstruction of Late-Quaternary ice flow and glacial history in the fjords and cross-shelf trough of the Scott Inlet area (northeastern Baffin Island, Arctic Canada). These combined datasets also provide a great opportunity to document a high-latitude fjord-to- continental slope glacial landsystem that has been strongly influenced by ice streaming during the last glacial episode.

The study area can be divided into two physiographic regions: the Clark and Gibbs fjords and the Scott cross-shelf trough. In the fjords, multibeam mapping reveals a morphology that alternates between sills (bedrock or morainic) and sedimentary basins, with the presence of moraines from the side valley glaciers. Offshore Scott Inlet, a deep (800 m) and large (30 km) cross-shelf trough incise the continental shelf. This trough is characterized by traces of a large paleo-ice-stream with an onset zones located off Clark and Gibbs fjords. Five sedimentary units have been identified on the seismic data: 1- A basal unit with a non-penetrable reflector that can be either bedrock or a basal till; 2- A unit with a series of parallel horizontal high amplitude reflections (observed in Clark Fjord); 3- A semi-transparent unit having little or no parallel reflections (Davis Strait silt); 4- A transparent unit corresponding to hemipelagic deposits that is present in the shelf trough (Tiniktartuq mud); 5- A series of parallel horizontal high amplitude reflections interpreted as estuarine sedimentation.

During the last glaciation, the Scott cross-shelf trough favored the formation of an ice-stream that extended upstream into the inner sections of Clark and Gibbs transferring large volume of glacial ice and glacigenic sediments to the continental slope to form an extensive trough-mouth fan. Deglaciation of the continental shelf from a late Foxe glacial maximum was completed by 15 ka BP. Ice retreat within the fjord occurred by steps as moraines sills represent periods of ice stabilisation during deglaciation. Ice retreat to the fjord heads is thought to have been completed by 8-9 ka BP. Sedimentation similar to present-day conditions have then been reached.

Title: Seismic Stratigraphy Since the Late Miocene of the Near Shore New Jersey Margin Between Barnegat and Manasquan Inlets, New Jersey

Presenter/First Author: Lindsey Lugrin, University of Texas-San Antonio, Houston, TX

Presenter/First Author Email: lindseylugrin@yahoo.com

Co-authors: Gregory S Mountain, Rutgers Univ, Piscataway, NJ

Abstract Body: In the summer of 2013, researchers from Rutgers University and the New Jersey Geological and Water Survey conducted 590 km of boomer seismic profiles 0-6 miles off the NJ coast between Barnegat and Manasquan Inlets. In the fall of 2014, 30 vibracores were taken to determine stratal relationships correlated to the seismic data. The seismic data show three main depositional units. The oldest unit is comprised of Upper Miocene fine quartz sand and silt with occasional interbedded clay layers, and characterized by prominent parallel reflectors that dip southeast. These strata are capped by an erosional surface that dips south-

southeast and crops out at the seafloor near the northern extent of the survey area. This surface is overlain by as much as 20 m of complexly arranged Pleistocene gravels, sands and silts with irregular reflectors traceable for distances of only 0.5 km or less. NE-trending Holocene ridges detached from the shoreface comprise the third and youngest depositional unit. Most ridges are isolated elongate features 5-10 km long and 1 km wide. All rest on a level reflector separating them from Pleistocene strata in most of the survey area, and from Miocene strata along the northern limit. The ridges are relict late-Pleistocene light grayish-white, well-sorted, fine-grained quartz sand deposited during periods of episodic sea level rise since the last glacial maximum and reworked by present day hydrodynamics. The parallel dipping reflectors of the Miocene suggest continuous delta-front marine deposition. Glacially-forced post-Miocene sea-level fall cut deeply into these strata, and sediments were not preserved at this nearshore location again until Late Pleistocene. Transgression since the Last Glacial Maximum and development of the adjacent barrier island landscape has resulted in minimal new sediment contribution to the nearshore. In its absence, relict sands have been reworked into ridges under a complex interplay involving ebb-tidal deltas, storms and longshore currents.

Title: Impact Melt Emplacement, Cooling, and Crystallization in the Sudbury Igneous Complex

Presenter/First Author: C Michael Lesher, Laurentian University, Sudbury, ON

Presenter/First Author Email: mlesher@laurentian.ca

Published Material: The last part was presented at the 2014 GAC-MAC meeting. This ties things together with the first two parts.

Abstract Body: Models for emplacement of mineralized quartz diorite dikes and cooling/crystallization of the Main Mass of the Sudbury Igneous Complex suggest that the dikes were emplaced during the crater modification stage, that the Main Mass cooled slowly from a superheated state, and that the mineralization exsolved from Main Mass during crystallization. Offset dikes have inclusion- and sulfide-poor QD margins and inclusion- and sulfide-rich IQD cores, implying emplacement of IQD into the semi-molten cores of QD dikes and therefore extremely rapid generation of IQD. During crater excavation impact melts are generated in a central melt pocket, injected into surrounding broken rocks, and driven upward and outward. Movement is reversed during formation of the central uplift, but returning melt is laden with fragments. Thus, it is more likely that QD was emplaced during melt excavation and that IQD formed by incorporation of fragments during formation of the central uplift. Incorporation of fragments into IQD and inclusion-rich Sublayer Norite would have rapidly cooled the melt to the liquidus. Contact ores are separated from the Main Mass by Sublayer Norite; although some sulfides may have percolated through partially-crystallized Sublayer, successively crystallizing norites would have isolated the ores from the melt, so observed depletion trends in upper norites may also reflect accumulation of sulfides in Sublayer and lower norites, not just the ore-forming process. Geochemical-petrographic data for traverses across the North and South Ranges show differences in composition across the melt sheet and that it was derived from at least two melts: 1) one that formed South Range Sublayer and Quartz-Rich Norite, and 2) one that formed overlying South Range Melanorite and Upper Norites, and North Range Mafic and Felsic Norites. Several models are being investigated: 1) inflow of melt from peripheral parts of the system (outer part of observed impact basin or a second impact basin), 2) collapse of the inner peak ring, and 3) collapse of crater walls.

Title: Geochemical Variation Along Strike of the Hess Offset Dyke at the Sudbury Impact Structure, Canada

Presenter/First Author: Eric Pilles, University of Western Ontario, London,

Presenter/First Author Email: epilles@gmail.com

Co-authors: Gordon Richard Osinski, University of Western Ontario, London, ON, Canada; Joshua Bailey, , , ; David Smith, , ,

Abstract Body: The Sudbury Impact Structure is a 1.85Ga impact structure located on the contact between the Superior Province Archean granite-greenstone terrain to the North and the Southern Province Huronian Supergroup to the south. The Offset Dykes extend radially outward from – and concentrically around – the Sudbury Igneous Complex (SIC), which is a ~3-km thick differentiated impact melt sheet. The Hess is the longest of the concentric Offset Dykes, with a strike length of ~60 km. It is located ~12–15km northwest from the SIC, hosted in the Superior Province. The Hess is up to 60m wide and is composed of two phases: an inclusion-poor granodiorite along the margins of the dike and an inclusion-bearing granodiorite in the centre of the dike.

There is very little difference in major element geochemistry when comparing the two phases, and only minor variations in trace elements. However, the matrix of the inclusion-bearing phase is notably enriched in light REEs compared to the inclusion-poor phase. This observed variation is minimal compared to the differences found along strike of the Hess – from the westernmost end in the Ermatinger Township to the northernmost end where the Hess intersects the Foy.

The samples closer to the west end of the dyke were more depleted in Si, K, Li, Ba, and light REEs; and more enriched in Ti, Fe, Mn, Mg, Sc, and V compared to the samples located near the Foy-Hess intersection. The samples located near the middle of the dyke show anomalous variation as well. At some locations they are more consistent with results from the west end samples, and at others they are more consistent with results from samples near the intersection. The reason(s) for these geographical variations in composition are currently being explored.

Title: Electron Microprobe Analysis of Sudbury Breccia from the Creighton and Coleman Mines, Sudbury Ontario: Constraints on the Extent of Hydrothermal Modification of Magmatic Footwall Ni-Cu-PGE Sulphide Mineralisation.

Presenter/First Author: Jonathan O'Callaghan, University of Western Ontario, London,

Presenter/First Author Email: jocalla@uwo.ca

Co-authors: Gordon Richard Osinski, University of Western Ontario, London, ON, Canada; Robert Linnen, University of Western Ontario, London, Canada; Peter C Lightfoot, Vale, Sudbury, ON, Canada

Abstract Body: The Sudbury Igneous Complex (SIC) represents the remains of a ~200-km diameter impact crater, formed 1.85 billion years ago. Ore deposits associated with the impact structure can be subdivided into

contact, footwall and offset types, and represent the end products of magmatic and hydrothermal processes. Footwall Ni-Cu-PGE deposits are hosted within zones of Sudbury breccias (pseudotachylitic), near to contact ore deposits at the margin of the SIC. Our study focuses on the application of ICP-MS and electron microprobe analyses of a suite of Sudbury breccia samples collected proximal to active mines in the North and South Ranges of the Sudbury Basin. We investigate subtle geochemical variations to mineralogy in barren and mineralised breccia matrix from different lithologies, and use this information to constrain the relative roles of magmatic and hydrothermal processes in the modification of primary Sudbury breccia and better understand the footwall ore deposits.

Our research has identified ilmenite-magnetite with titanite rims within breccia <10cm from footwall mineralisation in the McCreedy East 153 orebody at Coleman Mine. This assemblage is consistent with both high fO_2 and high fH_2O conditions. Samples from near the footwall orebodies at Creighton Mine contain heterogenous titanite that may be associated with later metamorphic alteration. In Sudbury breccia samples from Creighton mine, we also observe evidence of partial assimilation of host granite in hand-specimen and have identified two species of titanite, one showing Al/Fe substitution indicative of the presence of F-OH at the time of formation, and a second low Ti, low Al/Fe variety that may have been derived from the host granite. For the first time we also report chlorine zonation in amphibole at Creighton mine, similar to zonation features reported in the Fraser mine in the North Ranges.

Title: The Age of the Carswell Impact Structure

Presenter/First Author: Wouter Bleeker, Geological Survey of Canada, Ottawa, ON

Presenter/First Author Email: wbleeker@nrcan.gc.ca

Co-authors: Anthony N Lecheminant, , Manotick, ON, Canada; Carl Alwmark, , , ; Laurence Page, , , ; Anders Schérsten, Department of Geology, Lund University, Lund, Sweden; Ulf Söderlund, Lund University, Lund, Sweden

Abstract Body: A significant proportion of the ~60 confirmed and suspected impact structures in North America could be related to the Early/Middle Ordovician impact spike of L-chondrite meteorites [1]. First identified in various meteorites, and then in the stratigraphic record of southern Sweden, the onset of this event is now pegged at *ca.*470 Ma [2]. Based on numerous smaller Ordovician craters (e.g., Lockne, Brent), it is assumed that the event also resulted in a transient increase in the flux of larger fragments to Earth [e.g., 3].

Some important questions remain: 1) when was the exact onset of this event; 2) are there any big impact structures related to this event that remain in the geological record; and, if so, 3) how did the Earth system respond to these larger impacts?

In Canada, potential candidates for larger impact structures of approximately the right age are Carswell, Slate Islands, and possibly Charlevoix. None of these structures is well dated. Here we address the age of the large (~40 km) Carswell structure, which impacted the Paleo- to Mesoproterozoic Athabasca Basin of northern Saskatchewan. We have collected a suite of impact breccias from in and around the central core of the structure, ranging from fully melted and quenched melt rocks to partially melted pseudotachylites and intensely brecciated basement rocks. All contain shock features. Some of the breccias that show advanced melting contain gas vesicles formed during post-impact quenching and crystallization. These vesicles are lined with pristine quartz and adularia crystals (see image: mid-grey triclinic rhombs are adularia). It is from these pristine adularia crystals that we have obtained high-quality Ar-Ar plateau ages of 481±1 Ma. This age records the cooling and hydrothermal activity in the target area, immediately post-impact.

The precise adularia age of 481 Ma finally dates the large Carswell impact. Although we do not yet know the nature of the impactor, it appears that this large impact is remarkably close in time, but nevertheless ~5-10 Myr too old, relative to the accepted onset of the L-chondrite impact event.

Title: Examining Infrared Reflectance Spectra of Shocked and Unshocked Granites from Lake St. Martin Impact Structure: Implications for Detection on Mars.

Presenter/First Author: Rebecca Wilks, University of Western Ontario, London,

Presenter/First Author Email: rebeccaaiellowilks@gmail.com

Co-authors: Daniel M Applin, University of Winnipeg, Winnipeg, MB, Canada; Edward Cloutis, University of Winnipeg, Winnipeg, MB, Canada; Paul Mann, University of Winnipeg, Winnipeg, MB, Canada; Matthew R Izawa, University of Western Ontario, London, ON, Canada

Published Material: Lunar and Planetary Science Conference The Woodlands Texas March 2014

Abstract Body: Evidence for granitoid rocks on Mars has been obtained through remotely sensed imagery and spectroscopic data from the central uplifts of two craters near Syrtis Major. By investigating how to identify such materials with remote sensing techniques we can enhance the ability to detect exposed granitic and granitoid outcrops on the Martian surface. In order to do so, a spectroscopic-structural-compositional study of unshocked, shocked, and melted granites has been conducted. Samples were retrieved from various locations and depths at the Lake St. Martin (LSM) impact structure in central Manitoba. The goal of this study is to relate the spectral data to shock levels in order to better understand the possible effects of shock on the detectability of granitic rocks on Mars. The LSM samples have been analyzed using Fourier transform infrared reflectance spectroscopy, X-ray diffractometry (XRD) and X-ray fluorescence (XRF) spectroscopy.

Infrared spectra of the unshocked granitic country rock have a region of enhanced reflectance between ~1250 and 900 cm^{-1} which show a number of superimposed and unresolved peaks that are consistent with the unshocked nature of these materials. The granitic melt samples have a less strongly-featured interval of higher reflectance between ~1250 and 900 cm^{-1} which can be explained by the amorphization of silicates through shock. The shocked but unmelted samples have spectral features that are intermediate between the unshocked and melted granites, as can be expected, with more resolvable features on the reflectance hump than the melted spectra. By relating the spectral-structural-compositional data in terms of shock and melt we can gain a better understanding of how granitic rocks respond to impact shock and the effects of impact on their detectability by various remote sensing instruments.

Abstract Body: For 50 years, the two Clearwater Lake impact structures in Québec have been considered as a typical crater doublet formed by the impact of a binary asteroid. New $^{40}Ar/^{39}Ar$ dating of melt rocks from the ≥36 km West Clearwater Lake (WCL) impact structure yielded two Early Permian plateau ages with a weighted mean age of 286.2 ± 2.2 (2.6) Ma (2σ; MSWD = 0.33; P = 0.57). $^{40}Ar/^{39}Ar$ results for two chloritized melt rocks from the ~26 km East Clearwater Lake (ECL) impact structure produced age spectra suggestive of extraneous argon. The age spectra corrected for the trapped argon component and inverse isochron plots consistently yielded ages around ~460–470 Ma for ECL, reproducing the $^{40}Ar/^{39}Ar$ results by Bottomley et al. (1990) and contradicting an earlier Rb–Sr age of 287 ± 26 Ma. The Ar-Ar dates obtained from four different melt samples across the melt sheet favor an Ordovician age for the ECL impact and impact-induced hydrothermal overprint. WCL and ECL, moreover, show different natural remanent magnetizations indicating separate geologic histories. Whereas WCL has no resolvable geochemical impactor traces, the ECL melt rocks carry a strong (possibly L-) chondritic impactor signature. The WCL impact affected a thin layer of Ordovician target carbonates; such rocks are absent in the ECL impact breccia, which is overlain by >100 m of post-impact sediments. Biostratigraphic dating of the fossil-poor post-impact deposits at ECL is currently underway. In the light of the new $^{40}Ar/^{39}Ar$ dates and in combination with the paleomagnetic and geochemical findings, the close spatial arrangement of WCL and ECL is probably pure coincidence. The two impact structures seem to represent a 'false doublet' struck by impacts ~180 million years apart. ECL possibly represents one of several impact structures in North America and Europe potentially related to the Ordovician L-chondrite breakup event ~470 Ma ago.

Title: Impact-generated Hydrothermal Activity at the East and West Clearwater Lake Impact Structures

Presenter/First Author: Mary C Kerrigan, University of Western Ontario, London,

Presenter/First Author Email: marychristinekerrigan@gmail.com

Co-authors: Gordon Richard Osinski, University of Western Ontario, London, ON, Canada

Published Material: Preliminary results from this study will be presented at LPSC 2015.

Abstract Body: The Clearwater Lake complex is located in northern Quebec, Canada (56°10 N, 74°20 W). Originally thought of as a double impact structure dated at ~290 Ma, recent dating re-evaluated East Clearwater to have formed at ~470 Ma. Hydrothermal alteration has previously been noted at both structures but not investigated closely. We have examined drill core samples from the impact melt sheet of East Clearwater and field samples from West Clearwater to characterize and compare hydrothermal alteration and mineralization at both impact structures. The core from East Clearwater penetrates ~45 m of the impact melt sheet. Alteration is not common in the impact melt rock as a whole and mineralization is concentrated near the top of the melt sheet in a highly vesicular zone. Cavities are filled primarily with quartz mineralization and illmenite, galena, and millerite are common throughout. Sphalerite and chalcopyrite were identified closer to the middle of the sequence whereas magnetite and hematite are more commonly seen at greater depth. Calcite appears within the vesicular zone but is also more common at greater depth. At West Clearwater quartz-filled vugs and concentrated zones of vesicles occur within the impact melt rocks. Similar to the vesicular zone within the East Clearwater melt sheet, two outcrops within impact melt rock of West Clearwater have ~2-5 m highly vesicular zones. Vesicles here are also filled with quartz, calcite, and clay minerals yet the sulphide mineralization common in East Clearwater is not immediately evident at West Clearwater. Despite differences in the overall colour of the impact melt rocks at these locations the amygdales at both outcrops have pink, red, and dark purple haloes from their rims up to twice the diameter of the amygdale at the centre. A striking difference to East Clearwater however is the pervasive alteration evident in the impact melt rocks with their overall red colouration. The differences in colour between the impact melt rocks and the localised zones around the filled vesicles might represent different episodes of alteration. Further geochemical and fluid inclusion studies will be carried out to characterize the possible origin and evolution of the hydrothermal system generated by the impacts at this site.

Title: Geophysical Investigation of Charity Shoal Structure: A Suspected Impact Crater in northeastern Lake Ontario

Presenter/First Author: Mary-Helen Armour, McMaster University, Hamilton, ON

Presenter/First Author Email: armourm@mcmaster.ca

Co-authors: Joe I Boyce, McMaster University, Hamilton, ON, Canada; Philip A Suttak, , Orangeville, ON, Canada

Published Material: magnetic results presented at Large Impact 2013

Abstract Body: The Charity Shoal structure (CSS) is a 1.4 km diameter, 20 m deep circular basin located northeastern Lake Ontario. The CSS has been interpreted as an Ordovician-age meteorite impact based on multi-beam imaging of the lakebed but details of the crater's subsurface structure were unknown. In 2011 detailed magnetic and sub-bottom chirp seismic (>400 line km) surveys were conducted across a 9-km^2 area of Charity Shoal to investigate its subsurface structure. In 2014, a boomer seismic (1-2 kHz) survey was conducted over the same area to image the basin fill.

Total magnetic intensity (TMI) data reveal a large (>1400 nT) magnetic anomaly centered over the crater basin and a ring-like magnetic high (40-50 nT) corresponding with the basin rim. Depth to basement below the structure was estimated at ~600 m using extended Euler deconvolution. Forward 2-D models verify that the observed TMI anomaly requires a deep (>450 m) depression in Precambrian basement or a source body (e.g. diatreme) with a remanent magnetization opposing the main field. Boomer seismic profiles revealed >60 m of stratified glacial/post-glacial sediments overlying Paleozoic limestone bedrock. Apparent offsets in the bedrock surface may indicate the presence of high-angle faults. Magnetic and seismic results are not consistent with formation of the CSS as a shallow glacial erosional or karst feature or an early postglacial (Younger Dryas) impact event as proposed in previous work. Modelling and geophysical results are most consistent with an origin as a diatreme or pre-Paleozoic meteorite impact in the Precambrian basement.

Published Material: Discovery of bridgmanite, the most abundant mineral in Earth, in a shocked meteorite, O. Tschauner, C. Ma, J. Beckett, C. Prescher, V. Prakapenka, G.Rossman, Science 346, 110-1102, DOI: 10.1126/science.1259369 (2014)

Abstract Body: Recent advancements in micro-diffraction analysis in combination with SEM- and EPM-based chemical analysis provide us with a rapidly increasing set of high-pressure metamorphic minerals that occur in shocked meteorites. This includes bridgmanite (1), ahrensite (2), tissintite (3), liebermanite (4) and others. I will briefly introduce the methodology of synchrotron-diffraction/spectroscopy based identification and characterisation of shock-generated high pressure minerals. Then I will show how the high-pressure mineral paragenesis, their spatial distribution, and constraints from shock-physics provide us with surprisingly narrow constraints for peak shock conditions, and shock release paths (in P-T space). Finally, I will address the issue of shock duration in martian meteorites such as Tissint and in ordinaray chondrites.

Title: Volatile Elements in the Tissint Meteorite: Evidence for a Geochemical Signature for Martian Near-surface Alteration Preserved in Shock-generated Melt Pockets.

Presenter/First Author: Cody Robert Kuchka, University of Alberta, Edmonton,

Presenter/First Author Email: kuchka@ualberta.ca

Co-authors: Christopher D K Herd, University of Alberta, Edmonton, AB, Canada; Erin L Walton, Grant MacEwan University, Edmonton, AB, Canada; Yang Chen, JPL/NASA/Caltech, Pasadena, CA; Yang Liu, , ,

Published Material: Results from this work will be presented at the Lunar and Planetary Science Conference in March, 2015.

Abstract Body: Tissint contains an abundance of shock-generated melt glass formed by a variety of mechanisms including grain-boundary frictional melting, concentration of shockwaves along boundaries of minerals with contrasting shock impedance, and void collapse. Four shock melt pockets containing glass were analyzed by EPMA and SIMS. Melt pockets analyzed are basaltic in composition, consistent with the melting of local igneous phases; no excesses of P, Cl, or F are observed that could indicate a melted regolith component. H_2O content within glass ranges from <100 ppm to several thousand ppm. Cl exhibits a strong correlation with H_2O in shock melt glass, suggesting that Cl followed H_2O when introduced into the rock. This strong correlation is not observed for H_2O and F or P; H_2O and Cl concentrations within Tissint glass cannot be explained by melting igneous apatite and are most likely a remnant geochemical fingerprint of aqueous processes affecting the rock near the Martian surface after the rock's igneous crystallization. δD for Tissint melt glass exhibits a negatively-sloping trend against $1/H_2O$, indicating a mixing line between two reservoirs. High δD values for these reservoirs are consistent with Martian sources of water such as the crust and atmosphere and suggest an absence of terrestrial contamination. In one melt pocket, H_2O concentration decreases and δD increases when approaching a vesicle; this may be a function of prolonged cooling that allowed H_2O time to devolatilize to the vesicle before quenching completed after the peak shock wave passed. Conditions of melt pocket formation may contribute to local-scale variations in shock melt composition: void collapse is the most likely mechanism to trap alteration products as these materials would be concentrated in voids within the pre-shocked rock. Volatiles in these voids also contribute to preferential melting by suppressing the local solidus. It appears that some shock melt pockets in Tissint contain a geochemical signature characteristic of Martian alteration products, preserved primarily in H_2O and Cl concentrations. The distribution of such melt pockets is likely heterogeneous as the precursors to these melt pockets (voids and cracks hosting alteration products) were

likely heterogeneously distributed in the rock prior to shock melting induced by impact.

Title: Characterization of Mineral Assemblages Associated with Shock Veins in L5 Chondrite Dhofar 1970

Presenter/First Author: Sabrina McCarthy, MacEwan University, Edmonton, AB

Presenter/First Author Email: mccarthys14@mymacewan.ca

Abstract Body: The purpose of this research was to investigate a previously unstudied L5 chondrite, Dhofar 1970, available through loan from the University of Alberta Meteorite Collection. Dhofar 1970 was strongly affected by shock metamorphism, which caused small volumes of the rock to melt, forming a complex network of 10-1200 µm thick shock veins and isolated shock melt pockets. This study focuses on characterizing the composition and microtextures of minerals associated with Dhofar 1970 shock veins. Using a combination of optical microscopy, SEM, EMPA and Raman spectroscopy, the following minerals were identified: olivine, ringwoodite, jadeite, maskelynite, majorite and magnesiowüstite. Deformation in host rock minerals, including complete transformation of plagioclase to maskelynite, classify Dhofar 1970 as S6 or very strongly shocked. Majorite, observed as 1-3 µm size equant crystals has co-crystallized with magnesiowüstite from the shock melt. When compared to published experimental work on mineral stability and identical mineral assemblages in shock melts of other well-studied chondrites, this assemblage indicates Dhofar 1970 experienced a pressure of 18-25 GPa and temperature of 2000-2400 ^{o}C during impact collision. This estimate of shock conditions is significantly lower than estimates of ~55-75 GPa derived from the shock classification for ordinary chondrites. This discrepancy is attributed to the shorter duration of shock recovery experiments compared to those experienced by naturally shocked rocks and by reaction kinetics which are greatly enhanced close to hotter portions of the rock within and adjacent to the shock veins. Round clasts within the shock vein were also documented, with Fe-rich ringwoodite rims and Fe-poor olivine cores. Identical textures reported from Peace River and Y-74445 chondrites were interpreted to have formed by fractional crystallization. The textures documented in this study support solid-state transformation, which requires longer time for diffusion of Fe-Mg between ringwoodite and olivine.

Title: Shock Processes in Solar System Zircon

Presenter/First Author: Desmond Moser, Western University, London, ON

Presenter/First Author Email: desmond.moser@uwo.ca

Published Material: This is an invited talk that is a mixture of unpublished results (50%) and an overview of data presented at Goldschmidt 2013 in Florence and the Large Impacts workshop in Sudbury in 2013.

Abstract Body: Zircon is an extremely durable and refractory phase, now known to survive intense shock metamorphism, tectonic recycling and the erosion of continents and craters. It occurs throughout the Earth's lithosphere, and is increasingly being studied in returned or meteoritic samples of crusts of the Moon, asteroids and, most recently, the ancient highlands of Mars. This expansion to extraterrestrial materials has partly been driven by advances in electron microscopy that allow precise mapping and contextualization of grains as small as one micron in polished thick sections, techniques such as EBSD that afford mapping of lattice orientations, misorientations and high pressure polymorphs in micro-grains at angular and spatial resolutions of 0.2 degrees and 50nm, respectively, and the parallel advances in micro- to nano-scale isotopic analysis by SIMS, laser methods and atom probe tomography (APT). In this talk I will present examples of the growing diversity of shock processes recorded in zircon chemistry and/or microstructure from a range of deformation-temperature pathways experienced by inner solar system samples. Case studies will include; the ~250 km wide Vredefort impact structure, a natural laboratory for terrestrial shock processes in accessory minerals across a gradient of ~1000 degrees and 60 GPa where some zircons record the entire shock loading and unloading sequence, lunar zircons from Apollo and meteoritic samples that show features analogous to those at Vredefort, the 4 Ga population of meteorite NWA 7475 now being explored as our first zircons from the martian regolith, as well as shock-generated zircon in melt bodies on Earth and proximal to launch-melt pockets in 180 m.y. shergottite. The full potential of zircon as a recorder of the nature and timing of shock metamorphic processes is yet to be realized, and its future role will be discussed with regard to improving early bombardment chronologies that relate to the evolution and habitability of planetary crusts.

Title: Shock Veins in Terrestrial and Extraterrestrial Materials: Examples from the Steen River Impact Structure and NWA 8159 Martian Augite Basalt

Presenter/First Author: Erin L Walton, Grant MacEwan University, Edmonton, AB

Presenter/First Author Email: waltone5@macewan.ca

Co-authors: Thomas G Sharp, Arizona State University, Tempe, AZ; Jinping Hu, Arizona State University, Tempe, AZ

Published Material: A portion of this material will be presented at the LPSC conference in March 2015 (although the abstract has yet to be assigned to an oral / poster presentation)

Abstract Body: It is well documented that many meteorites contain shock veins where high temperature and high pressure minerals have been discovered. It is widely accepted that these veins are analogous to terrestrial micro-pseudotachylites, reported from only a few impact structures including Manicouagan, Ries and Vredefort. The importance of shock veins is twofold: 1) the minerals formed by crystallization from impact melt or solid-state transformation can give us a better understanding of the pressure-temperature conditions during shock, and 2) comparison between shock veins in terrestrial impact structures, where stratigraphic position within the crater is known, and shock veins in meteorites, can help provide context to impact ejection mechanisms. However, if shock metamorphism recorded in the meteorite occurred in a larger impact event prior to ejection, then comparison allows us to draw conclusions regarding the pre-ejection location on their parent body. The high pressure mineral inventory of thin shock veins from the central uplift of the 25-km diameter Steen River impact structure (SRIS) in NW Alberta and nearly identical features in a newly recognized type of martian meteorite – NWA 8159 augite basalt – have been characterized using SEM, EMPA, Raman and TEM. In the SRIS, shear-induced shock veins cut across the metamorphic fabric of a plagioclase-amphibole-biotite-quartz gneiss. Large mm-size grains of ferro-pargasite have undergone a nearly isochemical phase transformation to almandine garnet with 36% majorite component. This amphibole-garnet transformation is observed only in those grains in direct contact with the shock vein and in small fragments entrained within the vein. Likewise, plagioclase-maskelynite transformation is only observed near to the shock veins. The opaque, fine-grained, granular matrix of the shock vein contains euhedral almandine garnet with 11% majorite component and other minor phases such as

pyroxene and stishovite. The high-pressure mineral inventory of shock veins from the SRIS is similar to, but distinct from, veins in NWA 8159 where Na-rich almandine-grossular garnets (38% majorite) have crystallized with clinopyroxene (jadeite-ferroan augite s.s.) and stishovite. Shock pressure and temperature estimates for both rocks are within the range ~15–23 GPa.

Title: Labradoritic Hollandite in the Central Uplift of the Manicouagan Impact Structure

Presenter/First Author: Suporn Boonsue, University fo New Brunswick, Fredericton, NB

Presenter/First Author Email: sboonsue@unb.ca

Co-authors: John G Spray, University of New Brunswick, Fredericton, NB, Canada

Abstract Body: The mineralogy, texture and formation of new phases associated with shock veins developed in the central uplift of the Manicouagan impact structure, Canada, have been studied using micro-Raman spectrometry and analytical field emission scanning electron microscopy. The shock veins were formed in anorthositic and gabbroic gneisses as thin fracture-microfault systems during the contact/compression stage of crater formation at 214 Ma. The shock veins comprise an amorphous to nano-micro crystalline matrix, which may exhibit fluidal textures, hosting wall rock mineral fragments of hornblende, augite, plagioclase and garnet. Here we report the existence of high-pressure polymorphs of plagioclase (labradoritic-hollandite) that have been observed in natural terrestrial rocks. The chemical composition of the polymorph is $(Ca_{0.54},Na_{0.46})Al_{1.6}Si_{2.4}O_8$, which is compatible with the composition of the host rock labradorite. In many cases the labradoritic-hollandite (Lab-Holl) coexists with stishovite. The Lab-Holl displays intense Raman bands at 695-697 and 376-378 cm^{-1}, characteristic of a jadeite-structured phase with a broad band at ~997 cm^{-1}. The spectrum also consists of the superimposed Raman bands at 485 and 523 cm^{-1}, close to that of host rock labradorite (481 and 509 cm^{-1}). We suggest that the shock impedance contrast between components, and rarefaction, are responsible for shear failure or fracture and in situ shock melting of local portions of the host rock with associated crystallizing quench phases within the shock veins. The formation of high pressure phases is interpreted to be the result of the solid-state transformation of labradorite and/or direct crystallization from a labradorite melt. The development of mosaic-fractured stishovite crystals and neocrystallites of Lab-Holl with interstitial glass indicate metastable conditions in the melt veins due to the spatially and temporally heterogeneous shock process. The coexistence of the Lab-Holl and stishovite sets an upper bound for shock pressure in the shock vein to near 23 GPa.

Title: Manifestation of shock in plagioclase from shatter coned gneisses, Manicouagan impact structure.

Presenter/First Author: Lucy M Thompson, University of New Brunswick, Fredericton, NB

Presenter/First Author Email: lthompso@unb.ca

Published Material: I have previously presented preliminary microscopy and field observations associated with this work at Charlotte GSA and 2014 LPSC. This will be the first time presenting the Raman and FESEM work.

Abstract Body: The intensity of shatter cone development within intermediate gneisses of the Manicouagan impact structure increases along a transect from 27 km through to 12 km radius from the centre. Quartz and oligoclase within the shatter coned gneisses reveal an associated increase in the intensity of recorded shock deformation from the edge of the structure towards the centre.

Quartz grains within gneisses at 27 km rarely exhibit single sets of decorated PDFs. Oligoclase exhibits minor fracturing and development of fine planar features within twins. At a 15 km radius from the centre of the structure, multiple orientation, decorated PDFs are ubiquitous within quartz grains and multiple orientation, fine scale planar features are well developed within twins in oligoclase. In thin section, the gneiss has a "cloudy" appearance, owing to the preponderance of planar features in both the plagioclase and quartz. The shatter coned gneisses at 12 km radius, are even darker in thin section. Quartz grains exhibit high densities of multiple orientation, decorated PDFs, which give the grains a "toasted" appearance. Oligoclase grains also exhibit high densities of multiple orientation planar features within twins and the development of extensive isotropic, glassy-looking domains.

Shatter cones from the anorthositic gneiss central uplift at Manicouagan, 4 km radius from the centre, exhibit fractured labradorite grains. The intensity of the fracturing increases towards shatter cone surfaces. Fine scale, multiple planar features within twins, are only manifest in labradorite grains immediately adjacent to shatter cone surfaces.

This work summarizes the results of a Raman and FESEM investigation of oligoclase and labradorite grains from shatter cones at Manicouagan. This will allow a better understanding of the mechanisms of shatter cone formation, as well as the response of plagioclase to shock. Future work will aim to further constrain and calibrate shock in plagioclase.

Title: Shocked Biotite in Natural and Experimental Systems

Presenter/First Author: Natalie Deseta, Wits University, Johannesburg,

Presenter/First Author Email: suridae@gmail.com

Abstract Body: Shocked anhydrous minerals (e.g., plagioclase, Kspar, quartz) has been well documented using both natural and experimental samples. The goal has been to determine the initial shock and/or shock recovery pressure under which such minerals break down as a means to estimating the shock pressure conditions incurred by impacted materials. However, the behaviour of hydrous minerals, such as biotite, under shock conditions has not been well characterized. Hydrous minerals are common constituents in terrestrial rocks, and their presence may influence the shock recovery process within the bulk rock, as both a source of shock impedance contrast and fluids in the system. Research on the high-grade metapelites of the Vredefort Dome has suggested that the breakdown of hydrous minerals such as biotite within the host rock may have been a significant source of fluids in the shocked target rock.

Shock recovery experiments, using samples of migmatitic metapelites from the Etive aureole in Scotland as an analogue for the Vredefort Dome metapelites, were carried out at the Ernst-Mach-Institut, Germany. SEM-BSE data indicate that the breakdown of biotite to release fluids facilitated shock-related deformation by explosively injecting contiguous minerals (garnet, plagioclase, kspar, quartz) with fluids, locally fracturing some and facilitating the fusion of others. The biotite itself formed shock fractures perpendicular to (001), as well as having undergone intragranular vesiculation, sintering, shredding and extreme strain localization at increasing degrees at each shock pressure tested (from 12.5, 18, 25 34, 40

to 56 GPa). Shredding of the biotite structure appears to be due to a combination of shearing perpendicular to (001) and internal shock reflections that generated complex interaction between melt and kink bands. In comparison with natural samples from the Vredefort Dome, which are thermally overprinted, the microtextures of biotite shocked from 34 GPa upwards are comparable. Whether biotite occurs as an accessory mineral or as a principal mineral in the target rock assemblage, its break down under shock is likely to be a significant source of fluids in the system and a facilitator of damage to proximal phases under high secondary shock pressures.

Title: Implications of a hyperboloid transient cavity model for impact craters

Presenter/First Author: Michael R Dence, , Ottawa, ON

Presenter/First Author Email: mrdence@rogers.com

Co-authors: John G Spray, University of New Brunswick, Fredericton, NB, Canada; Lucy M Thompson, University of New Brunswick, Fredericton, NB, Canada

Published Material: Findings were submitted in part as an abstract and presentation to the May 2014 Annual General Meeting of GAC-MAC held in Fredericton, N.B. Findings have yet to be submitted for review.

Abstract Body: The hyperboloid model for the transient cavity stage of terrestrial hypervelocity impact craters is based on the position of shock features in two deep drill holes spaced 200m apart at the centre of the Brent crater. In the centre ~650m of breccia emplaced during late stage collapse overlies a 40m thick melt layer that is taken as the upper section of the ~100m thick lining of the residual transient cavity. Little melt is found 200m from the centre. In both holes shock levels diminish in the underlying 60m of breccia with a high apparent rate of attenuation of shock pressure versus depth from about -50 to -20, ending at the limit of total fragmentation where the shock level is about 5-10 GPa and the attenuation drops towards -2. The hyperbolic profile that satisfies these and other constraints has an eccentricity of about 1.6 and projects to the estimated original surface to give a diameter of 3.6km and a depth of 1.05km. This form resembles small fresh lunar craters and experimental craters formed by hypervelocity impacts into sand targets. The hyperboloid form can be applied to larger complex craters with little modification indicating no fundamental change in crater mechanic s and target properties at the simple to complex transition. This has important implications for the morphology and modification processes associated with complex craters. Compared to paraboloid models the rim is more subdued and near-surface motions are at lower inclinations, thereby placing more importance on radial displacement rather than ejection and implying buckling and slumping mechanisms for the formation of rings found outside the main rim, particularly in stratified targets. These results have direct implications for the modeling and understanding of the impact cratering process and highlight differences between explosion and impact craters.

Title: Post-Shock Oscillatory Slip: Displacement and Vibration Melting without Offset

Presenter/First Author: John G Spray, University of New Brunswick, Fredericton, NB

Presenter/First Author Email: jgs@unb.ca

Abstract Body: A series of experiments have been performed on Westerly granite using linear friction welding apparatus. For this application, two 24.8 x 47 x 63.5 mm machined blocks of the granite were brought into contact along their 24.8 x 63.5 mm faces. Westerly granite is a medium grained quartz-orthoclase-plagioclase (An<20)-biotite igneous assemblage, with accessory/secondary chlorite, clinozoisite, epidote, titanite, zircon, apatite and opaques. The friction apparatus was operated at a frequency of 20 Hz, an amplitude of 1 mm (wavelength of 4 mm), for 8.33 s, under a load of 5 kN. Total displacement was 666.40 mm and the mean velocity 80 mm/s. Following the experiment, the samples were mounted in epoxy and diamond-saw cut, and polished thins made of the slip face sections. The thin sections were examined using binocular and petrographic optical microscopes, and an Hitachi SU-70 field emission scanning electron microscope equipped with an energy-dispersive X-ray spectrometer. Oscillatory slip caused comminution and localized melting. Also, the transfer and "welding" of material occurred between the sliding faces. Two zones of damage are noted: a central partial melting zone (<300 microns wide) and a subsurface comminution/fractured zone developed either side of the slip surface (up to 50m microns wide). The partial melting zone comprises more rounded fragments, which are dominated by quartz, bonded by a submicroscopic matrix (seemingly amorphous). Biotite underwent breakdown via "bubbling" and dehydration, and has been preferentially incorporated into the melt. Orthoclase then plagioclase follow, leaving predominantly quartz with some plagioclase as clasts. Oscillatory slip may explain the production of friction melts in faults displaying negligible offset: the effective displacement can be substantial, yet the apparent slip is minimal. A scenario for facilitating this type of behaviour in nature can be sonic and subsonic vibrations associated with seismic events, including the post-shock phase of hypervelocity impact.

Title: Rosetta Lander – Philae: First Landing and Operations on a Comet

Presenter/First Author: Stephan Ulamec, German Aerospace Center DLR Cologne, Cologne,

Presenter/First Author Email: stephan.ulamec@dlr.de

Co-authors: Jens Biele, German Aerospace Center DLR Cologne, Cologne, Germany

Published Material: Status on Lander after November has been reported before. However, new information will be made available on results by May 2015!

Abstract Body: Philae is a comet Lander, part of Rosetta which is a Cornerstone Mission of the ESA Horizon 2000 programme. In August 2014 Rosetta did rendezvous with comet 67P/Churyumov-Gerasimenko (CG) after a 10 year cruise. Both its nucleus and coma have been studied allowing the selection of a landing site for Philae. Philae was separated from the Rosetta main spacecraft on November 12, 2014 and touched the comet surface after seven hours of descent. After several bounces it came to rest and continued to send scientific data to Earth. All ten instruments of its payload have been operated at least once. Due to the fact that the Lander could not be anchored, the originally planned first scientific sequence had to be modified.

Philae went into hibernation on November 15th, after its primary battery ran out of energy. Re-activation of the Lander is expected in spring/summer 2015 when CG is closer to the sun and the solar generator of Philae will provide more power.

The paper will give an overview of Separation, Descent and Landing, news on the search for the final landing spot as well as Lander Operations after separation. We will also report on the status regarding a probable re-activation of the Lander, by May 2015.

Rosetta is an ESA mission with contributions from its member states and NASA. Rosetta's Philae lander is provided by a consortium led by DLR, MPS, CNES and ASI.

Abstract Body: In August 2014, the Rosetta spacecraft encountered comet 67P/Churyumov-Gerasimenko at a distance of 3.5 AU from the Sun. Since then, the spacecraft has been observing the development of the coma around the comet. The spacecraft has a host of in situ instrumentation that includes the Rosetta Orbiter Spectrometer for Ion and Neutral Analysis (ROSINA) instrument suite and the Ion and Electron Sensor (IES). Part of the ROSINA suite is an ion and neutral mass spectrometer, the Double-Focusing Mass Spectrometer (DFMS). Most often, DFMS makes high mass resolution measurements of the neutral composition of the developing coma of the comet. However, the mass spectrometer is sometimes operated in an ion mode that makes in situ measurements of key components of the ion composition of the coma. This talk focuses on these ion measurements that were made far from the Sun, when outgassing is weak and there is minimal ion-neutral chemistry in the coma. The mass ratios of newly created cometary ions are consistent with this minimal ion-neutral chemistry. Ion and electron observations of the solar wind from IES indicate that no contact surface formed upstream of the spacecraft and that newly created cometary ions are ultimately picked up by the solar wind. In this talk, the ion measurements are described and compared with ionospheric models. The implications for cometary interactions with the solar wind from 3.5 to 2.5 AU from the Sun are derived from these comparisons.

Title: The plasma environment of 67P/Churyumov-Gerasimenko probed with the Rosetta orbiter: Current Observations

Presenter/First Author: Marilia Samara, NASA Goddard Space Flight Center, Greenbelt, MD

Presenter/First Author Email: marilia.samara@nasa.gov

Co-authors: James L Burch, Southwest Research Institute San Antonio, San Antonio, TX; Thomas W Broiles, Southwest Research Institute San Antonio, San Antonio, TX; George B Clark, Catholic University of America, Washington, DC; Thomas Cravens, University of Kansas, Lawrence, KS; Raymond Goldstein, Southwest Research Institute, San Antonio, TX; Kathleen Mandt, Southwest Research Institute San Antonio, San Antonio, TX; Prachet Mokashi, Southwest Research Institute, San Antonio, TX; Craig J Pollock, NASA Goddard Space Flight Center, Greenbelt, MD

Published Material: Findings related to IES have been presented at the Fall AGU meeting in San Francisco in December 2014.

Abstract Body: Rosetta is the first spacecraft to ever orbit a comet and closely monitor its nucleus activity and coma development as it travels through the inner solar system. Currently Comet 67P/Churyumov-Gerasimenko (67P/C-G) is still relatively far from the Sun (> 2.5 AU), and consequently, plasma activity was expected to be low or negligible. However, the first six months of measurements made with the Rosetta Plasma Consortium Ion and Electron Sensor (RPC-IES)—a dual top-hat electrostatic analyzer that measures the 3D fluxes of electrons and ions from ~4 eV to ~20 keV—have revealed a dynamic plasma environment that is both rich and diverse. The density of the plasma near the comet will increase as it approaches the Sun, and Rosetta will have an unprecedented opportunity to follow the evolution of the plasma environment close to 67P/C-G resulting in new insights and questions. We provide a summary of current observations and future questions that IES and RPC may address with new data as activity grows with the comet's approach to perihelion.

Published Material: Some of the results to be presented (e.g. total gas production and average thermal properties) have been accepted for publication by the journal Science, and have been discussed at the Fall 2014 AGU meeting. This presentation will focus, however, on analyses currently underway involving higher spatial and temporal resolution.

Abstract Body: The Microwave Instrument for the Rosetta Orbiter (MIRO) makes millimeter and submillimeter observations of the nucleus and coma of Rosetta's target comet. This presentation summarizes the instrument, its observations, and our team's scientific analyses to date. MIRO makes continuum measurements at 190 and 563 GHz (1.6 and 0.5 mm) to study the thermal and electrical properties of the nucleus near-surface (depths from ~1 millimeter to 10 centimeters). MIRO also makes spectroscopic measurements of 8 lines near 560 GHz (H_2O, $H_2{}^{17}O$, $H_2{}^{18}O$, CO, NH_3, and three CH_3OH transitions). The abundance, gas velocity, and temperature of those species are measured as functions of time and location. To interpret its data, the MIRO team has developed sophisticated nucleus and coma models. Our goal is to understand the dominant physical processes that create the coupled nucleus-coma system.

MIRO began measuring water in the coma on 6 June 2014, at a heliocentric distance of 3.9 AU. By October (3.3 AU from the Sun), the total production rate had increased a factor of 6. Water production varies both with location on the nucleus and time-of-day. At the time of this writing, H_2O and $H_2{}^{18}O$ have been clearly measured, with detections of $H_2{}^{17}O$ and CH_3OH. We will report on our composition measurements and on the time and spatial variability of nucleus outgassing. Our analysis of spectral data uses a non-LTE coma model, accounting for the boundary layer at the nucleus, regions dominated by gas collisions, electron collisions, and radiative processes.

MIRO's continuum channels have detected the nucleus since 19 July 2014, and the nucleus has been spatially resolved since early August. All surface regions appear to have a very low thermal inertia, as expected for a porous, dusty layer. We see variability in properties horizontally and with depth, and will present our latest results. MIRO has developed a 3-D nucleus thermal/radiative model to assist in observation planning and interpretation.

Abstract Body: Since the early summer 2014, the Microwave Instrument on the Rosetta Orbiter (MIRO) has been measuring emission from the coma of 67P/Churyumov-Gerasimenko in the sub-millimeter channel at 562 GHz and the millimeter channel at 190 GHz. The high-resolution spectrometer in the sub-millimeter channel is tuned to molecular lines of H_2O, CO, CH_3OH and NH_3. We will discuss the analysis of the three methanol lines at 553.146 GHz, 568.566 GHz and 579.151 GHz and present estimates of the gas abundance in the coma relative to water. The line shape analysis relies on our non-local thermal equilibrium radiative transfer software. Some of the key parameters needed to determine the population of the rotational levels, which enter the radiative transfer calculation, are the state-to-state collision coefficients between the methanol and water molecules. We have calculated theses collision coefficients using a dipole-dipole interaction Hamiltonian and first order perturbation theory for the collision process. Collisional cross-sections between rotational levels in the vibrational ground state will be given in ranges of gas temperature and density present in the coma.

Title: Evidence Of Metasomatism In The Lowest Petrographic Types Inferred From A Na-, K, Rich Rim Around A LEW 86018 (L3.1) Chondrule.

Presenter/First Author: Ritesh Kumar Mishra, NASA Johnson Space Center, Houston,

Presenter/First Author Email: riteshkumarmishra@gmail.com

Co-authors: Kuljeet Kaur Marhas, , , ; Justin I Simon, NASA Johnson Space Center, Houston, TX; Daniel Kent Ross, Jacobs Technology USOGS, Houston, TX

Abstract Body: Ordinary chondrites (OCs) represent the most abundant extraterrestrial materials and also record the widest range of alteration of primary, pristine minerals of early Solar system material available for study. Relatively few investigations, however, address: (1) the role of fluid alteration, and (2) the relationship between thermal metamorphism and metasomatism in OCs, issues that have been extensively studied in many other meteorite groups e.g., CV, CO, CR, and enstatite chondrites. Detailed elemental abundances profiles across individual chondrules, and mineralogical studies of Lewis Hills (LEW) 86018 (L3.1), an unequilibrated ordinary chondrite (UOC) of low petrographic type of 3.1 returned from Antarctica, provide evidence of extensive alteration of primary minerals. Some chondrules have Na-, K-, rich rims surrounded by nepheline, albite, and sodalite-like Na-, Cl-, Al-rich secondary minerals in the near vicinity within the matrices. Although, limited evidences of low temperature (~250°C) fluid-assisted alteration of primary minerals to phyllosilicates, ferroan-olivine, magnetite, and scapolite have been reported in the lowest grades (<3.2) Semarkona (LL3.00) and Bishunpur (LL3.10), alkali-rich secondary mineralization has previously only been seen in higher grade >3.4 UOCs. This preliminary result suggests highly localized metamorphism in UOCs and widens the range of alteration in UOCs and complicates classification of petrographic type and extent of thermal metamorphism or metasomatism. The work in progress will document the micro-textures, geochemistry (Ba, Ca, REE), and isotopic composition (oxygen, ^{26}Al-^{26}Mg) of mineral phases in chondrules and adjoining objects to help us understand the formation scenario and delineate possible modes of metamorphism in UOCs.

Abstract Body: Increasingly, magnetic susceptibility measurements are being used to rapidly and non-destructively characterize stony meteorites, and a meaningful database of measurements is already available. However, current data have been acquired by susceptibility meters that operate at only a few field strengths and frequencies.

The University of Toronto Electromagnetic Induction Spectrometer (UTEMIS) is a prototype instrument that measures AC complex susceptibility over a range of 35 frequencies between 90 Hz and 64 kHz by harmonic analysis of periodic signals at six different base frequencies. A very weak exciting field is employed (typically <10 A/m peak-to-peak) so a near linear magnetization response is expected, but the amplitude of the excitation signal can be varied by a factor of 15 to test this. With this instrument, the magnetic susceptibility of 27 ordinary chondrites from the LL, L, and H classes was measured over the entire UTEMIS spectral range and with variable exciting field strengths. The results have been analysed and compared with data measured with a SI-2B commercial susceptibility meter at 2 frequencies (825 Hz and 19 kHz). Systematic variation of susceptibility with both applied field and frequency were observed; susceptibility increasing with excitation amplitude and falling somewhat with increasing frequency.

Varying the applied field permits the apparent susceptibility to be separated into a field-dependent term, putatively contributed by the multi-domain ferromagnetic grain fraction, and a field-independent term likely contributed by the diamagnetic, paramagnetic, and single-domain ferromagnetic grains. Among the ordinary chondrites measured, a positive dependence of susceptibility on exciting field with increasing metal content is widely observed. The LL class displays little dependence with field strength, whereas the H class displays ubiquitous field dependence. Intermediate field dependence is found in the L class.

The degree of frequency dependence also varies with metal content; the H chondrites display a maximum of up to 17% measured from 810 to 64 kHz the L chondrites of up to 8%, and the LL chondrites up to 3%.

Title: Effects of Thermal Metamorphism on Spectral Properties of a Carbonaceous Asteroid Regolith Simulant

Presenter: Matthew R Izawa, University of Western Ontario, London, ON

Presenter Email: matthew.izawa@gmail.com

First Author: Edward Cloutis, University of Winnipeg, Winnipeg, MB

Abstract Body: Thermal processing has been invoked as a possible cause of some of the spectral features of the B-type near Earth asteroid Bennu, the target of the upcoming OSIRIS-REx asteroid sample return mission. In particular, thermal metamorphism may explain the anomalous 'blue' spectral slope (i.e., increasing reflectance towards short wavelength). It is expected that, to first order at least, the regolith of Bennu will resemble known carbonaceous chondrite meteorites (though it will very likely differ in detail). We have developed a regolith simulant consisting of nanophase magnetite (5%), natural serpentine (85%), shungite (5%; shungite is a refractory organic mineraloid), and troilite (5%). This mixture was designed to simulate the composition of CM2 chondrites largely in terms of phases expected to have the greatest influence on CM spectral properties; CMs are one of the most common carbonaceous chondrite types. The simulant was heated under partial vacuum (10-70 mbar) with a dry N_2 purge. The samples were heated at 100ºC increments from 100ºC to 1200ºC. X-ray diffraction data were collected at each heating stage, before and after heating, along with reflectance spectra covering 350-2500 nm. Overall reflectance increased with heating. Spectral changes include loss of OH-related spectral features above 700ºC, consistent with the dehydroxylation of serpentine. Enstatite and forsteritic olivine were observed by XRD at 900ºC. Hematite formed at the expense of magnetite beginning at 600ºC, but was less apparent with increasing temperatures and nearly undetectable above 1100ºC. It appears that heating alone cannot account for the spectral properties of Bennu, perhaps indicating that alternative mechanisms (e.g., enhanced aqueous or hydrothermal alteration, space weathering) or physical properties (grain size, compaction state) must be explored.

Title: 3D petrography of Enstatite achondrites via micro computed tomography scanning (µCT)

Presenter/First Author: Diego David Uribe, Western University, London,

Presenter/First Author Email: duribelo@uwo.ca

Co-authors: Phil J A McCausland, University of Western Ontario, London, ON, Canada; Matthew R Izawa, University of Western Ontario, London, ON, Canada; Roberta L Flemming, University of Western Ontario, London, ON, Canada; Joseph Umoh, Western University, London, ON, Canada; David Holdsworth, Western University, London, ON, Canada

Abstract Body: Enstatite achondrites are thought to have formed under highly reducing conditions, and are composed of enstatite, plagioclase, native iron (kamacite), troilite and various trace phases. Understanding the petrogenesis of these rare meteorites may provide information about early planetary formation processes, particularly in the region of the solar nebula near the proto-Sun. µCT allows for non-destructive analysis of meteorite samples and provides three dimensional imaging of internal density structures. Enstatite achondrite samples including Zaklodzie, NWA 4301, Itqy, Hvittis, NWA 8751, and Abee were imaged with the Locus RS-9 scanner, at an X-ray tube voltage of 80 kVp and a tube current of 0.45 mA. 900 views were collected at angular increments of 0.4º around the samples. The aforementioned meteorites were selected in order to observe and compare 3D structures of enstatite achondrites having different formation mechanisms. µCT images of the enstatite achondrites studied reveal density contrasts between high and low attenuation phases, and also show the overall distribution of metal and silicate throughout the samples. µCT may also be used to identify the weathering extent of the samples which is useful when trying to analyse the least altered material or when trying to identify where to cut the sample for thin section preparation. Threshold value limits were selected for high intensity and low intensity phases and were compared to reported values in literature. Although µCT cannot yet discern between each individual phase present in the samples, it is possible to determine a combined modal percent volume for metal + sulphides and silicates + plagioclase. Isosurface rendering of high-intensity phases was used to visualize the distribution, size, shape and interconnectedness of metal grains in the samples which may help further understand their petrogenetetic sequence.

Title: Structural Characterization of the Sudbury Impact Structure, Canada using current remote sensing datasets

Presenter/First Author: Bhairavi Shankar, University of Western Ontario, London,

Presenter/First Author Email: bshanka@uwo.ca

Co-authors: Gordon Richard Osinski, University of Western Ontario, London, ON, Canada

Abstract Body: This study uses current high resolution spatial and spectral orbital datasets to determine the extent and characterize structural features around the Sudbury impact structure, ON, Canada. With an apparent diameter anywhere from 150 to 290 km, the impact structure is proposed to be a multi-ring complex impact structure. Several ring structures have been hypothesized around the crater structure, extending 90 – 200 km beyond the main basin area. Due to the extensive post impact deformation and tectonism, this study focussed on areas north and west extending ~150 km beyond the Sudbury Igneous Complex (SIC). Lineament trends were extracted using automatic extraction algorithms on shaded relief maps (using DEMs, 30 m resolution), and Landsat-7 ETM+ SWIR data. Linear edge enhancement and directional filtering methods were applied to the data to enhance the edges of drainage systems, landforms, and linear features prior to extraction. Landsat-7 band 5 was determined to be the most suitable band for lineament extraction. A more comprehensive set of lineaments were extracted from shaded relief maps with different sun azimuth directions (between 0^o–315^o). The extracted lineaments were statistically analyzed to determine lengths, densities to generate rose diagram, and assess lineament density. In total 13,287 lineaments were extracted with feature lengths ranging from 1 to 9000 m. The lineaments were then compared to known geology in order to determine the source of deformation - either resulting from the main impact event or from later deformation. Three structural trends were observed from plotting rose diagrams- a majority trending north-south and northwest-southeast direction. A minor trend running northeast-southwest. Future work will include analyzing band ratio composite maps using Landsat 8, ASTER, and Radarsat data in order to extract lineaments, determine structural trends, types of lineament, and investigate any evidence of radial and concentric structures.

Title: Impact Melt Veins in the Central Uplift of the West Clearwater Lake Impact Structure, Northern Quebec, Canada.

Presenter/First Author: Rebecca Wilks, University of Western Ontario, London,

Presenter/First Author Email: rebeccaaiellowilks@gmail.com

Co-authors: Gordon Richard Osinski, University of Western Ontario, London, ON, Canada

Published Material: This material was part of a poster presentation at the Lunar and Planetary Science Conference in The Woodlands, Texas during the week of March 16-20.

Abstract Body: The West Clearwater Lake impact structure is a ~290 Ma impact structure located in Northern Quebec at 56°08'N 74°18'W, approximately 125 km east of Hudson Bay. Phaneritic plutonic target rocks of the Superior Province were impacted, resulting in a ~30 km diameter structure with a series of central islands. The process of impact cratering is still not fully understood, specifically, how the uplift of underlying rocks in the centre of large complex craters occurs. This study intends to investigate central uplifts; particularly impact melt veins and dykes observed in the uplifted target rocks of the West Clearwater Lake impact structure. Researchers have hypothesized that impact generated melt has played a role in the weakening of rocks in the crater floor, allowing for the central uplift process to occur. Melt is thought to lubricate faults, allowing for blocks to be more susceptible to displacement. Whether this melt is formed by the initial shock of the impact or due to frictional melting is unknown. The aim of this research is to better understand the formation processes of these melt veins and dykes.

We have used electron dispersive spectroscopy techniques and optical microscopy to analyze the chemical composition, petrography and mineral structure of three melt vein samples retrieved from the central islands in West Clearwater Lake. In order to determine the processes by which these melt veins formed, petrography and geochemistry data of both the host rock and melt veins have been acquired and used for comparative analysis. This will allow for a better understanding of the role of melt on central uplift formation on Earth and other planetary bodies.

Published Material: This is a mission overview abstract, and will provide an overview of where the mission has been abd is going.

Abstract Body: The Rosetta Mission is the third cornerstone mission the ESA programme Horizon 2000. The aim of the mission is to map the comet 67-P/Churyumov-Gerasimenko by remote sensing, to ex-amine its environment insitu and its evolution in the inner solar system. The lander Philae is the first device to land on a comet and perform in-situ science on the surface. Nearly 10 years after launch in 2004, on 20th January 2014 at 10:00 UTC the spacecraft woke up from hibernation. Following successful

instrument commissioning, Rosetta successfully rendezvoused with the comet. Following an intense period of map-ping and characterisation, a landing site for Philae was selected and on 12 November 2014, Philae was suc-cessfully deployed. This presentation will provide a brief overview of the mission up to date and where we stand in main science phase, which began with Philae's separation. It will also provide a look forward. IT is given on behalf of ALL Rosetta mission science, in-strument and operations teams.

Published Material: November 2014 DPS meeting. Shape and topography from early mapping phases.

Abstract Body: The 2015 Joint Assembly coincides with the autumnal equinox of comet 67P/Churyumov-Gerasimenko. Since August 2014, we have been mapping the surface of the comet, producing three dimensional topographic maps at one meter spatial resolution. These maps have been ingested into APL's Small Body Mapping Tool, enabling us to study the geology of 67P/CG in three dimensions and in its proper gravitational context. Until now, a significant portion of the comet has been in permanent shadow, but in the weeks before the meeting most of its surface will be revealed to ROSETTA's OSIRIS cameras. We shall present an almost complete topographic map of the surface of the comet, which will allow an accurate measurement of the nucleus density.

Title: Impact Induced Ballen Fracture Networks and their Formation in SiO2 Clasts

Presenter/First Author: Anna Chanou, University of Western Ontario, London, ON

Presenter/First Author Email: anna.chanou@gmail.com

Co-authors: Richard A F Grieve, Natural Resources Canada, Ottawa, ON, Canada; Gordon Richard Osinski, University of Western Ontario, London, ON, Canada

Abstract Body: Rocks affected by meteoritic impacts display impact-related microtextures as the result of shock processes, as well as the associated extreme temperatures. So-called "ballen" is a form of microfracture network observed exclusively in SiO_2 polymorphs. Ballen formation is expressed in the literature as a series of multiple steps and transformations between the low- and high polymorphs of quartz and mainly cristobalite; (Path 1) a solid-solid transition: a-quartz à diaplectic glass and then formation/crystallizationà β-cristobalite à α-cristobalite/ α-quartz; (Path 2) a solid-liquid transition: α-quartz à lechatelierite à β-cristobalite/β-quartz ballen à α-cristobalite/α-quartz. All variations of this model require multiple steps and transformations that would eliminate any pre-existing micro-structures, such as planar deformation features (PDF). PDF-bearing ballen were described and characterized under the optical microscope, as well as using electron microprobe and Raman spectroscopy. All ballen-bearing clasts were observed in impact melt-bearing breccias from the following impact structures Popigai, Siberia Russia; Mistastin and Deep Bay, Canada; and were always included in impact melt glass or vitric clasts. The PDF appear to be continuous through the cracks, as well as continuous between ballen-ridden parts of the clast and clear parts of the same clast. An additional formation mechanism of ballen fractures is proposed as the result of the above observations where ballen fractures form due to thermal shock without the need of the cristobalitization process and an amorphous phase. Our observations are in agreement with such a mechanism. In addition, we suggest that ballen development has no direct or indirect association to pressure levels and is only indicative of extreme thermal gradient. Finally, ballen although strongly suggestive of meteoritic impact it is not a diagnostic indicator and has been reported in other settings such as fulgurites.

Title: The Non-Destructive Measurement of Meteorite Density and Porosity

Presenter/First Author: Daniel Turner Britt, Univ Central Florida, Orlando, FL

Presenter/First Author Email: britt@physics.ucf.edu

Co-authors: Guy J Consolmagno, , , ; Robert J Macke, , ,

Published Material: This reviews the method and results that have been presented over the last 15 years.

Abstract Body: There are 44 compositional types, subtypes, and metamorphic grades of meteorites which represent an invaluable resource of "free" geological material from asteroids. The measurement meteorite density and porosity, provides fundamental data on asteroid physical properties and insight into their structure and evolution. Until the late 1990's measurements of meteorite density and porosity used the standard geological techniques. For bulk volume and bulk density, the sample was weighed first in air and then suspended in water. This method gives a good estimate of the bulk density, but does not take into account any penetration of the water into the pore space. Another approach for bulk density was to cut the meteorite into a standard cube. To determine porosity some workers used penetrating fluids like carbon tetrachloride to access internal void spaces. The major drawback of these methods is the contamination the meteorite, which increases its weathering and potentially damages its use for future studies.

Consolmagno and Britt (1998) developed a method for the measurement of meteorite bulk densities using glass beads instead of water. The glass bead method, combined with helium gas pycnometry minimizes sample contact and thus contamination. Since then, the combination of glass beads for bulk density and helium gas pycnometry for porosity has become the standard for meteorite physical property measurements. The new developing standard is the use of 3-D laser scanning for bulk volume allowing for very minimal contact with the meteorite during the measurements.

Title: Characterization of Meteorites by Focused Ion Beam Sectioning: Recent Applications to CAIs and Primitive Meteorite Matrices

Presenter/First Author: Roy Christoffersen, Jacobs Technology, JETS, Houston, TX

Presenter/First Author Email: roy.christoffersen-1@nasa.gov

Co-authors: Lindsay P Keller, NASA Johnson Space Ctr, Houston, TX; Jangmi Han, , , ; Zia Rahman, NASA Johnson Space Center, Houston, TX; Eve L. Berger, , ,

Abstract Body: Focused ion beam (FIB) sectioning has revolutionized preparation of meteorite samples for characterization by analytical transmission electron microscopy (TEM) and other techniques. Although FIB is not "non-destructive" in the purest sense, each extracted section amounts to no more than nanograms (~500 μm^3) removed intact from locations precisely controlled by SEM imaging and analysis. Physical alteration of surrounding material by ion damage, fracture or sputter contamination effects is localized to within a few micrometers around the lift-out point. This leaves adjacent material intact for coordinate geochemical analysis by SIMS, microdrill extraction/TIMS and other techniques. After lift out, FIB sections can be quantitatively analyzed by electron microprobe prior to final thinning, synchrotron x-ray techniques, and by the full range of state-of-the-art analytical field-emission scanning transmission electron microscope (FE-STEM) techniques once thinning is complete. Multiple meteorite studies supported by FIB/FE-STEM are currently underway at NASA-JSC, including coordinated analysis of refractory phase assemblages in CAIs and fine-grained matrices in carbonaceous chondrites. FIB sectioning of CAIs has uncovered epitaxial and other overgrowth relations between corundum-hibonite-spinel consistent with hibonite preceding corundum and/or spinel in non-equilibrium condensation sequences at combinations of higher gas pressures, dust-gas enrichments or significant nebular transport. For all of these cases, the ability of FIB to allow for coordination with spatially-associated isotopic data by SIMS provides immense value for constraining the formation scenarios of the particular CAI assemblage. For carbonaceous chondrites matrix material, FIB has allowed us to obtain intact continuous sections of the immediate outer surface of Murchison (CM2) after it has been experimentally ion processed to simulate solar wind space weathering. The surface amorphization and loss of OH produced by the irradiation provides important clues regarding space weathering on primitive asteroids such as the OSIRIS-Rex target 101955 Bennu.

Title: Investigation of Changes in Sample Density During Impact Processes Using X-Ray Analysis

Presenter/First Author: Melissa Strait, Alma College, Alma, MI

Presenter/First Author Email: straitm@alma.edu

Co-authors: Sarah Jack, , , ; Angela Clayton, , , ; George Flynn, , , ; Daniel D Durda, Southwest Research Institute, Boulder, CO

Abstract Body: Meteorites have been used as analogs for asteroids in experiments to study the results of catastrophic disruption. Samples with a variety of sizes, projectile velocities and material compositions have been shot and the resulting debris used to compare outcomes [1]. Currently there is interest in looking at changes in the physical properties of these same materials as a result of impact. To date we have investigated density, but are also looking at compression strength and speed of sound. The densities of 32 pieces of pumice from 8 shots were compared to the density of an unimpacted sample of pumice. There was a decrease from 0.90 g/cm^3 to an average of 0.77 + 0.09 g/cm^3. The range of densities for the individual pieces was 0.56 to 0.93 g/cm^3. The %RSD varied from 2 to 16% when measuring 3 to 6 pieces from the same shot. There does not appear to be a correlation between the density and the original sample size, the projectile velocity or extent of disruption (measured by the largest remaining fragment size). The X-Ray information can also be useful in studying changes in the texture of samples and in the porosity when exposed to processes such as impact disruption. We have previously shown there is no change in the layering texture of a highly porous pumice sample when exposed to impact disruption [2] and are investigating the effects of impact on the porosity of an ordinary chondrite.

Title: Non-destructive analyses of Martian meteorites using Raman Spectroscopy

Presenter/First Author: Kim Tait, Royal Ontario Museum, ,

Presenter/First Author Email: ktait@rom.on.ca

Co-authors: Matthew R Izawa, University of Western Ontario, London, ON, Canada; Desmond Moser, Western University, London, ON, Canada; Brendt C Hyde, Royal Ontario Museum, Toronto, ON, Canada

Abstract Body: Raman spectroscopy is an important tool to study highly shocked extraterrestrial materials. It provides complementary measurements of the short-range order phenomena in solid matter to other microstructural techniques to unravel the complex petrogenic history of these rare samples. Spectroscopy is of particular utility in studying amorphous materials such as maskelynite, metamict minerals and melt glasses and can also detect structural changes due to shock and inclusions of volatile or glassy material. Raman spectroscopy is also ideal in identifying high pressure polymorphs (e.g. the SiO_2 polymorphs) and weathering products. Characterization of the minerals present, with particular attention to the regions where it forms aids in the interpretation of the *P-T* formation conditions of the rocks. This could help answer the question whether high pressure phases are due to local (small-scale) pressure spikes or larger-scale pressures experienced by the whole rock.

Some recent work on martian meteorites have demonstrated the importance of detailed mineralogical characterization in interpreting geochronological data. Using a HORIBA Jobin Yvon LabRAM ARAMIS integrated confocal micro-Raman system with three excitation wavelengths of 532, 633, 785 nm we have non-destructively characterized a chemically diverse suite of martian meteorites. Through the use of our automated mapping stage and autofocus we are able to create mineral maps of areas much larger than generally achievable with Raman instruments. These maps can then be used for modal measurements allowing primary phases, and secondary weathering phases, to be quantified. Of particular interest were U-bearing phases such as zircon, baddeleyite, apatite-group minerals and merrillite as targets for subsequent studies.

Title: Nebular Conditions in the Early Solar System from the 3D Tomography of Chondrules.

Presenter/First Author: Christopher Charles, University of Ottawa, Ottawa,

Presenter/First Author Email: christopher.charles@uottawa.ca

Co-authors: Don Davis, University of Toronto, Toronto, ON, Canada; Phil J A McCausland, University of Western Ontario, London, ON, Canada; Pierre Yves Robin, University of Toronto, Toronto, ON, Canada; Joseph Umoh, Western University, London, ON, Canada; David Holdsworth, Western University, London, ON, Canada

Abstract Body: Chondrules are millimetre-sized igneous melt droplets formed in the early Solar System over 4.5 Gyr ago, and preserved in chondritic meteorites. Molten silicate droplets form spheroidal shapes due to a minimization of surface energy. In microgravity, a droplet may become perfectly spherical if no internal or external forces act during cooling and crystallization, but non-spherical shapes can arise if a droplet is perturbed by any number of forces during or after solidification. Many processes and diverse conditions in a range of nebular settings may be involved in chondrule formation. One key feature is the geometric shapes of chondrules themselves; the departure from perfect sphericity may provide clues for possible formation mechanisms. Here, X-ray micro-computed tomography (CT) was used to obtain the 3D shapes of >100 distinct chondrules in a 1 in^2 slab of the CR2 chondrite NWA801 at 50 µm/voxel resolution. For each chondrule, orientations of the three orthogonal symmetry axes and the lengths of the principal semi-diameters, A, B and C were determined by defining a minimum of 54 independently distributed points on the chondrule surface. A best-fitting ellipsoid was then calculated for each chondrule, characterized by a centre $\mathbf{X}_i$, and a symmetric 3×3 matrix $\mathbf{B}_i$. Axial ratios between $1.1< A/C<1.9$ and $1.0<B/C<1.3$ were observed with a clear preferred orientation of the short axes and the girdle pattern for the long axes. Thus some minor compaction (~10%) has acted on the chondrules. However, a range of original "nebular" shapes are present, from spheres, to oblate and prolate spheroids. Chondrule rotation (oblate sphereoids) or exposure to a ram-pressure headwind (prolate) could account for departures. Other forms may have been produced by ductile mergers. An alternate explanation may be that the chondrule shapes were produced by droplet vibration caused by melting of precursor dustballs in a nebular shock event.

Co-authors: Steven Pollmann, , , ; Daniel Lorusso, Robarts Research Institute, London, ON, Canada; Maria Drangova, , , ; Phil J A McCausland, University of Western Ontario, London, ON, Canada; David Holdsworth, Western University, London, ON, Canada

Abstract Body: Micro-Computed Tomography (µCT) enables access to spatial compositional and textural information in meteorites, to inform further investigation without the need for destructive analysis. Furthermore, high resolution images of meteorites attained in biomedical micro-CT scanners (GE eXplore Locus and GE eXplore speCZT at Robarts Research Institute) can be quantitative, with applicable correction. We report quantitative estimates for metal plus sulfide in H chondrites, as well as silicate phase discrimination in olivine diogenite, after image correction using a semi-empirical linearization of X-ray projection data using a custom calibration phantom to correct for beam hardening and scatter. Data from four meteorites are compared: Bassikounou H5, Gao-Guenie H5 and Grimbsy H4-5 ordinary chondrites and NWA 5480, a coarse-grained olivine diogenite. The chondrites demonstrated excellent agreement between % volume composition of dense metallic inclusions (metal plus sulfide) from corrected µCT images, as compared to literature values, point counting by reflected light microscopy, and SEM imaging (LEO 440 SEM at Surface Science Western), respectively. Silicate phases could not be discerned in the ordinary chondrites because of their fine-grained nature. By µCT, it is possible to distinguish the mineral phases in coarse-grained NWA 5480 (grains of mm size) using the large contrast between radiodensities of the different phases. The three most abundant phases in NWA 5480, enstatite, forsterite and chromite, as identified spatially by *in situ* µXRD analysis of the surface (Bruker D8 Discover), could be correlated to distinguishable mineral phases by µCT. Thus for this coarse-grained achondrite, the silicate minerals enstatite and forsterite could be distinguished easily by the lower radiodensity of the former. Medical CT imaging cannot reliably distinguish between sulphide and metal phases (both saturate) nor between silicates except in cases where the sample is coarse-grained.

Title: Non-destructive markers of parent body aqueous alteration in carbonaceous chondrites based on magnetometry and X-ray diffraction of mm-sized meteorite fragments

Presenter/First Author: Agnes Elmaleh, IMPMC Institut de Minéralogie et de Physique des Milieux Condensés, Paris,

Presenter/First Author Email: agnes.elmaleh@impmc.upmc.fr

Co-authors: Martine Gérard, Institut de Minéralogie, de Physique des Matériaux et de Cosmochimie (IMPMC), Paris, France; Benoît Baptiste, Institut de Minéralogie, de Physique des Matériaux et de Cosmochimie (IMPMC), Paris, France; Serena C. Tarantino, Dipartimento di Scienze della Terra e dell'Ambiente, Pavia, Italy; Brigitte Zanda, Institut de Minéralogie, de Physique des Matériaux et de Cosmochimie (IMPMC), Paris, France; Michele Zema, Dipartimento di Scienze della Terra e dell'Ambiente, Pavia, Italy

Abstract Body: We present a methodology for studying Fe-rich alteration assemblages, and its application to the study of aqueous alteration in C-rich asteroids. The more primitive chondrites are also the most altered. Early water-rock interactions probably occurred in their asteroidal parent bodies after ice that accreted with rocky materials have melted. In CM chondrites, serpentinization processes predominate and serpentines present a large diversity of compositions in the Si-Fe^{2+}-Fe^{3+}-Mg-Al system. The parameters controlling the variations are still poorly understood and may involve kinetic factors. It is important to evaluate bulk mineralogical changes in chondrites as alteration proceeds in order to understand the reaction pathways during alteration. X-ray diffraction (XRD) has proven useful although it gives limited information on complex solid solutions. In a recent study we showed that low-temperature (2-300 K) magnetometry was a powerful tool for evaluating the mineralogical changes in Fe-rich serpentines, and to estimate the proportions of other Fe-rich phases. We combined this approach with XRD using a microfocus (<100 µm beam) high brilliance rotating anode X-ray generator to evaluate the mineralogical changes among 100's of µm to mm size fragments of the Paris chondrite, the least altered CM known so far. Alteration is heterogeneous in the Paris chondrite, with mm to cm size domains where primary chondritic components are better preserved. This feature gives a unique opportunity to evaluate the reactions involved by comparing more or less altered

areas. Our results suggest that the (Fe^{2+},Fe^{3+})-rich serpentine cronstedtite, which formation may be kinetically favoured, is the predominant early alteration phase. They yield new constraints on Fe partitioning during alteration, which imposes an important control on dihydrogen production during serpentinization in terrestrial systems, and probably also in extra-terrestrial ones. Our results also help understanding the Al budget during alteration, which is still poorly known. Therefore, the present non-destructive approach allows 1) a quick identification of alteration products and 2) an evaluation of mass transfers during alteration, which may help understanding the fluid flow pattern in chondritic parent bodies.

Title: TOPOGRAPHIC ANALYSIS OF FLUVIAL LANDFORMS WEST OF NEWCOMB CRATER (MARS) FROM HRSC-MARS EXPRESS STEREO IMAGERY

Presenter/First Author: Veronique Ansan, University of Nantes, Nantes,

Presenter/First Author Email: veronique.ansan@univ-nantes.fr

Co-authors: Nicolas Mangold, LPGN Laboratoire de Planétologie et Géodynamique de Nantes, Nantes Cedex 03, France

Abstract Body: Based on Mars Express HRSC stereo imagery (resolution of ~10m/pixel) and DEMs (resolution of ~75m/pixel), well-developed fluvial valleys are mapped in highly cratered terrain dated of Noachian (t>3.6 Gyr), especially in Noachis Terra, west of Newcomb crater. The 2D organization of valleys is very similar to that observed in terrestrial fluvial basins. The exponent n of Hack's law is a well-known parameter for determining the distribution of valleys or stream inside their watershed. This scaling law is an empirical power law relationship between the drainage basin area and the length of the stream, measured from the mouth of the basin to the crest of the drainage divide along the stream channel. Whatever the area of watersheds, the mean exponent n is ~0.7, which is very close to values for terrestrial valley networks. The valley depth, which is relief between the valley bottom and the interfluve summits, is <500 m, with a mean value of 100 m from HRSC DEMs. There is a spatial evolution of valley depth between heads and outlet at each given Strahler order, with a systematic increase in depth with a higher Strahler order for valleys debouching into plains like on Earth. The volume of valleys reaches a few 10s of km3, which is relatively significative even in arid conditions and implies a large volume of liquid water in a river sustained during a minimum period of time of 100 kyr. The quantitative assessment of fluvial valleys provides new items for their formation processes. During the Noachian period, the main erosive process is a sustained fluvial activity due to rivers fed by precipitation, whatever the precipitation comes from rainfall or snowfall and subsequent melting.

Title: Numerical modelling of river deltas on Titan and the Earth

Presenter/First Author: Piotr Przemysław Witek, University of Warsaw, Warszawa,

Presenter/First Author Email: ppwit@igf.fuw.edu.pl

Co-authors: Leszek Czechowski, University of Warsaw, Warszawa, Poland

Published Material: Part of the results is to be presented at EGU 2015 and LPSC 2015 meetings.

Abstract Body: Fluvial processes change the landscape by removing surface material from one place and depositing it in another. Beside Earth, terrains shaped by fluvial activity are known from Mars and Titan. When the river enter the standing body of water, the material carried by the flow is deposited, creating specific landforms such as river deltas. Several factors are known to affect the shape and development of these deposits. The sediments might contain different mixtures of clay, sand or gravel-sized grains depending on the terrain and distance from the source, due to natural sorting of rocky material in streams and rivers. We investigated the role of grain size in shaping the river deltas in terrestrial and Titanian environment using numerical approach. This work is an extension of Witek and Czechowski (2015, Planet. Sp. Sci. 105, 65–79). The gravity and the chemistry are substantially different on these celestial objects, but the underlying physics is the same. We found many similarities in evolution of river deltas in both environments, such as the dependence of the delta slope and surface area of the delta plain on the grain size. In particular, the slope is smaller and larger part of the delta is submerged for smaller grains (silt, fine sand).

Title: Graben-fissure systems in the Mead Quadrangle, Venus

Presenter/First Author: Wenzhe Lu, Carleton University, Ottawa,

Presenter/First Author Email: wlu@connect.carleton.ca

Co-authors: Richard E Ernst, Ernst Geosciences, Ottawa, ON, Canada; Claire Samson, Carleton University, Ottowa, ON, Canada

Abstract Body: Detailed mapping of graben-fissure systems (the surface expressions of underlying dyke swarms) in a portion (10°-20° N, 30° -50° E) of the Mead Quadrangle is part of a systematic global effort to identify regional radiating systems (linked with known and cryptic magmatic centres), circumferential systems (linked with corona) and linear systems (linked with rifting).

A total of 32 different graben-fissure systems were mapped within the study area. Five are radiating systems, four of which (with maximum radii of 930, 210, 180 and 500 km) are associated with Pavlova, Didilia, Isong, and Ninmah corona, respectively. The fifth (with a maximum radius of 500 km) focusses on c. 37.1° E, 11.7° N, marked by a small edifice. An additional radiating system (1400 km in radius and spanning about 130 degrees of arc) has been identified based on converging trends from two spatially separate graben-fissure systems; its focal point (c. 39.5 ° E, 19.9°N) is not associated with any central volcanic/tectonic edifice and represents a newly-recognized cryptic magmatic center. Pavlova and Didilia coronae have graben-fissures along their annuli and these are interpreted as parts of circumferential systems. Additional systems are located on the corona annuli but these have trends that are oblique to the local trend of the annuli (neither normal nor parallel to it) and are therefore not part of radiating or circumferential systems genetically related to the coronae. Instead they are interpreted as part of older regional graben-fissure systems that are preserved in the uplifted corona annuli, but elsewhere are largely covered by lava flooding. An east-west linear system, in excess of 1800 km long and 900 km wide, is inferred to be the oldest in the study area, by the degree to which it is flooded by lavas.

Title: Determining Relative Ages of Structural Features Around Irnini Mons, Venus - A Comparison of Type Locations to Resolve the Timing of Cross-cutting Features

Presenter/First Author: M Alexandra Matiella Novak, Johns Hopkins University APL, Laurel, MD

Presenter/First Author Email: alexandra.matiella.novak@jhuapl.edu

Co-authors: Debra Buczkowski, JHU Applied Physics Laboratory, Laurel, MD

Published Material: Poster presentation at the 2015 Lunar and Planetary Science Conference in Houston, TX.

Abstract Body: Irnini Mons, a volcano in central Eistla Regio at 14ºN, 16ºE, is roughly centered on the V-20 quadrangle of Venus. While Eistla Regio as a whole is known to have the highest degree of polyphase deformation on Venus, the area immediately around Irnini Mons is particularly complex, even at the 1:5,000,000 scale of the quadrangle map. The arrangement of cross-cutting tectonic structures indicates a detailed and multipart stress history, which suggests Irnini Mons is an ideal location to identify distinct patterns of changes in stress orientation over time, as well as to ascertain the deformation associated with the volcano relative to the deformation of the local regional plains. A thorough investigation of the distribution and orientation of the numerous structures around Irnini Mons at the highest possible resolution (75 m/pixel) is likely to reveal the relative timing of the structures and thus shed light on the deformation history of this region of Venus. However, the complicated nature of these structures and their relationship to each other makes it difficult to resolve relative ages holistically across the map. For this reason, we attempt to determine the relative ages of structures within four distinct type locations within the region, fitting the outcomes of these analysis into an analysis of relative timing of structures within the greater mapped area. For this study, we build upon previous mapping and the determination of structural ages for four type locations spanning across the northwest and southeast regions of the map in an attempt to resolve the timing of features within an entire swath of the map stretching from the northwest corner to the southeast corner. Previous mapping in this area provided examples of how this high-resolution structural mapping may differ from the V-20 map and we will build upon this work by focusing on the high-resolution structural mapping of the four type locations described above.

Title: Effects of mechanical layering on magmatic reservoir failure and magma propagation within the Venusian lithosphere

Presenter: Patrick Joseph McGovern, Lunar and Planetary Institute, Houston, TX

Presenter Email: mcgovern@lpi.usra.edu

First Author: Nicolas Le Corvec, Lunar & Planetary Institute, Houston, TX

First Author Email: lecorvec@lpi.usra.edu

First Author Student?: No

Co-authors: Eric B Grosfils, Pomona College, Claremont, CA

Published Material: AGU 2013 and LPSC 2014

Abstract Body: Failure of magmatic reservoirs and propagation of magma is controlled in part by the state of stress within the lithosphere. Such stresses are induced by a range of loadings (e.g., gravitational, magmatic and tectonic). In addition, the response of the lithosphere to these loadings depends on its physical properties. Magmatic reservoirs and lithospheric stress states on planetary bodies have been studied using homogeneous lithospheres mainly composed of crustal material. However, planetary lithospheres may include substantial fractions of mantle material. The mechanics of a heterogeneous lithosphere may influence the failure of a magmatic reservoir and the propagation of the magma. To explore this scenario, we created two-layered axisymmetric elastic models made of mantle and crustal components using the COMSOL Multiphysics, in which a stiffer and denser mantle is underlying a softer and lighter crust. A spherical reservoir was created at the contact between the two layers. In these models, we analyzed magma reservoir stability, the amount of overpressure needed to reach failure, and the type of resulting intrusions within the two-layered lithosphere for three distinct environments: 1- lithostatic; 2- upward flexure due to a rising mantle plume; and 3- downward flexure due to a basaltic shield volcano. The results show that the difference in stiffness (>10%) between the crust and the mantle focuses the failure of the magmatic reservoirs at the mantle-crust contact. The resulting failure is driven by the in-plane stress tangential to the chamber, favoring lateral sill injections. In cases with flexure, magma chambers may become unstable (i.e., require no additional overpressure to fail) depending on the crust/mantle ratio. In some cases, we observed that failure of the magma chambers can be driven by the (out-of-plane) hoop stress favoring radial dike intrusions. The stability of magmatic reservoirs and the type and orientation of magmatic intrusions on Venus are influenced by the state of stress and heterogeneities within the lithosphere. Using our result, we can infer the potential crust/mantle ratios of the Venusian lithosphere in a particular tectonic environment in order to sustain stable and viable magmatic reservoirs and generate radial dikes as observed on the surface of Venus.

Title: Volcanism on Venus and Titan : Constraints from Present and Future Radar Observations

Presenter/First Author: Ralph D Lorenz, Applied Physics Laboratory Johns Hopkins, Laurel, MD

Presenter/First Author Email: ralph.lorenz@jhuapl.edu

Abstract Body:

One of the most pressing questions about our sister planet is the degree of present-day volcanism. Estimates range from around 0.01 km^3/yr to roughly that of the Earth, 10 km^3/yr, some three orders of magnitude. I consider how well a future radar mapper, with a resolution equal to or better than Magellan (~120m), might constrain this rate. Were such a mission to fly in the 2020s, three decades of volcanic change on the surface will have accumulated. I use observed lava volume/area relationships from terrestrial volcanoes to estimate the area change that may have occurred, and consider the issue of detection of new flows against old. In essence, a volcano may choose a new flow from a 'palette' of radar colors, and only if a new flow is the same (to within measurement accuracy) of the one(s) on which it is superposed. Again, terrestrial data offers some insights into how random the color selection may be. It is of note in this context that part of Venus' surface was imaged twice by Magellan, albeit with a relatively modest separation in time : the lack of any identifiable temporal change places a (probabilistic) constraint on the eruption rate. (Similar considerations confront Titan, but there the repeat coverage is rather small).

Microwave radiometry is another approach that might indicate present-day or recent volcanism; unlike near-infrared observations which only

sense the upper surface and therefore only active lavas, microwave thermal emission may probe deeper, older flows. Again, terrestrial examples, and the search for volcanism on Titan with the Cassini radar radiometer, inform the application of this technique to Venus.

Title: Major, trace element, and isotopic study of the Lonar Crater, India: new insights into the geochemical imprint of impact cratering on basaltic targets

Presenter/First Author: Anupam Banerjee, Indian Institute of Science, Bangalore,

Presenter/First Author Email: anupam.gg.2006@gmail.com

Co-authors: Ramananda Chakrabarti, Indian Institute of Science, Bangalore, India

Abstract Body: The 1.88 km diameter Lonar crater, hosted on the Deccan basalts, India, has age estimates ranging from 50-500 ka. Being a rare terrestrial impact crater on basalts, it provides a unique opportunity to study the geochemical imprint of impact cratering on basaltic host rocks which is relevant to other terrestrial planets, the Moon, as well as asteroids. We measured concentrations of 43 elements using ICPMS in recently collected samples of the target Deccan basalt, impact melts and spherules at Lonar. Compared to the basalt, the impact melts (tektites) are enriched in Rb, K, Ba, Pb, Mn, Cr, U, Th, as well as light REEs (La, Ce, Pr, Nd). The spherules broadly show similar geochemical characteristics as the melts. In addition, the spherules are depleted in P, enriched in Cr, Ni, and some heavy REEs like Tm and Lu, but markedly depleted in Mn compared to the target basalts. For most of these elements, the difference in concentrations between the target basalts and impactites is more than 20% and as high as 100%. We have also measured Sr and Nd isotopic compositions of the basalts, melts and spherules using TIMS and our data overlap with previously published data for the Lonar rocks that argued for melting of the Archean basement beneath the Deccan basalts during impact. The impact melts as well as spherules show more radiogenic Sr and less radiogenic Nd isotopic composition compared to the target basalts. The Sr isotopic composition co-varies with the Rb/Sr as well as K/Ca ratios while the Nd isotopic composition shows a positive correlation with the Sm/Nd ratio. Enrichments of Rb, Ba, K, Th, U, Pb and LREEs in the melts and spherules can be explained by mixing with Archean continental crustal rocks beneath the Deccan basalts. The Sr and Nd isotopic variations are also consistent with this explanation. However, enrichments in Cr, Ni compared to the target basalts are indicative of mixing with the impactor.

Title: Identifying "Pristine" Craters on Mars: Defining Criteria and Characteristics

Presenter/First Author: Livio L Tornabene, University of Western Ontario, Washington, ON

Presenter/First Author Email: ltornabe@uwo.ca

Co-authors: Jennifer L Piatek, Central Connecticut State University, New Britain, CT; Nadine G Barlow, Northern Arizona University, Flagstaff, AZ; Joseph M Boyce, HIGP, Honolulu, HI; Peter J Mouginis-Mark, University of Hawaii at Manoa, Honolulu, HI; Gordon Richard Osinski, University of Western Ontario, London, ON, Canada; Stuart J Robbins, , Lyons, CO

Published Material: The research and results presented herein are also being presented at the Lunar and Planetary Science Conference in March 2015.

Abstract Body: High-resolution meter-scale images of what are thought to be the youngest and best-preserved impact craters on Mars suggest that even the youngest craters on Mars show signs of modification by active geologic processes. As such, in order to constrain impact processes (e.g., ejecta properties and emplacement) and modification processes (i.e., various erosion and depositional processes), the visible and thermophysical characteristics of the most "pristine" craters on Mars must be constrained as a baseline. Indeed, various preservation/age terms (e.g., fresh, young, pristine, etc.) are used in the literature for Martian craters and often do not account for the fact that crater preservation and age may not be correlated. This is the case on a planet with active geologic processes, such as Mars, that exhibit both temporal and geographic variation in modification rate.

The objective of this study is to identify and characterize a set of physical properties associated with pristine Martian craters that will be utilized as a baseline for further studies. These craters will provide the best means to: 1) place further constraints on various aspects of the impact processes, and 2) examine how the physical properties of craters change as the crater and ejecta are modified over time, and as a function of target material and latitude. Here we define a "pristine" crater as a one that is both young (age) and appears morphologically "fresh" (i.e., the least-modified). In addition, we have begun to devise a crater classification scheme that couples both preservation and age of craters, which will prove useful for continued studies.

In summary, by using a synthesis approach that combines observations from both visible and thermal datasets, we are identifying examples of the youngest and best-preserved craters on Mars (i.e., "pristine"). These craters will provide a critical baseline for understanding the impact process and utilizing craters as a gauge for understanding the evolution of the Martian surface and past climates on Mars.

Table 1. Criteria for finding the best-preserved "pristine" Martian craters

Criterion	Assessment Difficulty	Preferred Data (Secondary)	Range	Limitations
Thermal Secondary Crater Rays	Easy	THEMIS day & night thermal infrared images	Below 60° latitude, range of good thermophysical data	Excludes craters at higher latitude (>±60°), craters well outside of Thermophysical Unit C (moderate TI, albedo and dust cover)
Pitted-Impact Deposits	Easy to Moderate	HiRISE (MOC & CTX)	Between 30-60° latitude,(Fig. 2, Tornabene et al., 2012)	Excludes high latitude (>±60°) craters
Depth-Diameter (d/D) Ratio	Moderate	MOLA PEDR (HiRISE CTX & HRSC stereo image derived DTMs)	MOLA PEDR coverage poorer at equator with respect to the poles	MOLA coverage limitations; craters below ~15 km are often poorly resolved; d/D may be exaggerated by pre-existing topographic effects
Preserved Secondary Crater Field	Moderate to Difficult	CTX (HiRISE, MOC & THEMIS VIS)	N/A	Small secondaries require higher-resolution datasets (e.g. HiRISE), which have less surface coverage
Low Size-Frequency Distribution (SFD) of Overprinting Impacts	Difficult	CTX or HiRISE	N/A	Time consuming to count small overprinting craters to derive a modeled age based on isochrons.

Title: Martian Dust and Deposition from Green Valley to Gale Crate

Presenter/First Author: John Moores, York University, Toronto, ON

Presenter/First Author Email: jmoores@yorku.ca

Co-authors: Mark T Lemmon, Texas A & M University, College Station, TX; Casey A Moore, York University, Concord, Canada; Robert Michael Haberle, NASA Ames Research Center, Moffett Field, CA; Kjartan Münster Kinch, Niels Bohr Inst p Rockefeller, Copenhagen K, Denmark; Kevin W Lewis, Johns Hopkins University, Baltimore, MD; Taesung Ha, , , ; Haraldur Pall Gunnlaugsson, , , ; Scot CR Rafkin, Southwest Research Institute Boulder,

Published Material: Dust Deposition on the Phoenix Telltale (Moores et al) accepted for publication in Planetary and Space ScienceSurpressed Boundary Layer during the first 360 days of MSL (Moores et al) is in press at IcarusTheir combination to describe dust & deposition over long timescales is new to this abstract.

Abstract Body: The atmosphere and surface of Mars both derive their characteristic colour from the presence of fine micron-sized dust. The two reservoirs are linked with the breakdown of surface materials creating the fine particulates that are lofted and redistributed across the planet. These particulates subsequently accumulate once again where atmospheric conditions permit.

This presentation will examine new data for dust deposition on Mars from recent results of the Phoenix and Mars Science Laboratory (MSL) Missions. First, the effect of surface orientation on accumulation rates is examined by comparing the Phoenix SSI Calibration targets with recent work on the wind telltale mirror, inclined at 50 degrees to the horizontal. Next we will describe estimated dust deposition rates from MSL.

The northern part of Gale Crater, where MSL is currently operating, is known to be a sink for dust. The suppressed boundary layer prevents vigorous atmospheric mixing and dust-devil formation and has been observed to be relatively dust-free (see Moore et al., this conference), consistent with a settling environment. As such, this location is a potential analogue for the kinds of environments that may have been involved in the formation of rhythmites on Mars.

To constrain the formation rates of such deposits, data from Gale for line-of-sight optical depth profiles will be used to estimate the net rate of delivery of dust to the surface. This will be compared to the rate of dust accumulating on the MastCam Calibration Targets and REMS UV sensors, as derived from the change in signal observed on these sensors over the first Martian Year of the Mission.

Title: A Full Martian Year of Atmospheric Monitoring Movies From Gale Crater

Presenter/First Author: Jacob Lawrence Kloos, York Universite, Toronto,

Presenter/First Author Email: jlkloos@yorku.ca

Co-authors: John Moores, York University, Toronto, ON, Canada; Raymond Francis, University of Western Ontario, London, ON, Canada; Mark T Lemmon, Texas A & M University, College Station, TX; Manuel De La Torre Juarez, NASA Jet Propulsion Laboratory, Pasadena, CA; David M Kass, NASA Jet Propulsion Laboratory, Pasadena, CA; Robert Michael Haberle, NASA Ames Research Center, Moffett Field, CA; Javier Martín-Torres, Centro de Astrobiologia, Madrid, Spain; Maria-Paz Zorzano, Centro de Astrobiologia, Madrid, Spain

Abstract Body: Using images from the Navigation Camera (NavCam) onboard the Mars Science Laboratory (MSL) Rover Curiosity, atmospheric movies were created to discern time-variable features, such as clouds, across a series of images. To detect these features, two different pointings of the NavCam were used: a vertical pointing, used to create Zenith movies, and a more horizontal pointing aimed just above Mt. Sharp, used to create Supra-Horizon movies. The analysis of these movies over long timescales allow large-scale atmospheric patterns to become apparent.

Now, with a full Martian year of atmospheric monitoring movies, seasonal trends in the water cycle and optical depth within Gale Crater have become noticeable. Of the 65 Zenith movies and 74 Supra-Horizon movies collected during the first 334 sols of the mission (LS 150° to 350°), features were apparent in 22 of each, most of these occurring before sol 60. During the second half of the first Martian year (sols 335- 668), 25 of the 46 Zenith movies acquired showed some discernible feature upon mean-frame subtraction. The increase in cloud features can in part be attributed to the cooler temperatures and increased humidity within the crater due to Mars approaching aphelion near sol 475 (LS 60°).

Title: Update on Line-of-Sight Extinction Seen within Gale Crater, Mars

Presenter/First Author: Casey A Moore, York University, Concord,

Presenter/First Author Email: moore.casey@gmail.com

Co-authors: John Moores, York University, Toronto, ON, Canada; Mark T Lemmon, Texas A & M University, College Station, TX; John R Burton, York Universite, Toronto, Canada; Scot CR Rafkin, Southwest Research Institute Boulder, Boulder, CO; Raymond Francis, University of Western Ontario, London, ON, Canada; Henrik Kahanpää, Finnish Meteorological Inst, Helsinki, Finland; Jorge Pla-García, INTA-CSIC, Madrid, Spain; Keri M Bean, Jet Propulsion Laboratory, Los Angeles, CA; Robert Michael Haberle, NASA Ames Research Center, Moffett Field, CA

Published Material: Sols 100 - 360 initially reported in: Moores, J.E. et al., 2014. Observational evidence of a suppressed planetary boundary layer in northern Gale Crater, Mars as seen by the Navcam instrument onboard the Mars Science Laboratory rover.
http://dx.doi.org/10.1016/j.icarus.2014.09.020

Abstract Body: The line-of-sight optical depth within Gale Crater has been derived using the Navigation Cameras (Navcam) of the Mars Science Laboratory rover, Curiosity. The images used were initially obtained to observe dust devil frequencies within Gale Crater. All images point due north and contain the local ground, the distant crater rim, and the sky above the crater. The imaging parameters for this observation were standardized on sol 100. The line-of-sight optical depth is compared to column optical depth (using Mastcam) for sols 100 – 360 and is discussed by Moores et al. (2014). As we now have data up to sol 844, this observation has covered more than an entire Martian year. Moores et al. (2014) concluded that values for the line-of-sight extinction were less than the extinction seen in the column optical depth measurements made by Mastcam. After continuing observations we can draw similar conclusions. For the majority of the Martian year, we see a line-of-sight extinction that is less than the column extinction, indicating that the air within the crater is less dusty than the air above the crater. There is a period of 50 sols (sols 600-650; Ls ~ 130°) in the data in which the derived line-of-sight extinction matches the Mastcam column extinction; this suggests a period in which atmospheric mixing between the air inside the crater with the air surrounding the crater may occur.

Title: Transmission Spectroscopy of Packed Simulated Mars Regolith

Presenter/First Author: Casey A Moore, York University, Concord,

Presenter/First Author Email: moore.casey@gmail.com

Co-authors: John Moores, York University, Toronto, ON, Canada; Andrew C. Schuerger, University of Florida, Ft Walton Beach, FL; Liam S Morrissey, , ,

Abstract Body: An investigation into how to better understand the phase-function of transmitted UV and VIS irradiation through packed Mars regolith stimulants is ongoing. The transmission spectra of Mars analog soils irradiated with a 300 Watt Xe arc lamp were collected using a mini-goniometer and spectrometer (wavelength range: 151.04 – 598.82 nm).

The regolith catalogue includes several sizes of sieved (45 – 850 µm) and un-sieved JSC Mars-1; other analogs that include acidic, alkaline, high salt, Phoenix, and aeolian martian simulants;, and a terrestrial basalt in fine and medium grain varieties. Samples were prepared to a thickness of 0.5, 1.0, and 2.0 mm using aluminum templates. Thicknesses less than 0.5 mm are in preparation to analyze the finer grain regolith simulants that have proven to be completely opaque at 0.5 mm.

Preliminary results showing the UV-VIS transmission as a function of wavelength and 3-diminsional space will be presented. The goals of this project are to both improve modeling of martian analog regoliths in radiative transfer codes and to assess the evaluation of the habitability of such analogs under martian conditions.

Title: Raman analyses of thermolabile samples in various Martian conditions: implications for ExoMars

Presenter/First Author: Guillermo Lopez-Reyes, University of Valladolid, Boecillo,

Presenter/First Author Email: lopezrge@cab.inta-csic.es

Co-authors: Rafael Navarro, , , ; Aurelio Sanz, , , ; Fernando Rull, Universidad de Valladolid, Valladolid, Spain

Abstract Body: The Raman Laser Spectrometer instrument (RLS) onboard the ExoMars rover will fly to Mars in 2018. This rover will provide powdered samples to a suite of instruments inside the analytical laboratory drawer of the rover, including the RLS instrument. RLS will analyze up to 30 randomly selected points along a flat surface of the powdered samples. RLS will work autonomously by self-regulating the Raman acquisition parameters (integration time, number of accumulations) as a function of the sample under analysis. However, not all parameters can be adjusted during the operation phase, namely, the laser power and irradiance level on the sample. So, this parameter has to be fixed by design prior to flight. It is well known that thermolabile samples can be damaged (which means a reduction of the signal to noise ratio of the resulting spectra) if the energy provided by the laser cannot be thermally dissipated by the sample. Furthermore, this effect is worsened in low-pressure conditions, where the convective dissipation of the atmosphere is greatly reduced.

In order to study the performance of the instrument with different laser irradiance levels, we have performed a series of analysis on several thermolabile sulfates and oxides, including hematite, jarosite, coquimbite, and also organic carbon. These tests were performed at different temperatures ranging from -40 to -5ºC, in a 6mbar CO_2 atmosphere, which will be the operational conditions in which the samples will be found inside the ExoMars rover. A customized vacuum chamber was used to allow analyzing the samples under these conditions.

Though the behavior of the samples can be theoretically established, there are many factors that cannot be easily modeled in the theoretical calculations. Thus, this work in mainly aimed at experimentally observing the resilience of the samples with increasing laser irradiance on the sample surface, and the influence of the sample temperature on these results. The analysis is performed by evaluating the SNR values obtained with each different irradiance level. For these tests, 5 different points of each sample at 4 different temperature levels and 8 different irradiance levels were studied. This provided thousands of spectra that have been analyzed to obtain graphs and to assess the behavior of the samples vs the temperature and irradiance applied.

Title: Andesite Weathering in a Hyperarid, Periglacial Environment: Implications for Mars

Presenter/First Author: Jennifer Lynn Bentz, Queen's University, Kingston,

Presenter/First Author Email: jennifer.bentz@queensu.ca

Co-authors: Ronald Peterson, Queen's University, Kingston, ON, Canada

Abstract Body: Widespread phyllosilicates have been identified in Noachian (4.5-3.7 Ga) terrains on Mars inferring the presence of past liquid water on the surface, and thus a habitable environment. To date, investigations of the potential weathering reactions on Mars have focused on basalt given the ubiquity of mafic minerals on the planet. However, there is increasing evidence of more siliceous deposits on Mars, especially in the Noachis Terra dacitic lava in the Nili Patera region and coarse-grained felsic deposits at the Bradbury landing site in Gale Crater. Therefore, there is a need to understand the weathering patterns and reactions of felsic materials on Mars. Full cycle weathering reactions under a hyperarid, periglacial environment were investigated in a dry, isolated depression in the Sur Lipez region of the Bolivian Altiplano (21º25'53.6" S 67º59'08.5" W). Andesitic Quaternary lavas, high sulfur concentrations, high temperature fluctuations, aridity, low ozone concentrations, and high solar radiance dominate the geology and climate of the region making the Altiplano an environmental analogue to early Mars. Preliminary XRD, SEM, and NIR investigations suggest freeze/thaw reactions dominate within the boulders surrounding the basin producing a series of fractures throughout the rocks. Physical degradation of the boulders results in small, highly weathered pebbles around the basin's edge. Within the pebbles glass is most susceptible to weathering followed by pyroxene > plagioclase laths > plagioclase phenocrysts > Fe-Ti oxides. Evidence of chemical weathering is also present as cavities within the pebbles become lined or filled with alunite from dissolution/ re-precipitation reactions with the aluminosilicates. Visible and near infrared data suggest the < 2 µm fraction collecting in the basin's center is dominated by montmorillonite and hematite. Further results from this study will aid in understanding the weathering processes of siliceous volcanic rocks during early Mars including the chemical trends during alteration and potential clay-forming processes.

Abstract Body: One mineral that may be particularly relevant to prebiotic chemistry on the early Earth, early Mars, and other wet rocky worlds is Green Rust (GR), a double layered Fe(II,III) oxyhydroxide with a hydroxylated brucite structure. Green rust forms readily in natural environments, and would have comprised a large fraction of chimneys precipitated at submarine alkaline hydrothermal vents on the early Earth where it has been proposed that metabolism emerged. As a double layer hydroxide GR has many interesting and useful properties: it can concentrate a variety of organic and phosphorus species in its interlayers, preserving them against degradation, and it is a versatile redox catalyst for reactions that might drive the emergence of life; e.g., the reduction of nitrate to ammonium. It is likely that GR and related minerals are still present on Mars today. If so, they may preserve biosignatures or tell us about the early Martian environment and its potential to give rise to life. To address these science questions and the challenges associated with the analysis of GR, we are simulating its formation in ancient hydrothermal systems and developing methods to detect, analyze, process, and preserve/cache these delicate minerals – particularly using spectroscopic technologies that will fly on upcoming Mars missions. GR was synthesized anaerobically in laboratory systems using chloride or carbonate iron salts, and the resulting precipitate analyzed laser Raman spectroscopy time-series. A total of 20 spectra were recorded at 5-min intervals. By the end of the experiment the initial green rust was completely oxidized into maghemite and ferrihydrite. The laser power at the sample surface was kept below <1mW in order to prevent thermally-induced oxidation. Quantitative analysis of the spectral time-series allowed us to constrain the kinetics of green rust oxidation and determine intermediate oxidation products, including goethite and hematite. Future experiments will study the stabilization of GR by trace components such as phosphates, and its ability to drive other proto-metabolic reactions and sequester organic molecules.

Title: Spectral Reflectance Properties of Underdense Asteroid Regoliths Simulated by Pressed Pellets

Presenter/First Author: Rebecca Wilks, University of Western Ontario, London,

Presenter/First Author Email: rebeccaaiellowilks@gmail.com

Co-authors: Matthew R Izawa, University of Western Ontario, London, ON, Canada; Paul Mann, University of Winnipeg, Winnipeg, MB, Canada; Edward Cloutis, University of Winnipeg, Winnipeg, MB, Canada

Abstract Body: A number of upcoming spacecraft missions are targeting low albedo asteroids, particularly the NASA-CSA OSIRIS-REx and JAXA Hayabusa-2 asteroid sample return missions. The target asteroids of these missions are a few hundred meters in diameter, and as a result their surfaces have microgravity environments. Due to the effects of microgravity and vacuum, the regoliths on the surfaces of these asteroids will likely be very loosely packed (termed underdense regoliths). Prior to sample acquisition, the target asteroids will be subjected to comprehensive mapping campaigns which will include a number of imaging spectrometers. This research aims to examine the spectral properties of dark asteroids by simulating loosely packed regolith in the laboratory, with the goal of aiding in the identification and remote characterization of scientifically interesting targets.

Underdense regolith samples were simulated by mixing potassium bromide (KBr, an optically transparent material) with serpentine. A spectral reflectance study (0.35-2.5 µm) was conducted on various ratios of KBr to serpentine, to simulate varying densities of underdense regolith. We measured the KBr-serpentine concentrations in two forms: pressed pellets (smooth and roughened surface) and loosely packed poured powder. This allows for a comparative analysis of the two forms as well as gaining a better understanding of how and whether properties of the mixtures we produced in the lab differ from properties of underdense regoliths. The spectral data has been analyzed in order to look for patterns in band depth, albedo and slope of the various sample concentrations. Preliminary findings show an increasing blueness of slope with an increase in the KBr:serpentine ratio, and this is qualitatively similar to the blue slope observed in Bennu spectra. Quantitative analysis of band depth in the 1 µm region indicates that a slight deepening occurs with increasing KBr percentage, however band positions do not appear to be affected. This data helps us to determine whether optically robust underdense regoliths can be simulated using pressed pellets and whether spacecraft measurements can be used to identify loosely packed regolith for suitable sampling regions.

Title: The Io Volcano Observer (IVO)

Presenter/First Author: Elizabeth P Turtle, Applied Physics Laboratory Johns Hopkins, Laurel, MD

Presenter/First Author Email: Elizabeth.Turtle@jhuapl.edu

Co-authors: Alfred S McEwen, University of Arizona, Tucson, AZ

Published Material: Abstract submitted for EGU

Abstract Body: IVO, first proposed as a NASA Discovery mission in 2010, uses advanced lightweight solar arrays and a 1-dimensional pivot to achieve observing flexibility during a series of fast (~18 km/s) flybys of Io. All science objectives from the Io Observer New Frontiers concept recommended in the 2011 Planetary Science Decadal Survey are addressed by IVO's five instruments plus gravity science: Narrow- and wide-angle cameras (NAC and WAC), dual fluxgate magnetometers (DMAG), a thermal mapper (TMAP), and particle environment package for Io (PEPI) consisting of an ion and neutral mass spectrometer (INMS) and a plasma ion analyzer (PIA). A student collaboration hotspot mapper (HOTMAP) is also an option. The NAC and TMAP are on a ±90° pivot for off-nadir targeting during encounters and for distant monitoring. WAC and HOTMAP are mounted on the S/C nadir deck, and observe during ±20 minutes of Io closest approach. PEPI is mounted on the S/C structure with the INMS field of view in the ram direction when the S/C nadir deck points at Io, and the PIA and has a large (hemispheric) field of view to include the upstream direction. The DMAG sensors are on the end and middle of 3.8-m boom and collect data continuously.

IVO launches in 2021, arriving at Jupiter in early 2026. Its highly elliptical orbit with perijove near Io is inclined >40° to Jupiter's orbital plane, which provides opportunities to observe Io's poorly explored high latitudes and also minimizes total ionizing radiation dose compared to other Jupiter orbiters (<10% that of JUICE). Four of the encounters are designed for optimal measurement of induced magnetic signature from mantle melt. Two can be used for gravity science, pointing the high-gain antenna at Earth during the encounters. The final flyby includes a flythrough of Pele's plume, if it is active, for gas composition. Encounter periods last ~1

week, including global monitoring and four Io eclipses, with distant monitoring and data playback near apojove. The apoapse period of each orbit provides extended monitoring of Io and Europa at high phase angles (>120°), best to detect and monitor volcanic plumes as well as high-temperature hot spots on Io. IVO will collect at least 20 Gb of science data per encounter: 100 times the Io data from the 8-year Galileo tour.

Title: Some remarks on global tectonics of Enceladus

Presenter/First Author: Leszek Czechowski, University of Warsaw, Warszawa,

Presenter/First Author Email: lczech@op.pl

Published Material: Parts of the results are presented in EGU 2014.

Abstract Body: Enceladus, a satellite of Saturn, is the smallest celestial body in the Solar System where volcanic activity is observed. Every second, the mass of ~200 kg is ejected into space from the South Polar Terrain (SPT) – [1] .

The loss of matter from the body’s interior should lead to global compression of the crust. Typical effects of compression are: thrust faults, folding and subduction. However, such forms are not dominant on Enceladus. We propose here special tectonic model that could explain this paradox.

We consider here hypotheses stating that the mass loss from SPT is the main driving force of the following tectonic processes: subsidence of SPT, flow in the mantle and motion of plates. It is an extension of [2] and [3].

The numerical model is developed. It is based on the equations of continuous media. We found that the loss of the volatiles results in a void, an instability, and motion of solid matter into the hot region to fill the void.The motion is presented at the Figure and includes:

(i) Subsidence of the ‘lithosphere’ of SPT.

(ii) Flow of the matter in the mantle.

(iii) Motion of plates adjacent to SPT towards the active region.

If emerging void is being filled by the subsidence of SPT only, then the velocity of subsidence is ~0.05 $mm \cdot yr^{-1}$. However, all three types of motion are probably important, so the subsidence is slower but mantle flow and plates’ motion also play a role in filling the void. The preliminary results of the numerical model indicate that the the subsidence rate of ~0.05 $mm \cdot yr^{-1}$ is possible if we assume Newtonian rheology.

Note that in our model the reduction of the crust area is not a result of compression but of the plate sinking. Therefore the compressional features do not have to be dominant. Experimental model is developed to investigate the surface effects of the subsidence. I

Title: Self-tuned tidal resonance and the heating of oceans on icy satellites in the Solar System (and Universe)

Presenter/First Author: Robert Tyler, NASA Goddard Space Flight Center, Greenbelt, MD

Presenter/First Author Email: robert.h.tyler@nasa.gov

Published Material: Icarus, 2014

Abstract Body: Observations by the Galileo and Cassini spacecrafts have provided a strong indication that our massive water ocean is only one of at least several others in the Solar System. It seems clear that these oceans would have long ago frozen if not for an internal heat source. It also seems clear that in at least some of these cases (e.g. Enceladus), the heat sources previously presumed are insufficient. Recently, it has been shown by the author that if these oceans occupy one of several plausible resonant configurations, then the tidal response and associated dissipative heat can easily maintain liquid oceans on most of the large satellites in close orbits. It has also been shown that these resonant configurations are not just possible but may be inevitable because of a self-tuning effect; as an ocean attempts to freeze, it's eigenmodes are altered and it is pushed into the resonant configurations, with the increase in heat acting to stall further freezing.

More specifically, study of the parameter space of ocean tidal scenarios (where the parameters controlling the tidal response act as coordinates) show that energetic, resonantly forced tidal scenarios are stable configurations, at least until the available tidal energy in the orbit has been expended. Conversely, a satellite with thick ice and no water ocean is possible only if one or more of the following apply: 1) There was never

once a liquid ocean; 2) Available tidal forces were once insignificant, allowing the ocean to freeze; 3) The idealizations used in this study were once invalid for the ocean considered. Because of this expected feedback and self-tuning effect, a forward speculation is therefore that liquid oceans may be very common in the Universe.

Title: Constraints on Lower Atmosphere Clouds from Perturbation Images Using the Huygens' Probe Descent Imager and Spectral Radiometer (DISR)

Presenter/First Author: Brittney Cooper, York University, Toronto,

Presenter/First Author Email: bhopson92@gmail.com

Co-authors: John Moores, York University, Toronto, ON, Canada

Abstract Body: The Huygens Probe landed on the surface of Titan in early 2005 after separation from the Cassini spacecraft upon which it resided during its seven-year journey to the Saturn system. During its descent within the Titanian atmosphere, Huygens captured hundreds of still images using its three visual imagers, contained within the DISR instrument.

Following Huygens' landing, DISR continued to take images of the same scene of the surface for approximately an hour. At first glimpse these post-landing visuals may appear to be redundant; but in actuality they provide a rare opportunity to observe subtle changes within Titan's atmosphere when calibrated and compared with each other. Of the three imagers of DISR, only the Side Looking Imager (SLI) offered a view above the horizon once Huygens touched down on Titan. Our analysis will be restricted to data from this instrument.

For each image we isolated the pixels above the horizon, then radiometrically calibrated and co-added the images to increase the signal to noise ratio. Mean frame subtraction was performed on image sets which accentuated the differences between adjacent images following histogram stretching. The resulting image sets were animated in a loop to observe anomalies and patterns of interest for further analysis and to calculate the magnitude of the radiometric variation across the sky.

Title: Seasonal Volatile Transport and Plumes on Pluto

Presenter/First Author: Bonnie J Buratti, NASA Jet Propulsion Laboratory, Pasadena, CA

Presenter/First Author Email: bonnie.j.buratti@jpl.nasa.gov

Abstract Body: The New Horizons spacecraft will reach Pluto for a close flyby in July 2015. To place this singular event within the context of temporal changes on Pluto, ground-based monitoring programs have been gathering observations on this dwarf ice planet for decades. Several lines of evidence support volatile transport on its surface: changes in the rotational light curve of Pluto beyond those expected from viewing geometry alone; changes in albedo patterns mapped by ground-based Hubble Space Telescope Maps (Buie et al., 2010, A. J. 139, 1117); and changes in atmospheric pressure(Young et al. 2013, Ap. J. Lett. 766, L22). Both Mars and Triton, the Neptunian moon that is Pluto's twin, exhibit seasonal volatile frost transport, and both have plumes or plume deposits on their polar caps that are believed to result from the sublimation of the cap. A dark substrate (dust in the case of Mars, and photolyzed methane in the case of Pluto) below nitrogen ice (Triton or Pluto) or carbon dioxide ice (Mars) heats up under solar insolation to create a solid state greenhouse effect. Subsurface volatiles sublimate and catastrophically outgas to form dark plumes. The similarities between Triton and Pluto, including surface temperature, size, obliquity, distance from the sun, and composition, coupled with the good evidence for currently active seasonal volatile transport of Pluto, lead us to predict this dwarf planet will have plumes similar to those on Triton. Given the lack of tidal heating on Pluto, these plumes will be the prime active process on Pluto's surface. During our campaign monitoring the lightcurve of Pluto, we discovered a remarkable opposition effect with the 24-inch telescope at Table Mountain Observatory. As this surge is not visible with the New Horizons spacecraft (it never achieves sufficiently small solar phase angles), its discovery illustrates another example in which ground-based observations are complementary to those of spacecraft.

Title: Global 3D Radiation-Hydrodynamics Calculations of the Envelopes of Forming Planets Interacting with a Protoplanetary Disk

Presenter/First Author: Gennaro D'Angelo, NASA Ames Research Center, Moffett Field, CA

Presenter/First Author Email: gennaro.dangelo@nasa.gov

Co-authors: Peter Bodenheimer, University of California Santa Cruz, Santa Cruz, CA

Abstract Body: We present 3D radiation-hydrodynamics calculations of envelopes of forming planets, during the phase of sustained solids' accretion. The planets reside in a protoplanetary disk at orbital radii a_p=5 and 10 AU from a sun-like star, and are assumed to have formed according to the Core Nucleated Accretion scenario. The planets have cores ranging from 5 to 15 Earth masses. The protoplanetary disk extends radially from a_p/2 to 2a_p. The planets' envelopes are resolved at the core-radius length scale by using a system of nested grids. The gas is assumed to be a solar mixture of H2, H, He, and their ions. The equation of state includes contributions from non-translational states of H2 and from ionization of atomic species, as well as from radiation energy. The dust opacity assumes a distribution of grains ranging from 5e-6 to 1 mm and multiple grain species. The opacity calculation applies the Mie theory for non-porous particles. We use 1D calculations of planet formation to supply the 3D calculations with solids accretion rates. Results show that temperatures, masses, and gas accretion rates of 1D and 3D envelopes agree within factors of 2. Passive tracers are employed to study the circulation of the gas flow around the cores and identify the spherical region of bound gas, which formally defines the envelope of the planet. We find envelope radii comparable to or smaller than the Bondi radius, and significantly smaller than the Hill radius. We find differential (i.e., depth-dependent) rotation at the envelope equators, and an overall slow bulk rotation of the envelopes compared to that of the solar system outer planets. Yet, specific angular momenta of the planets are comparable to those of the solar system giant planets. The polar flattening is estimated at values <~0.05. We also use passive tracers to study the dynamics of the accretion flow. We find that this flow is not isotropic around the planet and characterize its angular dependence. We find that it preferentially impacts the envelope surface at mid to high latitudes. Support from NASA Outer Planets Research and Origins of Solar Systems Programs is gratefully acknowledged. Computing resources were provided by the NASA High-End Computing Program through the NASA Advanced Supercomputing Division at Ames Research Center.

Published Material: The topographic profile and facies interpretations of the Peace Vallis fan have been published in Science and JGR. 2/3 of the abstract data have not been published.

Abstract Body: NASA's *Curiosity* rover has documented predominantly fluvial sedimentary rocks along its path from the landing site to the toe of the Peace Vallis alluvial fan (0.5 km to the east) and then along its 8 km traverse across Aeolis Palus to the base of Aeolis Mons (Mount Sharp). Lacustrine facies have been identified at the toe of the Peace Vallis fan and in the lowermost geological unit exposed on Aeolis Mons. These two depositional systems provide end members for martian fluvial/alluvial-lacustrine facies models. The Peace Vallis system consisted of an 80 km^2 alluvial fan with decimeter-thick, laterally continuous fluvial sandstones with few sedimentary structures. The thin lacustrine unit associated with the fan is interpreted as deposited in a small lake associated with fan runoff. In contrast, fluvial facies exposed over most of Curiosity's traverse to Aeolis Mons consist of sandstones with common dune-scale cross stratification (including trough cross stratification), interbedded conglomerates, and rare paleochannels. Along the southwest portion of the traverse, sandstone facies include south-dipping meter-scale clinoforms that are interbedded with finer-grained mudstone facies, interpreted as lacustrine. Sedimentary structures in these deposits are consistent with deltaic deposits. Deltaic deposition is also suggested by the scale of fluvial to lacustrine facies transitions, which occur over >100 m laterally and >10 m vertically. The large scale of the transitions and the predicted thickness of lacustrine deposits based on orbital mapping require deposition in a substantial river-lake system over an extended interval of time. Thus, the lowermost, and oldest, sedimentary rocks in Gale Crater suggest the presence of substantial fluvial flow into a long-lived lake. In contrast, the Peace Vallis alluvial fan onlaps these older deposits and overlies a major unconformity. It is one of the youngest deposits in the crater, and requires only short-lived, transient flows.

Berger, University of Western Ontario, London, ON, Canada; Nick Boyd, University of Guelph, Guelph, ON, Canada; Beverley Elliott, University of New Brunswick, Fredericton, NB, Canada; Betina Pavri, JPL, NASA, Pasadena, CA; Glynis M Perrett, , Guelph, ON, Canada; John G Spray, University of New Brunswick, Fredericton, NB, Canada; Scott Van Bommel, , , ; Albert Yen, NASA Jet Propulsion Laboratory, Pasadena, CA

Abstract Body: Since landing within Gale crater, the MSL Curiosity rover has encountered a variety of sedimentary rocks as it traversed the crater floor, and since arriving at the base of Mount Sharp. Curiosity initially drove towards the Yellowknife Bay (YKB) area before driving towards Mount Sharp. Three waypoint locations: Darwin, Cooperstown, and the Kimberly were selected for more in-depth exploration by the rover along the route to Mount Sharp. Specifically, Curiosity's APXS instrument has acquired 138 rock and soil analyses since landing and embarking along the traverse to Mount Sharp, recording a diversity of rock compositions. A further 37 APXS analyses of the Murray Formation at the base of Mount Sharp have also been obtained. This has enabled the classification of sedimentary rocks into several primary compositional classes:

- The basaltic John Klein class, typified by the mudstones and siltstones encountered in YKB, as well as one sedimentary rock target at the base of Mount Sharp
- The basaltic, high Cr_2O_3 (~0.8 %) Shaler class, typified by cross-stratified sandstones encountered as Curiosity exited YKB, as well as one sedimentary rock target at the base of Mount Sharp
- The K_2O (~3 %), MgO (9-13 %), MnO (~0.5 %), and Zn (1200-4000 ppm) rich, Bathurst class typified by sandstones encountered at a number of different locations along the traverse, including on Bradbury Rise, and at the Cooperstown and Kimberley waypoints
- The moderate SiO_2 (~50 %) and alkali (~4.8%) content Darwin class, typified by coarse grained to pebbly sandstones at the Darwin waypoint and several other conglomeratic outcrops
- The low MgO (~5 %) and CaO (~4.1 %) Pahrump class, typified by mudstones and sandstones encountered within the Murray Formation at the base of Mount Sharp

We will examine how these classes, and comparisons to other, more likely igneous compositional classes, can be used to investigate provenance, as well as the diagenetic and alteration history of Gale crater sedimentary rocks.

Title: Phyllosilicates in fluvial-lacustrine sediments in Gale Crater as revealed by the Curiosity rover.

Presenter/First Author: Richard J Leveille, McGill University, Montreal, QC

Presenter/First Author Email: richard.leveille@mcgill.ca

Published Material: Some of the mission results have been presented in papers by Vaniman et al. (2013), Léveillé et al. (2014) and in LPSC abstracts. This presentation summarizes some of the specific findings on phyllosilicates and adresses new questions related to cements and habitability.

Abstract Body: The Mars Science Laboratory (MSL) rover Curiosity has encountered diverse sedimentary rocks within Gale Crater. These rocks

provide an opportunity to understand weathering and diagenesis on early Mars and to assess past habitable conditions. Determining the chemical and mineralogical composition of rocks involves the coordinated interpretation of data from multiple instruments on Curiosity. CheMin X-ray diffraction results for the Yellowknife Bay mudstone (Cumberland, John Klein) and the Windjana sandstone established the presence of significant amounts of poorly crystalline phyllosilicates. The XRD features are most consistent with ferromagnesian smectites with and without collapsed interlayers. The Windjana sandstone also contains a high abundance of magnetite and K-feldspar. The Confidence Hills target in the Pahrump sandstone contains a lesser amount of a 1.0 nm phyllosilicate (10%), but more iron oxides, dominantly hematite. An amorphous component, present in all rocks analysed by CheMin so far, is likely Fe-rich. In the Yellowknife Bay lacustrine mudstone, fine-scale analyses by ChemCam of sub-cm diagenetic raised-ridges suggests the presence of Fe-Mg-phyllosilicates. As fluids deposited these clays in fractures, they may also have influenced pre-existing neoformed clay minerals in the mudstone. Geochemical modelling, using data from CheMin, ChemCam and APXS suggests that brackish, near-neutral pH fluids existed at moderate temperatures in a shallow near-surface environment. Analyses of elemental composition and mineralogy in Gale Crater are consistent with alteration of basaltic material with Fe and Mg mobility and the possible presence of nanophase Fe-oxide or Fe-Mg phyllosilicate cements. Rocks at Pahrump show evidence for greater chemical alteration; some phyllosilicates may have been removed or altered further by circulating fluids. As Curiosity is now exploring the base of Mt. Sharp, more Fe-Mg-bearing phyllosilicates are expected to be found based on orbital observations.

Abstract Body: The Curiosity rover has encountered a diversity of sedimentary rocks, which overall have displayed significant variations in both texture and composition. Early observations by the Curiosity rover in Gale crater revealed isolated outcrops of cemented pebbles and sand grains with textures typical of fluvial sedimentary conglomerates (Williams et al., Science, 2013). Conglomerates observed by Curiosity contain clasts with a strong diversity in albedo and textures indicating multiple sources on the Gale crater rims. Sandstones and mudstones observed at Yellowknife Bay were interpreted as having been deposited in a fluvio-lacustrine environment (Grotzinger et al., 2014). More stratified sandstones have been observed in the second and third terrestrial years of investigation in the outcrops named Cooperstown, Kimberley, and Pahrump. The latter outcrop corresponds to the lower Mt Sharp/Aeolis Mons based on orbital images and its facies is interpreted as fluvio-lacustrine sediments (Sumner et al., this meeting). The Pahrump sediments have major elements chemistry close to that of the conglomerates, suggesting a genetic relationship through the deposition of fluvial sediments from a similar source, likely the Gale crater rim. Pahrump sediments display subtle variations in major elements connected to variations in facies. There is an enhanced Mg content in resistant layers, which is correlated with a depletion in Fe and enhanced Al/Si ratios as well as enhanced hydrogen emission. These resistant layers have also a higher CIA (Chemical Index of Alteration) compared to the sediments previously encountered. These observations point towards the role of alteration during deposition and/or diagenesis during cementation in these sediments. Diagenesis did leave its imprint to these sediments as seen from the presence of cm-scale dendritic concretions, often enriched in Mg, S and Ni, suggesting fluid circulation during burial. Light-toned veins, observed as being calcium sulfates, postdate layers cementation as well as all other diagenetic features. In summary, Pahrump outcrop exhibits layers with a multiple role of water from the deposition of sediments in a fluvio-lacustrine system to their alteration and diagenetic evolution pointing towards a complex evolution in a climate warmer than the present one.

Title: Fresh Shallow Valleys in Northern Arabia Terra, Mars: Implications for the Post-Noachian Climate

Presenter/First Author: Sharon A. Wilson, Smithsonian National Air and Space Museum, Washington, DC

Presenter/First Author Email: purdys@si.edu

Co-authors: Alan D Howard, University of Virginia Main Campus, Charlottesville, VA; Jeffrey M Moore, NASA Ames Research Center, Moffett Field, CA; John A Grant, Smithsonian National Air and Space Museum, Washington, DC

Published Material: About 30% of this material was presented as a poster at Fall 2014 AGU and at Mars 8 Conference in July, 2014.

Abstract Body: The working paradigm of the hydrologic evolution of Mars for many years envisioned a sudden decline in fluvial activity around the Noachian-Hesperian boundary, possibly related to the collapse of the early, dense atmosphere. A growing inventory of post-Noachian fluvial features, however, date to the late Hesperian to early Amazonian and may represent the last widespread episode(s) of aqueous activity that occurred during a climate characterized by a relatively thin atmosphere and thick global cryosphere. For example, concentrations of fresh shallow valleys (FSVs) are more widespread than previously reported, occurring in a latitude band from ~30-45° in both hemispheres. FSVs occur in the equatorial regions as well (e.g., possibly Gale crater and vicinity) but are often harder to distinguish from the older, Noachian valleys. FSVs in the northern hemisphere occur along the dichotomy boundary, with the highest concentration in northern Arabia Terra from 35-40°N between 0-20ºE. In this region, FSVs developed both on and away from ejecta of relatively fresh craters, making the direct association between impact processes and formation less likely. Many FSV systems are 150+ km long, and in several cases appear to cross depressions that were likely filled with ice or water during FSV formation. Most FSV systems could have formed from a single episode of erosion but incision of the main channel in some locations may imply episodic formation. Widespread occurrence of FSVs, their similar morphology, and modest state of degradation is consistent with most forming during one or more global intervals of favorable climate, likely through snowmelt from surface or sub-ice flows during the Hesperian. Craters with a single fluvial exit breach (nicknamed “pollywog craters”) imply the involvement of artesian groundwater flow. Crater statistics and cross-cutting relationships indicate the formation of FSVs terminated prior to about 1.4 Ga, suggesting they may be contemporaneous with alluvial fan and delta formation in the equatorial and mid-latitudes.

Title: Ancient Martian Lakestands and Fluvial Processes in Iani Chaos: Geology of Light-Toned Layered Deposits and their Relationship to Ares Vallis Outflow Channels

Presenter/First Author: Luca Guallini, University of Bern, Bern,

Presenter/First Author Email: luca.guallini@space.unibe.ch

Co-authors: Martha S Gilmore, Wesleyan Univ, Middletown, CT; Lucia Marinangeli, University of Chieti-Pescara, Pescara, Italy; Nicolas Thomas, University of Bern, Bern, Switzerland

Published Material: LPSC 2012, Italian Geological Society Conference 2014, EGU 2015

Abstract Body: Iani Chaos lies at the head of the Ares Vallis outflow channels. Mapping of Ares Vallis reveals multiple episodes of erosion, probably linked to discharge events from the Iani Chaos aquifer. We present the first detailed geomorphological map of the region. Among five chaos units, distinguished by varying levels of modification (by erosion and fracturing), Light-toned Layered Deposits (LLD) have been mapped and described in Iani Chaos. LLD are characterized by a light-toned albedo, high thermal inertia and a pervasively fractured morphology. The LLD both fill the basins made by the collapsed chaotic terrains and are partially modified by the chaos formation. LLD also overlap chaos mounds or are themselves eroded into mounds after deposition. These stratigraphic relationships suggest that LLD deposition occurred episodically in the Iani region and throughout the history of the development of the chaos. Water seems to have had an active role in LLD deposition and erosion. The composition and morphologies of the LLD are consistent with deposition in an evaporitic environment, entailing stable water on surface. At the same time, we observed potential fluvial features (i.e., channels, streamlined islands, terraces, grooved surfaces) on the surface of the LLD. These landforms mark a fluvial system that can be traced from central Iani northward. Using topographic data, we compared the elevation of the LLD and channel units and find that their altitudes have been controlled by the Ares Vallis outflow events. This demonstrates that 1) a fluvial system within Iani was linked to the Ares Vallis channels system, characterized by five episodes of outflow at least, 2) the LLD are coeval with the Ares Vallis outflow channels. On the basis of our analysis, we propose a formation model of Iani Chaos, given by a cyclic alternation of two stages with time: 1) Fracturing and tectonic subsidence of the bedrock and outflows. Fluvial erosion of LLD; 2) Evaporitic deposition of LLD.

Title: Formation of Fluvial Gravel Pavements as an Explanation for Persistence of Ancient Cratered Terrain on Titan

Presenter/First Author: Alan D Howard, University of Virginia Main Campus, Charlottesville, VA

Presenter/First Author Email: ah6p@virginia.edu

Co-authors: Sylvain Breton, , , ; Jeffrey M Moore, NASA Ames Research Center, Moffett Field, CA

Abstract Body: Portions of the equatorial region of Titan are fluvially eroded into banded (crenulated) terrain, some of which contains numerous circular structures that are likely highly degraded large impact craters. Such cratered terrain probably survives from the late heavy bombardment. A number of explanations for the survival of such terrain to the present epoch include very inefficient fluvial erosion, late acquisition of a dense atmosphere, and intermittent presence of sufficient methane in the atmosphere to support precipitation and runoff. No mechanism has been unambiguously demonstrated to operate on its surface that can chemically of physically break down ice that is likely the most important component of Titan's crust. We quantitatively model a scenario in which fluvial erosion on Titan has largely involved erosion into an impact-generated megaregolith that contains a modest component of gravel-sized debris. As the megaregolith is eroded, coarse gravel gradually accumulates as a lag pavement on channel beds, limiting further erosion and creating a dissected, but largely inactive, or senescent, landscape.

Title: Some Thoughts on Lithospheric Overturn on Venus

Presenter/First Author: Scott D King, Virginia Tech, Blacksburg, VA

Presenter/First Author Email: sdk@vt.edu

Co-authors: Aaron C Prunty, Virginia Polytechnic Institute and State University, Blacksburg, VA

Published Material: Some of this was shown at the Fall Meeting.

Abstract Body: Impact crater distribution on Venus indicates that the present surface is on average 750 Myr old. There has been considerable debate regarding the nature of the resurfacing, with progressive volcanism or catastrophic overturn endmember models. We present a series of 3D spherical convection simulations with a reasonable yield stress rheology and show that even with an initial degree-1 mantle structure, a lithospheric overturn event is characterized by a number of small downwelling instabilities. We constrain our simulations using the observed geoid, topography, heat flow, and melt production. Very large yield stresses result in a degree-1 type overturn; however the resulting geoid and topography are too large by at least an order of magnitude. We compare the distribution of downwelling instabilities with the global distribution of subduction sites proposed by Schubert and Sandwell (Icarus, 117, 173-196, 1995).

Title: Lithospheric Flexure, Stress, and Volcanic Edifice Morphology: A Connection for a Subset of Coronae on Venus?

Presenter/First Author: Patrick Joseph McGovern, Lunar and Planetary Institute, Houston, TX

Presenter/First Author Email: mcgovern@lpi.usra.edu

Abstract Body: The lithosphere responds to emplacement of volcanic materials by flexing. Flexure induces stress in the lithosphere that can influence subsequent ascent of magmas and thereby affect the shapes of the resulting volcanic edifices. Principal stress orientations and considerations of force balance on vertical dikes provide two stress-based criteria for determining where magmas can ascend. A key finding is that lithospheric thickness T_e and edifice shape are linked: thick lithospheres produce low stresses consistent with broad conical edifices, while thinner lithospheres produce higher stress magnitudes and shorter-wavelength flexural responses that can lead to construction of domical edifices and, at the lowest T_e values, annular-shaped topographic ridges. Annular structures are the primary characteristics of the morphometric (not genetic!) class of features known as coronae. Thus, I propose that construction of volcanic edifices upon lithosphere with low T_e can account for the formation of a significant fraction of coronae on Venus.

To constrain this fraction, I consider constraints on T_e from analysis of gravity and topography. Hoogenboom et al. [2004] used spatio-spectral localization of gravity/topography relationships to estimate T_e at 103 coronae on Venus, using top- and bottom-loading models of lithospheric flexure. Here I focus on the 65 coronae determined to be best-fit with a top-loading model, in accordance with the volcanic construction hypothesis. The overall distribution of best-fit T_e is skewed toward low values (mean 12 km, median 6 km), but with a long tail of values stretching up to 48 km. The high T_e values in this tail have been used to argue against the idea that thin lithospheres favor corona formation, but the strong skewing of the distribution toward zero supports this idea. Further, when coronae in the “Fracture Belt” geologic setting are excluded, the best-fit T_e distribution of the remaining 20 coronae has a mean of 6.4 km and median of 4.5 km, with all values less than 20 km (i.e., no tail). The distribution of the 45 coronae in the Fracture Belt setting, therefore, has all the members of the long tail. Further analysis of coronae in the Fracture Belt setting is warranted, to determine if the coronae composing the tail are anomalous in some structural or geographical manner.

Title: Refining the Stratigraphy of Venus Using the Distribution of Features in Shield fields: A Numerical Modeling and Mapping Study

Presenter/First Author: Bradley J Thomson, Boston University, Boston, MA

Presenter/First Author Email: bjt@bu.edu

Co-authors: Nicholas P. Lang, , ,

Published Material: Preliminary work on this topic was presented in LPSC abstracts in 2013 and 2014 by the two authors. Here we present expanded findings that are soon-to-be submitted to Computers and Geosciences (methods) and JVGR (results).

Abstract Body: Inferring the relative age of geologic units on Venus is challenging due to the paucity of impact craters. Although abundant cross-cutting relationships exist to provide insight into relative ages at the local scale, it is difficult to infer relative timing between distant units that do not have any features or structures in common.

Here we attempt to refine our stratigraphic knowledge of geologic units on Venus by using a suite of statistical tools to infer the relative timing between shield fields (clusters of small volcanoes) and the surrounding structures, particularly fracture sets. Specifically, we have developed MATLAB-based models to search for and characterize potential anisotrophy in the distribution of volcanic edifices in shield fields [1, 2]. Numerical model results are then compared with geologic mapping results to test for potential areas of correspondence [3-5]. The objective is to infer which set(s) of fractures may have been active when the shields were emplaced, thus helping to better place the shields into the local stratigraphic column.

An initial examination of four shield fields (Chernava Colles, Ran Colles, Jurate Colles, Urutonga Colles) yields some results as expected as some surprises. In Chernava Colles, the shield field exhibits a preferred orientation consistent with the dominant NNW-trending fracture set. However, in Ran Colles and Jurate Colles, the preferred orientation of the shields are consistent with the trend of wrinkle ridges rather than fractures, suggesting the reactivation of extensional fractures that may have previously served as conduits of flow material [4].

Title: Giant circumferential graben-fissure systems: A key to the recognition of Venusian corona analogues on Earth

Presenter: Richard E Ernst, Ernst Geosciences, Ottawa, ON

Presenter Email: Richard.Ernst@ErnstGeosciences.com

First Author: Erin Bethell, Carleton University, Ottawa,

First Author Email: ErinBethell@cmail.carleton.ca

First Author Student?: Yes

Co-authors: Claire Samson, Carleton University, Ottowa, ON, Canada; Kenneth L Buchan, Geological Survey of Canada Ottawa, Ottawa, Canada

Abstract Body: Coronae are sub-circular tectono-magmatic structures on Venus, which typically have a raised annulus (up to c. 5 km in relief) and variable interior and exterior topography that allow division into a number of sub-types. The annulus is typically associated with a circumferential graben-fissure system and minor ridges. Graben-fissure systems are potentially linked to underlying dykes. Corona diameters are typically 200-300 km, but diameters up to >1000 km (and in the case of Artemis, 2600 km) are observed.

On Earth, several circumferential dyke swarms which are hundreds of kilometres in diameter have been recognized and are considered to be potential corona analogues (Ernst & Buchan, 1998, LPSC XXIX; Mäkitie et al., 2014, J. Afr. E. Sci.; Ernst et al., 2014, GSA Ann. Mtg.; Klausen et al., 2014, GSA Ann. Mtg.; Buchan & Ernst, this conf.). We summarize the characteristics of Venusian circumferential graben-fissure systems as a predictive guide to the recognition of terrestrial corona analogues: 1) sizes are typically hundreds of kilometres in diameter but can sometimes extend beyond a thousand kilometres ; 2) circumferential systems often only partially circumscribe their related corona; 3) circumferential systems are occasionally associated with radiating graben-fissure systems, and when they are, the foci of the radiating component can be offset from the center of the circumferential component; and 4) circumferential systems can occur as clusters. In addition, it should be noted that if circumferential dyke swarms on Earth are analogues to Venusian coronae then they should have had a primary raised annulus and other related topographic features that have since been eroded, but which may be recognized from the sedimentary record.

Title: A Giant Circumferential Dyke Swarm Associated with the High Arctic Large Igneous Province (HALIP) – a Possible Analogue for Coronae on Venus

Presenter/First Author: Kenneth L Buchan, Geological Survey of Canada Ottawa, Ottawa,

Presenter/First Author Email: kbuchan@nrcan.gc.ca

Co-authors: Richard E Ernst, Ernst Geosciences, Ottawa, ON, Canada

Abstract Body: Giant sub-circular tectono-magmatic features called coronae are common on Venus. They may be associated with mantle plumes or diapirs, are typically hundreds of kilometres in diameter, and usually have a raised annulus with an associated circumferential graben-fissure system that may be underlain by dykes. On Earth, corona analogues appear to be rare, perhaps because erosion has removed the distinctive topographic features. However the dyke swarms should persist. An excellent example of a giant circumferential swarm has been reported recently at Lake Victoria in Africa and there are several other tentative examples. We identify a giant circumferential swarm associated with the 125-80 Ma High Arctic Large Igneous Province (HALIP) and its previously documented giant radiating swarm. The circumferential dykes are roughly perpendicular to the radiating dykes. However, the centre of the circumferential swarm appears to be slightly offset (~200 km) from the focus of the radiating swarm, a feature of some venusian coronae. The circumferential swarm has a diameter of ~1200-1600 km. It is most clearly visible in reconstructions of North Greenland, Svalbard and Franz Josef Land, where segments of the swarm fall along an arc of ~100°. An extension of the swarm into the Canadian Arctic islands is likely, but more speculative, because of uncertainties in undoing deformation associated with the Eurekan orogeny on Ellesmere and Axel Heiberg islands and the presence of dykes of other discordant trends. The age ranges of the circumferential and radiating swarms are uncertain, although many radiating dykes are associated with the early part of the HALIP event and a single dyke associated with the North Greenland portion of the circumferential swarm has previously been dated at 82±1 Ma (Ar-Ar), near the end of the event. Identifying giant circumferential swarms on Earth is important for understanding the evolution of large igneous provinces and interpreting coronae on Venus.

Title: Emplacement of Volcanic Domes on Venus

Presenter/First Author: Lynnae C. Quick, NASA Goddard Space Flight Center, Greenbelt, MD

Presenter/First Author Email: lynnae.c.quick@nasa.gov

Co-authors: Lori Sherea Glaze, NASA Goddard Space Flight Center, Greenbelt, MD; Stephen Michael Baloga, Proxemy Research, Gaithersburg, MD

Published Material: A portion of the findings in this abstract were presented at the 2014 Lunar and Planetary Science Conference in The Woodlands, TX, USA. As of the submission date of this abstract, none of the findings are under review and they have not been recently accepted by a scientific journal.

Abstract Body: One key to understanding the resurfacing history of Venus is placing firmer constraints on the emplacement timescales of visible volcanic features. 175 steep-sided domes, with diameters ranging from 19-94 km and estimated thicknesses as great as 4 km, have been identified on Venus. These domes are thought to be volcanic in origin. Among the unanswered questions surrounding their formation are their composition, emplacement duration, and the rheology of the lava that formed them. Rheologically speaking, maintenance of 1-4 km thick flows necessitates higher viscosity lavas, while the domes' smooth upper surfaces imply the presence of lower viscosity lavas. We have investigated the emplacement of volcanic domes on Venus, exploring the effect of boundary conditions on a similarity solution of the Boussinesq equation for pressure driven fluid flow in a cylindrical geometry. The new approach used here addresses time dependent changes in lava viscosity due to cooling and eliminates singularities inherent in previous models for dome relaxation. Two distinct scenarios are explored: one in which a constant volume of fluid (i.e., lava) is rapidly emplaced onto the surface, and another in which the volume of lava on the surface increases over time (i.e., a volumetric flowrate approach). We compare theoretical dome thickness profiles for radially expanding Newtonian fluid to the shape of a typical Venus dome. For the constant volume approach, we find that at the onset of relaxation, bulk lava viscosities lie between 10^{10}-10^{16} Pa-s. Results for the volumetric flowrate scenario suggest a bulk lava viscosity of 10^{12} - 10^{13} Pa-s and emplacement times of approximately 2 - 16 years. Because the chilled lava crust can increase the apparent viscosity of lava flows up to four orders of magnitude greater than the actual viscosity of the fluid lava, our results suggest dome compositions more consistent with terrestrial basaltic andesites than rhyolites.

Title: Laboratory high-temperature emissivity measurements of Venus analog measurements in the near-infrared atmospheric windows

Presenter/First Author: Jorn Helbert, German Aerospace Center DLR Berlin, Berlin,

Presenter/First Author Email: joern.helbert@dlr.de

Co-authors: Sabrina Ferrari, Univ. degli Studi di Padova, Padua, Italy; Alessandro Maturilli, German Aerospace Center DLR Berlin, Berlin, Germany; Melinda Darby Dyar, Mount Holyoke College, South Hadley, MA

Published Material: First findings have been reported at the AGU fall meeting

Abstract Body: The permanent cloud cover of Venus prohibits observation of the surface with traditional imaging techniques over most of the visible spectral range. Venus' CO_2 atmosphere is transparent exclusively in small

spectral windows near 1 µm. The Visible and Infrared Thermal Imaging Spectrometer (VIRTIS) team on the European Space Agency Venus-Express mission have recently used these windows successfully to map the southern hemisphere from orbit. VIRTIS is showing variations in surface brightness, which can be interpreted as variations in surface emissivity. Deriving surface composition from these variations is a challenging task. Comparison with laboratory analogue spectra are complicated by the fact that Venus has an average surface temperature of 730K. Mineral crystal structures and their resultant spectral signatures are notably affected by temperature, therefore any interpretations based on *room temperature* laboratory spectra database can be misleading.

In order to support the interpretation of near-infrared data from Venus an extensive measurement campaign is underway at the Planetary Emissivity Laboratory (PEL, Institute of Planetary Research of the German Aerospace Center, Berlin). The PEL facility, which is unique in the world, allows emission measurements covering the 1 to 2 µm wavelength range at sample temperatures of up to 770K. Conciliating the expected emissivity variation between felsic and mafic minerals with Venera and VEGA geochemical data we have started with a set of five analog samples. This set includes basalt, gneiss, granodiorite, anorthosite and hematite, thus covering the range of mineralogies. Preliminary results show significant spectral contrast, thus allowing different samples to be distinguished with only 5 spectral points and validating the use of thermal emissivity for investigating composition.

This unique new dataset from PEL not only allow interpretation of the Venus Express VIRTIS data but also provide a baseline for considering new instrument designs for future Venus missions.

Abstract Body: We analyzed night-time near-infrared (NIR) thermal emission images of the Venus surface obtained with the 1-micron channel of the Venus Monitoring Camera onboard Venus Express. There were several directions of our analysis. (1) We studied if tessera terrain has the different NIR emissivity (and thus might have different mineralogic composition) in comparison to the surrounding basaltic plains. Our analysis showed that NIR emissivity of tessera surface material is by 15–35% lower than that of relatively fresh supposedly basaltic lavas of plains. This is consistent with hypothesis that the tessera material is not basaltic andmaybe felsic. (2) We found that the surface materials of plains around Chimon-mana tessera are very variegated in their 1-micron emissivity, probably reflecting differences in degree of their chemical weathering. (3) We also found a possible decrease of NIR emissivity at the top of Tuulikki Mons volcano which may be due to different, possibly more felsic composition of volcanic products on the volcano summit. (4) We have also foundseveral transient bright spots which suggest ongoing extrusions of lava flows causing significant elevation of surface temperatures. These bright spots occur in Ganiki Chasma, an extensive linear rift zone known to represent a stratigraphically youngest tectonic activity. The very strong spatial correlation of the transient bright spots and the Ganiki rift zone boundaries and their similarity to locations of rift-associated volcanism on Earth, provide strong evidence for their volcanic origin

Published Material: Only some preliminary U-Pb results by SHRIMP were reported in an article to the OGS Summary of Field Work and Other Activities and within a poster at the Centre for Exploration Targeting Members' Day.Bjorkman, K.E., McCuaig, T.C., Lu, Y.J., Beakhouse, G.P., Hollings, P. and Smyk, M.C. 2014. The Marmion terrane four-dimensional crust–mantle evolution and mineral systems: An update; in Summary of Field Work and Other Activities 2014, Ontario Geological Survey, Open File Report 6300, p.12-1 to 12-13.Bjorkman, K.E., McCuaig, T.C., Lu, Y.J., Hollings, P. Fiorentini, M.L., Kemp, A.I.S (2014) The 4D crust-mantle evolution and mineral system distribution of the 3.0 Ga Marmion Terrane, Western Superior Craton, Canada; in CET Corporate Members'' Day 2014, University of Western Australia, Crawley, 6009, WA, Australia

Abstract Body: The architecture of the lithosphere focuses the transfer of fluid, mass and energy from the Earth's mantle to crust, thereby controlling the location of many major mineral systems. Modeling the crust-mantle evolution through time and space can therefore provide mappable exploration criteria for mineralization. Isotopes of Hf and O provide insight into rates, processes and setting of crust-mantle growth and can serve as "paleogeophysics" to image the 4D lithospheric architecture. We use isotopes of U-Pb, Lu-Hf and O in zircons to identify major lithospheric blocks of the Marmion Terrane (3.02-2.68 Ga), Wabigoon Subprovince, Superior Craton. This provides insight into crustal growth rates and processes across the Meso to Neoarchean transition.

Other multi-isotopic mapping of Archean cratons has typically been craton-wide, and because of the scale have large sample spacing. This study focuses on a geologically complex, yet well-characterized terrane to give detailed context to the results of larger studies. Nine lithotectonic domains

over 300 myr are preserved in crustal and supracrustal events in the south-central Wabigoon Subprovince. U-Pb geochronology by SHRIMP confirms magmatic age domains at 2.99-3.02, 2.93-2.94, 2.89, 2.82-2.83, 2.78-2.80, 2.70-2.73, and 2.67-2.68 Ga. Large portions of postulated terrane boundaries within the study area are obscured by post-tectonic granitoid batholiths and are not observable in geophysics or geology. Au, Ni-S, Cu-Zn and Fe mineralization are localized in Meso-Neoarchean greenstone belts and proximal TTG batholiths of the terrane.

We present multi-isotopic, geochemical and petrographic results of granitoid rocks across the Marmion terrane. The results map the internal and external boundaries of the Marmion Terrane, showing that crustal growth across the Marmion terrane largely occurred by progressive magmatic addition and reworking of older crust.

Title: Ca. 2.17 Ga mafic magmatism in the Superior Craton: a case for a rift-related LIP

Presenter/First Author: Dejan Milidragovic, Laval University, Quebec City, QC

Presenter/First Author Email: dejan.milidragovic604@gmail.com

Co-authors: Georges Beaudoin, Laval University, Quebec City, QC, Canada; Michael A Hamilton, University of Toronto, Toronto, ON, Canada

Abstract Body: Significant volumes of mantle-derived magma, evidenced by extensive mafic dyke swarms and thick gabbroic sills, intruded the Superior Craton during the Paleoproterozoic (ca. 1880-2500 Ma). The Otish Gabbro, Biscotasing, and Payne River suites and the coeval mafic volcanics in the Labrador Trough were emplaced along the southern and eastern present-day margins of the Superior craton at ~2.17 Ga. The ~2.17 Ga magmas were variably enriched in FeO, TiO_2, and incompatible elements relative to modern mid-ocean ridge basalts, suggesting contributions from at least three geochemical reservoirs (continental crust, asthenosphere, and metasomatized lithosphere). The relatively unfractionated Ti/Yb_{MORB} ratios (0.9-3.0) suggest that the ~2.17 Ga mafic magmas largely equilibrated at depths ≤100 km, near the spinel-garnet transition.

Estimated potential temperatures during the Paleoproterozoic (≥1550ºC) constrain the pressure of melting of ambient mantle to a minimum depth ~50 km under a thin crustal lid. Due to a sharp increase in dP/dT slopes of mineral stability surfaces at higher temperatures, melting in a significantly hotter Proterozoic mantle (ΔT =+100ºC) will cease at significantly greater depths, well within the garnet stability field. Consequently, the relatively shallow depths of equilibration of ~2.17 Ga mafic magmas of the Superior Craton are inconsistent with derivation from anomalously hot mantle plume(s). Instead, the geochemical character of ~2.17 Ga magmas suggests derivation by decompression melting of metasomatized lithosphere and of upwelling asthenospheric mantle during regional lithospheric thinning. The metasomatism of lithosphere is attributed to prior Paleoproterozoic events, possibly involving ca. 2.5 Ga mantle plume activity. The lithospheric thinning along the eastern and southern margins of the Superior Craton resulted in extensive replacement of the depleted Archean lithospheric root by fertile Proterozoic lithospheric mantle to depths of ≤ 100 km.

Title: Visualisation of Plate Reconstructions for the Archaean: an example from the Superior Craton

Presenter/First Author: Bruce M Eglington, University of Saskatchewan, Saskatoon,

Presenter/First Author Email: bruce.eglington@usask.ca

Co-authors: Cameron MacKay, University of Saskatchewan, Saskatoon, SK, Canada; Robert Kerrich, University of Saskatchewan, Saskatoon, SK, Canada

Abstract Body: Investigation of deep time plate tectonic reconstructions and of the blocks they represent is possible, using modern software tools and a number of simple approximations for the spatial context of the various blocks. Although not spatially accurate in a true global geographic setting, relative spatial and time constraints can be honoured. This has the advantage that one can investigate various reconstruction settings and scenarios so as to develop a better understanding of the geological evolution. Reconstructions reflect palaeolatitude derived from palaeomagnetic data, where available, together with structural vergence directions as a way to move apart crustal blocks. GPlates or Paleogis software platforms may be used for representation, so permitting one to illustrate changing location of igneous and metamorphic activity (as points for individual geochronology samples and as polylines for dyke swarms); changes in geochemical signature relative to location and time; location of different styles of ore deposit and mineralisation and any other features that can be captured in GIS with time attribute information. In cases where lithostratigraphic attribute information are available from digital geological maps, it is also possible to use these in continuously varying time or as a succession of integrated time-slice maps. Background raster images reflecting regional gravity, aeromagnetics or radiometrics move with the associated domain blocks so facilitating the matching of features across blocks in cases where alternative reconstructions may need to be considered. In the case of the Superior Craton, utilisation of these techniques helps emphasise the unique isotopic character of the Abitibi domain relative to other blocks, requiring a protracted depleted source in its lithosphere for millions of years prior to the development of volcanic-hosted massive sulphide mineralisation at about 2700 Ma, quite unlike the situation in the other terrains of the craton.

Title: Age and Evolution of Deep Continental Roots beneath Northern Canada

Presenter/First Author: Jingao Liu, University of Alberta, Edmonton, AB

Presenter/First Author Email: gobyliu@gmail.com

Co-authors: Amy J Riches, University of Alberta, Edmonton, AB, Canada; Laura Brin, University of Alberta, Edmonton, AB, Canada; Graham D Pearson, University of Alberta, Edmonton, AB, Canada; Bruce Kienlen, , , ; Bruce A. Kjarsgaard, Geological Survey of Canada, Ottawa, ON, Canada; Thomas Stachel, University of Alberta, Edmonton, AB, Canada; John P. Armstrong, Lucara Diamond Corp, Vancouver, BC, Canada

Published Material: Part of the data were recently presented in a poster at AGU, 2014. No journal publication yet.

Abstract Body: The age, composition and extent of Archean lithosphere is well documented beneath the Slave Craton. Little is known, however, about the deep continental roots beneath the rest of Canada's vast north, despite the discovery of many new diamond-bearing kimberlites. Here we present age and composition information for kimberlite-borne peridotite xenoliths from the central Rae Craton (two localities: Repulse Bay and Pelly

Bay) and central Victoria Island (CVI - a possible northern extension of the Slave Craton), and the Parry Peninsula (a possible new micro-craton- the Mackenzie craton), to investigate the nature and evolution of the deep lithosphere in these regions.

The peridotites from the central Rae Craton, CVI and Parry Peninsula are generally characterized by high forsterite contents (Fo 92-93) and low whole-rock Al_2O_3 contents (< 2 wt.%, many < 1wt.%), similar to typical cratonic peridotites worldwide. However, these peridotites show a large span in Re-depletion model ages (T_{RD}). For the central Rae Craton, both localities preserve evidence of Archean parentage, with more of the Repulse Bay samples yielding Archean T_{RD} ages (>2.5 Ga) than for Pelly Bay. They also show significant Paleoproterozoic (1.6 to 2.2 Ga) ages that indicate reworking or newly formed lithospheric mantle in this period, contrasting with the little disturbed central Slave lithosphere by other studies. This event was most likely associated with either the Thelon-Taltson orogen in the west or the Trans-Hudson orogen in the southeast.

Despite having highly depleted mineral and bulk compositions, we find no definitive evidence of Archean lithosphere beneath the Mackenzie craton (Parry Peninsula peridotites). Similarly, the CVI peridotites yield no Archean TRD ages but are dominated by Paleoproterozoic ages (1.5 to 2.3 Ga). For both CVI and the Mackenzie craton, the local deep lithosphere is more likely an extension of the Wopmay orogen (ca. 1.9 Ga) rather than the northern or western extension of the Slave Craton.

Deep, refractory, diamond-bearing lithosphere can form in post-Archean times, perhaps in subduction zone settings.

Title: Geochemistry of the Wijinnedi-Snare, Courageous-MacKay, and Lac du Rocher/Camsell Lake volcanic belts of the Slave craton

Presenter/First Author: Benjamin Williams, Carleton University, Ottawa,

Presenter/First Author Email: benjaminwilliams@cmail.carleton.ca

Co-authors: Brian Cousens, Carleton University, Ottawa, ON, Canada; Alexandra Berger, , , ; Luke Ootes, Northwest Territories Geoscience Office, , Canada; Valerie Jackson, Northwest Territories Geoscience Office, Yellowknife, NT, Canada; Michael A Hamilton, University of Toronto, Toronto, ON, Canada

Published Material: Earlier/preliminary findings were presented at the 2014 Yellowknife Geoscience Forum, NWT.

Abstract Body: Archean volcanic belts throughout the Slave craton host gold deposits, several volcanogenic massive sulphide (VMS) deposits and numerous VMS prospects. This study provides a comprehensive comparison of three bimodal volcanic belts across the southern Slave craton; the ca. 2674 Ma Wijinnedi-Snare volcanic belt; the Courageous-MacKay volcanic belt, with ca. 2810 Ma basement overlain by ca. 2700 Ma Cycle I and ca. 2670 Ma Cycle II volcanic packages; and the ca. 2672 Ma Lac du Rocher/Camsell Lake volcanic belt.

Mafic volcanic rocks are tholeitiic to calc-alkaline and display MORB – BABB signatures, with flat chondrite-normalized patterns. The associated intermediate and felsic volcanic components are calc-alkaline and have two predominant chondrite-normalized patterns; the first group shows enrichment in LREE and a steep HREE slope, while the second has similar LREEs, a negative Eu anomaly, and a distinctly flat HREE pattern. Within the Courageous-MacKay belt, Cycle I volcanic unit hosts the DEB VMS deposit, while the Cycle II sequence hosts the Tundra, Salmita and FAT gold deposits. The lower stratigraphic felsic unit hosting the DEB deposit are FII rhyolites, referred to a Superior craton-type classification scheme. While FIII rhyolites are characteristic of most large VMS deposits in the Superior, FII rhyolites are host to a number of Archean VMS deposits. The depositional settings of all three volcanic belts are consistent with a VMS-bearing environment, with VMS-like occurrences recorded at multiple locations.

Neodymium (Nd) isotope analyses of whole-rock samples were targeted for individual belts, stratigraphic levels, and relationship to basement material. Intermediate to felsic volcanic rocks from Wijinnedi-Snare belt have εNd_i values between +0.9 and +2.1. Lac du Rocher samples have εNd_i between +2.0 and +2.5. The Courageous-MacKay belt has a range between εNd_i of +0.7 and +5.2. The data indicate that volcanic rocks include a dominant mantle component, with some crustal assimilation, regardless of proximity to basement. Results are anticipated to advance the knowledge of the Slave craton stratigraphy, provide further insights into Archean magmatism, and assist in the identification of VMS prospective volcanic belts.

Title: The Complex History of the Slave Craton Lithospheric Mantle Root in the Context of Regional Tectonics

Presenter/First Author: D. Graham Pearson, University of Alberta, Edmonton, AB

Presenter/First Author Email: gdpearso@ualberta.ca

Co-authors: K. A. Mather, , , ; Bruce A. Kjarsgaard, Geological Survey of Canada, Ottawa, ON, Canada; J Liu, , , ; M Kopylova, University of British Columbia, Vancouver, BC, Canada; Christopher W Dale, University of Durham, Durham, United Kingdom; John P. Armstrong, Lucara Diamond Corp, Vancouver, BC, Canada; G Irvine, , ,

Abstract Body: The Slave craton is one of the smallest recognised cratons worldwide. It is surrounded by Paleoproterozoic orogenic belts, Wopmay/Great Bear on the west and the Taltson-Thelon on the east and south. Several Proterozoic diabase dike swarms cut the Slave, the most intensive of which being the ~1.27 Ga Mackenzie LIP. Using peridotite xenoliths derived from kimberlites we present a N-S transect across the craton with the aim of examining the effects of these post-Archean events on the composition, age and depth of the lithospheric root. We present new Re-Os isotope data for peridotite xenoliths from Gahcho Kue (southeast Slave), Diavik (central Slave), and the Artemisia kimberlite (northern Slave), that are integrated with previously available data. Late Archean minimum Re-depletion ages dominate the lithospheric mantle of the central Slave and the small available dataset for the southern Slave. Archean ages are present at Jericho, in the lower part of the North Slave but there is an increasing proportion of Paleoproterozoic and Mesoproterozoic Re depletion ages. In contrast, Archean depletion ages are absent from Artemisia, where the peridotite suite is dominated by Proterozoic depletion ages. Progressing North from the Central Slave there is a decreasing proportion of Archean model ages in the lithosphere, through Jericho to Artemisa. Approximately 70% of the dataset at Artemisia give Re depletion ages within error of the Mackenzie LIP event, with a secondary component (~ 30%) close to the Wopmay/Taltson orogenic events. This age spectrum in the far North of the Slave Craton, combined new data from regions to the N and NW of the Slave craton indicate the likelihood of major new lithosphere generation in both the Paleoproterozoic and Mesoproterozoic and adds to the growing evidence for the generation of stable "cratonic-like" lithospheric mantle in the

Proterozoic (e.g., the Siberian craton). This observation, if correct, has major implications for post-Archean diamond sources.

Final Number: PG11A-07

Title: Age and provenance of Archean basement and Paleoproterozoic supracrustal rocks within Wopmay orogen

Presenter/First Author: Luke Ootes, Northwest Territories Geoscience Office, ,

Presenter/First Author Email: luke_ootes@gov.nt.ca

Co-authors: Valerie Jackson, Northwest Territories Geoscience Office, Yellowknife, NT, Canada; William James Davis, Geological Survey of Canada, Ottawa, ON, Canada

Published Material: A previous version of the this oral presentation was given at the Yellowknife Geoscience Forum, November 2013, Yellowknife, NT

Abstract Body: The Paleoproterozoic Wopmay orogen is bounded in the east by the Slave craton. Bisecting the orogen is the Wopmay fault zone (WFZ) and west of it is the >1.93-1.89 Ga Hottah terrane and 1.875 to 1.85 Ga Great Bear magmatic zone. East of WFZ and west of Slave craton, polydeformed Neoarchean rocks are overlain by Paleoproterozoic strata. In one interpretation, these rocks began as part of the Hottah terrane, were thrust over the Slave craton during Calderian orogeny, and are preserved as a klippe ("Turmoil klippe"). Other interpretations suggest these Archean rocks are reworked from the Slave craton.

The extent and character of Archean rocks in the southern Wopmay orogen (between 63°N and 66°N) has been refined through bedrock mapping, U-Pb geochronology, and Nd isotope geochemistry. Results indicate the Mesoarchean and ca. 2580 Ma plutonic rocks have a Slave craton provenance, including those in the type section to the Turmoil klippe (Bent gneiss). Screens of Archean supracrustal rocks occur within granites and are correlatable to the Duncan Lake Group of the Slave craton. Paleoproterozoic quartzite, marble, and siltstone were deposited directly on deformed Archean basement and exposed as a series of domes and basins, metamorphosed between greenschist and granulite grade. Detrital zircons from the overlying quartzites have 2.7, 2.67, 2.60, 2.58 Ga, and 2.03 Ga ages, supporting a provenance from the Slave craton and the initial rift in Wopmay orogen. One sample contains the Slave spectra, along with ca. 2.33, 1.97, and 1.93 Ga detrital zircons that are similar to the Hottah terrane and Taltson magmatic zone. These strata may best be correlated to the Akaitcho Group, although a high component of Slave detritus has not been previously recognized in these sedimentary rocks.

The Archean rocks in Wopmay orogen began as part of the Slave craton. However, ca.2580 Ma granitic rocks in the Slave craton are not deformed, whereas those in Wopmay orogen underwent ductile deformation prior to and after deposition of the overlying strata. The post-Archean deformation is interpreted to be a result of initial rifting at ca. 2.02 Ga, followed by post-sedimentation folding and thrusting. The area east of WFZ is interpreted as an imbricate structure (duplex?) shoved over the western margin of the Slave craton during ca. 1.88 to 1.85 Ga deformation.

Title: Questioning Myths of the Middle Proterozoic Time

Presenter/First Author: Andrey Bekker, University of California Riverside, Riverside, CA

Presenter/First Author Email: andrey.bekker@ucr.edu

Abstract Body: The middle age of the Earth, the so-called 'Boring Billion', attracted growing interest in the last decade. It is generally accepted that C isotope variations in seawater were muted in the aftermath of the ~2.22-2.1 Ga Lomagundi C isotope excursion until ~1.3 Ga. Seawater Sr composition, a proxy for hydrothermal vs. terrestrial fluxes, seems to be also invariant during that time, while it subsequently sharply rose starting at ~800 Ma. Redox history of the atmosphere and oceans in the Middle Proterozoic seems uneventful; it is generally assumed that deep oceans were anoxic and Fe-rich (ferruginous) and atmospheric oxygen was low until the late Neoproterozoic. The exact timing and trend of the Neoproterozoic oxygenation event are still uncertain, with views ranging from those favoring the Ediacaran to those arguing for pre-Sturtian oxygenation recently advocated. These patterns were broadly related to sluggish tectonics, with possible shutdown or slowdown of plate tectonics limiting nutrient fluxes and biological productivity.

We will present results of our ongoing work challenging some of these interpretations and pointing towards a more dynamic history of seawater redox and its chemical composition in the Middle Proterozoic. Specifically, our data point to a short-lived carbon isotope excursion with a large magnitude at ~2.03 Ga. Deep-oceans were likely in a suboxic state during the 'Boring Billion', e.g., capable to partially oxidize Fe and, possibly, Mn. Atmospheric oxygen started to rise before 1.3-1.4 Ga, reaching the peak before the ~810 Ma Bitter Springs Excursion and was highly variable in its aftermath in association with climatic changes and changes in biogeochemical C cycle. Atmospheric oxygen likely rose high and fell back several times in the Proterozoic before the emergence of Metazoans in the late Neoproterozoic.

Title: Proterozoic Atmospheric Oxygen Levels

Presenter/First Author: Noah J Planavsky, Yale University, Riverside, CA

Presenter/First Author Email: planavsky@gmail.com

Co-authors: Christopher Reinhard, Georgia Tech, Atlanta, GA; Xiangli Wang, Yale University, New Haven, CT; Timothy Lyons, University of California-Riverside, Riverside, CA

Published Material: A portion of this reasearch was publisehd in Science in 2014.

Abstract Body: The oxygenation of Earth's surface fundamentally altered global biogeochemical cycles and ultimately paved the way for the rise of metazoans at the end-Proterozoic. However, current estimates for atmospheric O_2 levels during the billion years leading up to this time vary widely. Based on Cr isotope data from a suite of Proterozoic sediments from China, Australia and North America, interpreted in the context of data from similar depositional environments from Phanerozoic time, we find evidence for inhibited Earth surface Cr oxidation in the mid-Proterozoic (1.8 to 0.8 billion years ago). These data suggest that atmospheric oxygen levels were at most 0.1% of present atmospheric levels. Direct evidence for such low O_2 concentrations in the Proterozoic helps explain the late emergence and diversification of metazoans.

Title: Sedimentary and Geochemical Heterogeneity in the Mesoproterozoic: A Natural Consequence of Protracted Oxygenation?

Presenter/First Author: Linda C Kah, University of Tennessee, Knoxville, TN

Presenter/First Author Email: lckah@utk.edu

Co-authors: Ashley R Manning-Berg, University of Tennessee, Knoxville, TN; Geoffrey J Gilleaudeau, University of Copenhagen, Copenhagen, Denmark; Julie K Bartley, Gustavus Adolphus College, Saint Peter, MN

Abstract Body: Late Mesoproterozoic (1.3 to 1.0 Ga) sedimentary basins have long been considered enigmatic. Despite relative stability in the biological realm, late Mesoproterozoic strata preserve an incredible diversity of stromatolite morphology. Carbonate facies similarly display a broad range of carbonate fabrics, including water-column micrite, sea-floor precipitates, molar-tooth microspar, and herringbone carbonate, each of which had been described previously as time-distinctive Precambrian facies. Late Mesoproterozoic sedimentary basins are also increasingly likely to preserve deposits of bedded marine gypsum, compared to older sedimentary successions, despite geochemical evidence for extremely low marine sulfate concentration. Finally, although early data suggested prolonged geochemical stasis, a growing body of evidence from black shale facies indicates variably oxic, euxinic, and ferruginous marine conditions.

At first glance, the diversity of sedimentary facies and geochemistry preserved in these basins hampers efforts to define long-term changes in the Earth's global biosphere. Do differences between basins reflect local overprinting of a global signal? Do differences between basins reflect secular change at rates unresolvable by our current geochronology? Or do differences between basins reflect an underlying heterogeneity of the late Mesoproterozoic ocean system?

Here we review sedimentary fabrics and geochemistry of the 1.12 Ga Atar Group, Mauritania, West Africa. The Atar Group preserves nearly the full range of sedimentary facies that is observed in other Late Mesoproterozoic, carbonate-dominated basins. The arrangement of these facies, both spatially and stratigraphically, in combination with geochemical evidence, suggests that much of the heterogeneity preserved across late Mesoproterozoic basins can be explained by the dynamic interaction of the marine substrate, sea level, and a chemically stratified water column. We highlight a scenario wherein heterogeneity of both facies and geochemistry is a natural consequence of protracted biospheric oxygenation.

Title: Trends in Nutrient Supply, Productivity and Atmosphere Oxygenation through the Boring Billion

Presenter/First Author: Indrani Mukherjee, University of Tasmania, Hobart, TAS

Presenter/First Author Email: Indrani.Mukherjee@utas.edu.au

Co-authors: Ross Raymond Large, University of Tasmania, Hobart, TAS, Australia; Leonid V Danyushevsky, University of Tasmania, Hobart, TAS, Australia

Abstract Body: The redox sensitive and nutrient trace elements in marine sedimentary pyrites in Proterozoic black shales have been used to provide clues to nutrient supply, productivity and atmosphere oxygenation during the boring billion years. Using the nutrient trace elements adsorbed in marine pyrite (Zn, Cd, Cu, Ni, Mo and Se) as a proxy, reveals that following the GOE1, nutrient supply to the oceans dropped to a minimum around 1650 Ma, peaked at 1300 to 1000 Ma dropping again to a second minimum around 850 Ma, before rising gradually and then steeply toward the end of the Proterozoic. Using uranium in the shale matrix as a biological productivity proxy reveals a similar pattern with productivity at a minimum between 1400 and 1600 Ma, with a second minimum at 800 to 1000 Ma. The opposing patterns of Se (oxidation proxy) and Co (reduction proxy), indicates the Se/Co ratio in marine pyrite maybe a useful atmosphere oxygenation proxy. The pattern of this proxy compared with Mo and Se in pyrite suggests atmosphere O_2 was at a relative maximum at the start of the boring billion and declined in several steps to a relative minimum around 1000 Ma, corresponding with the second minimum in nutrient supply and productivity. These patterns may possibly relate to the supercontinent cycles, tectonic activities (plate collision) leading to uplift, erosion and increased nutrient supply to the ocean.

Title: Sedimentology and Geochemistry of a 1.4 Ga Continental Playa System, the Lower Sibley Group, Northwestern Ontario: Implications for the Mesoproterozoic Hydrosphere and Atmosphere

Presenter/First Author: Philip William Fralick, Lakehead University, Thunder Bay,

Presenter/First Author Email: pfralick@lakeheadu.ca

Co-authors: Riku T Metsaranta, Ontario Geological Survey, Sudbury, ON, Canada

Abstract Body: The 900 m thick Sibley Group consists of playa to deltaic to aeolian deposits outcropping north of Lake Superior and east of Thunder Bay. The lowermost 100 m thick succession of highly oxidized siliciclastic rocks and dolostone was deposited in a north-south trending half graben. The sediments can be divided into 15 lithofacies associations representing distinct depositional environments. The lower siliciclastic unit contains: boulder conglomerate-sandstone-dolocrete (proximal ephemeral braided stream), pebble to cobble conglomerate (ephemeral braided stream), trough cross-stratified sandstone (braided stream), green sandstone-siltstone (delta), massive cobble conglomerate (transgressive shoreline lag), planar cross-stratified sandstones (nearshore lacustrine sandwaves), and thinning-upward sandstones (lacustrine storm sand sheets). The overlying mixed siliciclastic-carbonate unit contains: red siltstone (non-saline lake), red siltstone-dolostone or dolomitic sandstone (saline lake), and halite-mudstone (ephemeral salt pans). Next is the upper siliciclastic unit with: sheet sandstones (lake infilling) and stromatolitic dolostone-chert (shoreline). After final desiccation of the lake terra rosa soils, collapse breccias and intraformational conglomerates developed. Paleocurrents, detrital zircon geochronology and sulfur isotopes indicate a change in drainage directions resulting in sand sheets infilling the saline lake. Sr isotopes reflect shallow groundwater circulation and lacustrine dolostone containing significant radiogenic Sr. Carbon and O isotopes are heavier upward in the saline lake deposits, probably due to evaporation and residence time effects. Most interestingly, REE patterns for dolomite in the dolocrete, stromatolitic shoreline deposits and overlying intraformational conglomerates have patterns similar to modern oxygenated groundwater, whereas the saline lake dolomites have hat-shaped patterns resembling modern groundwater draining waterlogged, organic-rich areas.

Title: Deep-water Seep-related Carbonate Mounds: Implications for Seawater and Vent Fluid Geochemistry in the Mesoproterozoic Borden Basin, Nunavut

Presenter/First Author: Katherine Elizabeth Hahn, Laurentian University, Sudbury, ON

Presenter/First Author Email: kx_hahn@laurentian.ca

Co-authors: Elizabeth Turner, Laurentian University, Sudbury, ON, Canada; Balz Samuel Kamber, Trinity College Dublin, Dublin, Ireland

Published Material: A government summary of activities summarizes geochemical results but very little interpretation. (Canada-Nunavut Geoscience Office Summary of Activities, 2014).Early versions of interpretations and results have been presented at GAC-MAC (2014-Fredericton) and GSA (Vancouver-2014).Most interpretations presented in this paper are new and have not been presented.

Abstract Body: Large deep-water dolostone mounds (Ikpiarjuk Formation) formed by fluid venting through subaqueous faults during black shale deposition in the Mesoproterozoic Borden basin (NU, Canada). Mounds consist of pelagic dolomudstone and clotted benthic dolostone with marine cement: well-preserved, bladed, length-slow dolomite (originally herringbone calcite or primary dolomite), fibrous length-fast dolomite (originally HMC) and blunt-tipped prismatic crystals replaced by blocky dolomite (originally aragonite). This mineralogy is identical to Phanerozoic cements when seawater Mg/Ca is high (>2), usually associated with global tectonic quiescence.

Detritus-corrected REE+Y patterns show binary mixing of marine and seep fluids. The seawater-dominated end-member has a positive slope in shale normalization, indicating a marine heritage, and a +ve Ce anomaly, indicating deposition below a redoxcline. REE+Y patterns show a strong local runoff influence and hence basin restriction. The seep-dominated end-member has flat REE+Y patterns, no Ce anomaly, and a -ve Eu anomaly. Carbon isotope values are typical for Mesoproterozoic seawater (~3.5‰). The absence of a +ve Eu anomaly suggests that seep fluids were <300°C and not influenced by an anomalous heat source (intrusion). The lack of light $\delta^{13}C$ in mound dolostone indicates that methane was not a major component of seep fluid. Seep fluids may have originated as seawater-derived brines that became concentrated evaporatively and sank to interact with basement rocks where their REE pattern was modified, before being vented as high-Mg/Ca, <300°fluids. Although trace elements indicate a marine basin water heritage, the Borden basin was epicratonic, its geochemistry influenced by local weathering, and redox-stratified. Such conditions are common in Mesoproterozoic basins, complicate understanding global seawater conditions, and imply that controls on Phanerozoic carbonate mineralogy may not adequately explain Mesoproterozoic carbonates.

Title: Stratigraphy, Architecture and Morphodynamics of an Early Neoproterozoic Alluvial Plain: The Nelson Head Formation of Brock Inlier, NWT, Canada

Presenter: Robert Rainbird, Geological Survey of Canada, Ottawa, ON

Presenter Email: Rob.Rainbird@NRCan-RNCan.gc.ca

First Author: Alessandro Ielpi, Geological Survey of Canada Ottawa, Iqaluit, NU

First Author Email: alessandro.ielpi@nrcan.gc.ca

First Author Student?: No

Published Material: The research deals with 1 Ga fluvial deposits superbly exposed in the Brock River Canyon, NWT. New data on depositional architecture and moprhodynamics of Precambrian rivers will be presented and discussed.

Abstract Body: The Nelson Head Formation is a *ca* 1.0 Ga sandstone exposed within several western Canadian Arctic inliers, including the Brock Inlier, where it is superbly exposed along extensive canyon cliffs. We present stratigraphic and architecture data consisting of line drawing, logging and paleocurrent analysis of 3D sections. Fluvial deposits record vertical and lateral alternation of coarse-grained, tan-yellow pebbly sandstone (mainly quartz arenite) and, recessive, maroon-red, fine-grained silty sandstone.

Strata are organized in 2 to 8 m thick bedsets that continue for >800 m along strike and >300 m down-dip. Trough-cross bedding is dominant, forming compound sets that reach 4 m in thickness. Subordinate planar-cross bedded deposits form sets up to 50 cm thick, and preferentially occur in the upper parts of bedsets. Soft-sediment deformation structures include common ball-and-pillow, convolute bedding, heavy mineral sags and fluid-escape conduits. Bedsets comprise lower, large inclined sets and upper, cross-cutting lithosomes with planar to concentric fill. Coarser units are somewhat thinner but are laterally more homogeneous up-section. Lower in the section, paleoflow indicators point to northwestern to northeastern transport, with high dispersion in individual units and upward flow rotation in some cases. Up-section, paleoflow is more focussed to the northwest.

Finer-grained units are micaceous (sericitic) and their maroon-red colour reflects an abundance of iron-oxide cement. Bedding units are 10 to 70 cm thick, planar-bedded, and continue for >600 m along strike and >300 m down-dip. Finer units are normally graded, thicker and more laterally continuous lower in the section. Ripple-cross lamination, climbing in places, is common and alternates with minor wavy plane-parallel lamination. Rare trough-cross bedding occurs in dm-thick sets in the lower parts of thicker units. Paleoflow is consistently north-northwest with low dispersion.

Correlative exposures of the Nelson Head Formation in the Minto Inlier of Victoria Island and the Katherine Group of the Mackenzie Mountains comprise remnants of continental-scale fluvial system that drained vast portions of the Canadian Shield. The formation is additionally one of very few Proterozoic sandstones where fluvial sinuosity has been documented.

Title: New Meso-Neoproterozoic Paleomagnetic Results from the Congo-Sao Francisco Craton

Presenter/First Author: Tierney E Larson, Yale University, New Haven, CT

Presenter/First Author Email: tierney.larson@yale.edu

Co-authors: David AD Evans, Yale University, New Haven, CT; Richard E Hanson, Texas Christian University, Fort Worth, TX; Mandy Hofmann, , , ; Ulf Linnemann, , , ; Ian W D Dalziel, University of Texas at Austin, Austin, TX

Published Material: Approximately 10% of material presented is in press with Geological Society of London Special Publications

Abstract Body: The Congo-Sao Francisco (SF) craton is a keystone of Gondwana and also a possible part of the Precambrian supercontinent Rodinia, but its movement through Meso-Neoproterozoic time still remains mostly unconstrained due to sparsity of reliable paleomagnetic data. Paleomagnetic results from 1.4 to 0.6 Ga igneous rocks, spanning southern Congo-SF from Tanzania to Namibia and eastern Brazil, help define a new apparent polar wander path for the craton. The youngest rocks in our paleogeographic reconstruction, the Sanyika redbeds of Tanzania, are still under geochronological investigation, but detrital zircon analyses demonstrate sedimentation ages of less than ~684 Ma. Five sites within the redbeds yield a shallow ESE-WNW dual-polarity remanence direction held by hematite. Together with published data from the Gagwe lavas, Mbozi Complex, and Luakela volcanics, our new data suggest complicated motions of Congo-SF craton through the Tonian-Cryogenian interval. These results are combined with a key pole from Brazil dated at 920 Ma, which is used to better define continuous motion of the craton relative to Laurentia and Baltica. We also sampled Mesoproterozoic rocks from three different geological units in northern Namibia. The oldest of these is the Kunene Anorthosite Complex, dated at ~1370 Ma. In the southern Kunene area, the anorthosite complex is intruded by Epembe syenites (~1220 Ma) and related dolerite dykes, and in the eastern area near Swartbooisdrif, the anorthosite is intruded by both dolerite and carbonatite dykes (~1130 Ma). Initial results from Namibia appear promising, including a possible positive baked-contact test for a Swartbooisdrif dyke intruding Kunene anorthosite. All of the new results are incorporated into an animation of Congo-SF motion through Mesoproterozoic Nuna breakup to terminal Proterozoic-Cambrian Gondwana assembly.

Title: Deformation, Lithogeochemistry and New U-Pb Geochronology of the Aberdeen Lake Area, Central Rae Craton, Nunavut

Presenter/First Author: Rebecca Corrine Hunter, Laurentian University, Saskatoon, SK

Presenter/First Author Email: reba_hunter@mac.com

Co-authors: Bruno Lafrance, MERC, The Goodman School of Mines, Laurentian University, Sudbury, ON, Canada; Larry Heaman, University of Alberta, Edmonton, AB, Canada

Abstract Body: A new lithostratigraphy is proposed for the Neoarchean Woodburn Lake group (WLg) in the Aberdeen Lake area of the Rae Domain, western Churchill Province. The WLg has been correlated with the Prince Albert Group in the Melville Peninsula and the Mary River Group in north-central Baffin Island. Thus, knowing how and when the WLg formed is important for understanding the tectonic history of the Rae Domain. The WLg can be subdivided into three lithostructural sequences comprising a lower mafic volcanic package with local komatiite and felsic volcaniclastic interlayers, a middle clastic to intermediate volcaniclastic package with abundant banded iron formation and a distinctive trachydacite unit, and an upper semipelite-dominated sedimentary package with local graphitic, psammitic and banded iron formation interlayers. Based on LA-MC-ICPMS U-Pb zircon dating, the lower sequence was deposited ca. 2.74 Ga, the middle sequence between ca. 2.68 and 2.71 Ga, and the upper sequence is bracketed between ca. 2.68 Ga, the age of the trachydacite unit, and ca. 2.66 Ga, the inferred age of an intrusive monzodiorite gneiss in the study area. The geochemical signature of the WLg suggests that these rocks represent a back-arc to marginal arc environment. The ca. 2.68 Ga felsic volcanism observed in the middle sequence is similar to volcanism observed in the Henik Group of the Hearne Domain, and indicates that these Neoarchean supracrustal belts could have a similar tectonic history. The implications are that comparable geological settings are recorded in the Neoarchean within the two separate domains or alternatively, it records a single igneous event across an amalgamated Rae-Hearne craton at 2.68 Ga.

Title: Neoarchean continental arc construction followed by collisional deformation along the eastern Rae domain, western Churchill Province: implications for fingerprinting tectonic processes

Presenter/First Author: Sean P Regan, Organization Not Listed, Amherst, MA

Presenter/First Author Email: sregan@geo.umass.edu

Co-authors: Michael L Williams, University of Massachusetts, Amherst, MA; Kevin H Mahan, University of Colorado at Boulder, Boulder, CO; Greg Dumond, University of Arkansas, Fayetteville, AR; Michael J Jercinovic, University of Massachusetts, Amherst, MA

Published Material: Initial findings were reported during an "arc" session at GSA, 2014.

Abstract Body: The western Churchill Province provides an opportunity to study the growth and evolution of Archean continental lithosphere. It is been divided into the Rae and Hearne domains, but the nature and history of the boundary between them remains enigmatic. The Athabasca granulite terrane (AGT), located on the eastern margin of the Rae domain, was host to a prolonged phase of magmatism and tectonometamorphism during the Neoarchean. Geochemical analysis of ca. 2.61 Ga plutonic rocks paired with structural analysis and in-situ monazite geochronology have yielded insight into the Archean infrastructure of the eastern Rae domain, and show that ca. 2.61 Ga plutonic rocks represent the roots of a continental arc. Plutonic rocks range from 58.01 to 73.71 % SiO_2, and form linear trends on modified alkali-lime index plots, plotting largely in the calc-alkaline field. On Pearce diagrams, all samples plot in the volcanic arc granite field. Samples are LREE enriched, and contain flat and relatively depleted HREE when normalized to chondrites, indicative of a garnet bearing source. The entire Neoarchean plutonic complex, independent of bulk SiO_2 content, contains systematic enrichment in LILE and Pb, and depletions in HFSE and is interpreted to have been derived from a metasomatized lithospheric mantle source. Collectively, these data suggest that ca. 2.61 plutonic rocks represent a large continental arc complex. In-situ U-Th-total Pb monazite geochronology indicates that regional tectonism occurred immediately following the cessation of arc plutonism from ca. 2.59 – 2.53 Ga. This involved crustal thickening, lateral flow of plutonic rocks, and extensive migmatization at conditions exceeding 1.3 GPa and 800°C. The Neoarchean history of the Athabasca granulite terrane, thus, records a phase of arc construction followed by a period of crustal thickening, high pressure granulite facies metamorphism, and migmatization. This sequence of events is interpreted as the transition from a continental arc to a collisional setting during the Neoarchean, and perhaps, the amalgamation of the western Churchill Province. In addition, the AGT is a deep-crustal view of the accretionary process that can provide insight into the deeper parts of other orogenic belts.

Title: Assembly of the Paleoproterozoic Core of Laurentia: New Results from the Churchill Province and its Bounding Orogens

Presenter: Edith Martel, Northwest Territories Geoscience Office, Yellowknife,

Presenter Email: edithmartel@hotmail.com

First Author: Sally Jane Pehrsson, Geological Survey of Canada Ottawa, Ottawa,

First Author Email: edith_martel@gov.nt.ca

First Author Student?: No

Co-authors: Robert G Berman, , , ; William James Davis, Geological Survey of Canada, Ottawa, ON, Canada; Michael A. Hamilton, University of Toronto, Toronto, ON, Canada; Mary Sanborn-Barrie, , , ; Joseph Clancy White, University of New Brunswick, Fredericton, NB, Canada

Abstract Body: Integration of over sixty new U-Pb isotopic ages from the Churchill Province and its bounding orogens yields new insights and questions about the assembly of Laurentia as part of Earth's first supercontinent Nuna.

A transect across the Thelon Tectonic Zone (TTZ) from the Mesoarchean Queen Maud block finds the latter reworked during Arrowsmith and Thelon orogenesis and the former characterized by a major 2.03-1.99 Ga magmatic and thermal pulse. A widespread 1.91 Ga thermal event is also recognized. The TTZ appears structurally complex, with imbricated slices of Mesoarchean basement and differing Paleoproterozoic crustal levels possibly due to thick-skinned thrusting also involving the adjacent Slave Province. Previous models of an east-facing rift margin on the Slave, now possibly coeval with the start of TTZ subduction, raise questions about subduction polarity, microcontinent formation and the heretofore simple Slave-Rae collisional interface.

Other Churchill studies reveal a Paleoproterozoic lower crustal domain stretching from Athabasca basin to Hudson strait and characterized by 8-12 kbar paleopressures in both Archean basement and Paleoproterozoic supracrustal rocks. A transect of this domain in the NWT reveals a shallowly-dipping crustal stack of 2.7-2.0 Ga ortho- and paragneisses transected by ductile shear zones and blastomylonites. Archean rocks record MacQuoid and Arrowsmith tectonometamorphism at MPHT conditions. U-Pb metamorphic zircon ages (*ca.* 1.88 Ga and 1.83 Ga) in 2.3-2.0 Ga magmatic rocks show that regional 10-12 kbar assemblages (Grt-Cpx; Grt-Hbl) are Paleoproterozoic.

Exhumation of the lower crust was largely complete by ca. 1.82 Ga when ultrapotassic volcano-sedimentary rocks were deposited in transtensional basins. The scale and character of the Churchill-wide lower crustal domain is reminiscent of the Western Gneiss region of Norway and consistent with others formed worldwide during major collision-accretion events.

Title: Is there an Archean lithospheric mantle root beneath the Sask Craton, Canada? Constraints from peridotite xenoliths in the Fort à la Corne kimberlite field.

Presenter/First Author: Janina Czas, University of Alberta, Edmonton,

Presenter/First Author Email: jczas@ualberta.ca

Co-authors: D. Graham Pearson, University of Alberta, Edmonton, AB, Canada; Thomas Stachel, University of Alberta, Edmonton, AB, Canada; George H Read, Organization Not Listed, Washington, DC; Bruce A. Kjarsgaard, Geological Survey of Canada, Ottawa, ON, Canada

Abstract Body: Peridotite xenoliths from kimberlites at Fort à la Corne (FALC) present a unique opportunity to study the lithospheric mantle beneath the Sask Craton. Archean (2.4 – 3.2 Ga) crustal ages have previously been reported for the craton. Little is known about this craton, yet it hosts a major diamond deposit within the Fort à la Corne kimberlite field. Establishing the age of the lithospheric mantle beneath this newly recognised craton is essential to constrain its origin and evolution. From a diamond perspective it is also important a) to understand whether the cratonic crust is underpinned by an Archean mantle and b) to constrain the possible influence of the Trans-Hudson Orogeny (THO; 1.79 – 1.91 Ga), representing the collision of the Superior and the Hearne-Rae provinces. Re-Os isotope systematics and platinum group element (PGE) concentrations have been obtained for olivine separates of 24 lherzolite xenoliths from two volcanic centres (Orion South and Star) in the FALC kimberlite field. The Os isotopic compositions vary significantly, yielding T_{RD} model ages ranging from 0.3 to 2.4 Ga (mode at 1.8 – 2.0 Ga) that provide minimum estimates for the timing of melt depletion. Mean Fo values ($Fo_{90.3-91.9}$) of olivines from the lherzolites constrain the fraction of melt extracted to be 20 – 25%. Such moderately high levels of melt depletion would almost quantitatively remove Re ($Re/Os_{elemental}$=0.0005 – 0.00001) and hence T_{RD} ages should approximate the actual ages of melt depletion. On this basis, there are no Archean ages recorded in the Os isotope composition of the Sask Craton lithospheric mantle. The mode of Re depletion ages at 1.8 to 2.2 Ga, with the oldest T_{RD} ages at 2.4 Ga, provides a strong indication that the majority of the lithospheric mantle was depleted and stabilised significantly later than the Archean crust. Hence, the evolution of the Sask Craton may have been similar to the Siberian Craton, where the bulk of the lithospheric mantle seems to have been constructed during craton amalgamation in the Paleoproterozoic (1.8 to 2 Ga).

Title: Direct U-Pb evidence for Paleoproterozoic subduction-related metasomatism of the sub-Gardar lithospheric mantle, SW Greenland

Presenter/First Author: Michael A. Hamilton, University of Toronto, Toronto, ON

Presenter/First Author Email: mahamilton@es.utoronto.ca

Co-authors: Brian G.J. Upton, , , ; Michael A.W. Marks, University of Tübingen, Tübingen, Germany; Kathryn M. Goodenough, , ,

Abstract Body: Rift-related alkaline magmas of the Mesoproterozoic Gardar Igneous Province in south Greenland comprise nearly a dozen large central complexes of gabbro-syenite, volcanic rocks and dyke swarms ranging from transitional olivine basalts to hawaiites, emplaced in a continental intraplate setting at ca. 1300-1140 Ma. Subordinate volumes of carbonatite and alkaline ultramafic lamprophyre occur locally. Gardar intrusions stitch the boundary between the Archean North Atlantic (Nain) craton and the largely juvenile Paleoproterozoic Ketilidian orogen to the south. Most Gardar magmas were emplaced into calc-alkaline magmatic arc rocks of the expansive Julianehåb batholith (outcrop area ~30,000 km^2), formed at 1855-1795 Ma as a consequence of oblique, N-directed subduction of oceanic lithosphere beneath a southern Archean plate margin. The region remained unaffected by tectonomagmatic activity until the onset of Gardar magmatism.

Previous geochemical and tracer isotopic studies of Gardar mafic magmas have ruled out a significant role for crustal contamination or involvement of an ancient (Archean) enriched lithospheric keel; enrichments in K, Rb, Ba, P, F and LREE and depletions in Nb-Ta have instead been attributed to metasomatic modification of the sub-Gardar mantle by melts or fluids rising from the subducting Ketilidian oceanic plate. Mantle xenoliths in the Gardar Province are currently only known to occur in a single locality. On Igdlutalik Island, a Gardar mela-aillikite dyke carries abundant rounded,

ultramafic nodules (variably altered peridotites), locally with relic olivine (Fo91.5) and Cr-spinel. Peridotites with cross-cutting veins, and discrete nodules of phlogopite-rich glimmerite attest to volatile-charged, K-rich metasomatism in an assemblage that also comprises subordinate calcite, apatite, zircon and titanite. CA-ID-TIMS U-Pb analyses of single zircon grains from glimmerite yield ages of 1800 Ma, directly implicating Paleoproterozoic subduction with attendant metasomatic enrichment of Ketilidian refractory mantle residual after major arc construction.

Title: Petrogenesis and Geodynamic History of the Lynn Lake Greenstone Belt, Manitoba: Implications for Trans-Hudson Orogen Tectonics

Presenter/First Author: Michael W P Glendenning, University of Windsor, London,

Presenter/First Author Email: glendenm@gmail.com

Co-authors: Joel E Gagnon, University of Windsor, Windsor, ON, Canada; Ali Polat, University of Windsor, Windsor, ON, Canada

Published Material: A version of these findings were submitted to Lithos in November of 2014 and is currently under review.

Abstract Body: The circa 1.9 Ga old Paleoproterozoic Lynn Lake greenstone belt in north-western Manitoba has been previously interpreted to be the product of a collage of subaqueous volcanic rocks formed in oceanic volcanic arcs, ocean islands, intra-arc rifts, and mid-ocean ridges, all of which included little to no contribution from continental crust. Despite these interpretations, lithogeochemical data from the southern terrane and isotopic data from the northern terrane suggest the involvement of continental crust during the formation of the metamorphosed volcanic and igneous rocks that comprise the Lynn Lake greenstone belt. The results of new outcrop mapping, core logging, petrographic characterization, and lithogeochemical analyses were integrated with historic lithogeochemical data in order to: 1) quantify the importance of continental crust in the formation of the northern terrane; 2) re-interpret the tectonic evolution of the Lynn Lake greenstone belt; and 3) assess the implications of this re-evaluation for the tectonic evolution of the Trans-Hudson Orogen. Based on high-field strength element abundances and Th-Nb-La systematics, the ultramafic to intermediate metavolcanic rocks comprising the Lynn Lake greenstone belt can be subdivided into two distinct tectonic environments: 1) mantle plume-derived crustally-contaminated oceanic plateau, continental rift, or rifted continental margin; and 2) continental volcanic arc. This study indicates that the Lynn Lake greenstone belt formed during either formation of the Manikewan Ocean via rifting of the Superior Craton to form the Hearne Craton, or during formation and closure of the Snowbird Tectonic Zone via rifting of the Rae Craton to form the Hearne Craton, which resulted in redirection of plume material to the passive Hearne margin. Consequently, re-examination of the mineral deposit potential of the Lynn Lake greenstone belt, in the context of the revised tectonic environment, is warranted.

Title: Structural geology of the McLeod Road - Birch Lake sequence, Snow Lake, Manitoba, and implications for the evolution of the southeastern Trans-Hudson Orogen

Presenter/First Author: Kate ELIZABETH Rubingh, MERC, The Goodman School of Mines, Laurentian University, Sudbury, ON

Presenter/First Author Email: kate.rubingh@gmail.com

Co-authors: Bruno Lafrance, MERC, The Goodman School of Mines, Laurentian University, Sudbury, ON, Canada; Harold Lorne Gibson, MERC, Department of Earth Sciences, The Goodman School of Mines, Laurentian University, Sudbury, ON, Canada

Abstract Body: The McLeod Road – Birch Lake (MB) sequence is a fault bounded panel of bimodal volcanics and volcaniclastic rocks in the Paleoproterozoic Flin Flon – Snow Lake greenstone belt of the southeastern Trans-Hudson Orogen (THO). It is bounded to the north by the Birch Lake Fault and to the south by the McLeod Road Thrust (MRT). It hosts the past gold-producing Snow Lake Mine (1.4 M oz) and is immediately north of the major volcanogenic massive sulphide camp of Snow Lake. The MB sequence underwent three major deformational events. Early D1 collision of the Flin Flon – Snow Lake greenstone belt with the Sask craton produced early thrust faults that repeat the stratigraphy of the MB sequence. The latter is folded by the F1 Nor-Acme anticline (NAA), which formed during thrusting and has a strong axial planar NE trending S1 foliation and coaxial NE plunging L1 stretching lineation. D1 is a progressive deformation event and later during D1, the NAA is cut by the MRT, which juxtaposes the (1835 – 1842 Ma) Burntwood turbidites with the (1.89 Ga) MB sequence volcanics. The Birch Lake Fault is parallel to the MRT, but it juxtaposes younger Missi conglomerates (1845 Ma) over the MB sequence volcanic rocks and has normal shear sense indicators. Thus, the MB sequence is bounded by parallel thrust and extensional faults, a geometry analogous to that produced by channel flow in the Himalayas. During D2 collision with the Superior craton, a NNE-striking, regional S2 cleavage formed transecting the NAA and MRT and reactivating the MRT as a sinistral shear zone. Continued shortening and ongoing collision of the Superior craton during D3 forms broad open NE trending map scale F3 folds. The orthogonal collisions of the Sask Craton and then Superior Craton with the Flin Flon – Snow Lake greenstone belt both contributed to the thrusting and folding history of the southeastern THO, resulting in its complex dome-and-basin geometry.

Title: Nd Isotope Mapping of Crustal Boundaries within the Makkovik Province, Labrador, Canada.

Presenter/First Author: Rebecca Madelaine Moumblow, Self Employed, Washington, DC

Presenter/First Author Email: moumblrm74@gmail.com

Co-authors: Alan P Dickin, McMaster University, Hamilton, ON, Canada; Charles F. Gower, Organization Not Listed, St. John's, NL, Canada

Published Material: Submitted to Precambrian Research

Abstract Body: Abstract: The Makkovik Province of eastern Labrador represents part of an accretionary orogen active during an early stage in the development of the Paleoproterozoic southern Laurentian continental margin. New Nd isotope data for the eastern Makkovik Province suggest that accreted juvenile Makkovik crust was generated in the Cape Harrison domain during a single crust-forming event around 1.95 Ga.

As previously proposed, an arc accretion event around 1.9 Ga is argued to have triggered subduction-zone reversal and the development of an ensialic arc on the composite margin. After the subduction flip, a temporary release of compressive stress around 1.86 Ga led to the development of a retro-arc foreland basin on the downloaded Archean continental edge, forming the Aillik Group. Unlike previous models, a second arc is not envisaged. Instead, a compressive regime around 1.82 Ga is attributed to continued ensialic arc plutonism on the existing margin.

The tectonic model for the Paleoproterozoic Makkovikian orogeny proposed here is similar to that for the Ketilidian orogeny.

Major and minor trace element analyses suggest that much of the magmatism in the Makkovik orogen results from post-accretionary ensialic arc activity, and that few vestiges remain of the original accreted volcanic arc. This pattern of arc accretion and intense post-accretion reworking is common to many accretionary orogens, and is revealed by a combination of Nd and U-Pb isotopic data.

Title: Supercontinent-superplume coupling in Earth history: toward a new tectonic paradigm

Presenter/First Author: Zheng-xiang Li, Curtin University, Perth, WA

Presenter/First Author Email: z.li@curtin.edu.au

Published Material: The ideas have been published in various papers, particularly the Li and Zhong 2009 paper in PEPI. This talk will be an update in preparation for the new IGCP project.

Abstract Body: The question of what drives plate tectonics remains a major challenge to geoscientists. Major breakthroughs over the past 30 years include (1) the recognition of a likely cyclic nature of supercontinent evolution, including the Pangea (320–170 Ma), Rodinia (900–700 Ma), and Nuna/Columbia (1600?–1300? Ma) cycles; (2) seismic tomographic evidence for subducting slabs reaching the lower mantle; (3) the discovery of the two equatorial, antipodal, large low shear-wave velocity provinces or superplumes in the lower mantle that underlie (and feed?) almost all the know mantle plumes since the Permian; and (4) the increasing recognition of TPW events (True Polar Wander – rotation of the entire mantle and lithosphere relative to the planetary rotation axis) in Earth history that reflect changes in mantle structure and convection patterns. Although many believe that subducting slabs can influence lower mantle structure and dynamics, some believe that the two superplumes are long-lived in Earth history and are thus independent of the plate system. Here I present a self-consistent working hypothesis that features the followings: (1) the Earth's history has been dominated by cycles of supercontinent assembly and breakup coupled by antipodal superplume events; (2) circum-supercontinent subduction leads to the formation of two antipodal superplumes (and individual plumes above them) corresponding to the positions of the supercontinent and the superocean, respectively; (3) the superplumes can bring themselves and the coupled supercontinent to equatorial positions through TPW events, and eventually lead to the breakup of the supercontinent; equatorial antipodal superplumes also allow for inertial interchange true polar wander; and (4) the breakup of the supercontinent gradually changes the Earth from a dominantly circular subduction system to scattered multiple-subduction systems, thus weakening the antipodal superplumes until after the formation of the next supercontinent.

Title: PALEOPROTEROZOIC PALEOGEOGRAPHIC RECONSTRUCTIONS: BASED ON PALEOMAGNETIC DATA AND LIPS BARCODE CONSTRAINTS

Presenter/First Author: Sergei A Pisarevsky, University of Western Australia, Crawley, WA

Presenter/First Author Email: sergei.pisarevsky@uwa.edu.au

Co-authors: Richard E Ernst, Ernst Geosciences, Ottawa, ON, Canada

Published Material: 20% of the content has been recently accepted (Pisarevsky et al., 2014, Precambrian Research, http://dx.doi.org/10.1016/j.precamres.2014.05.023). Now these data are integrated with a broader sets of data and new implications are found.

Abstract Body: Using two independent datasets – Large Igneous Provinces (LIPs) database and recently updated 2.5-1.8 Ga paleomagnetic database – we built a series of global paleogeographic reconstructions. The data do not contradict the existence of a supercontinent around 2400 Ma, but its exact configuration and the timing of its assembly and breakup are speculative. However, some plausible models are considered. Both paleomagnetic and LIPs data are unevenly distributed both in time and in space. Consequently paleopositions of some ancient cratons are not always constrained by data. We demonstrate that the Superior, Kola-Karelia, Yilgarn, Zimbabwe, Kaapvaal, Nain (North Atlantic), Dharwar, Wyoming and Rae cratons could be assembled into a supercontinent (or a supercraton, Superia), which could exist between 2500 and 2370 Ma only if moving relatively fast. The paleogeography before 2500 Ma and between 2370 and 1800 Ma is less clear, but we consider several alternative scenarios. In addition to abovementioned cratons we establish permissive positions for the Slave craton and for the ancient fragments of Siberia, Amazonia, Congo and São Francisco cratons, in view of new paleomagnetic data. It is likely that the Slave craton was distal from the Superior craton (and possibly from Superia) around 2200 Ma, as has been suggested in several publications.

Title: Targeting Comprehensive Visualisation of Precambrian Geological Evolution of the Earth's Crust and its Mineralisation

Presenter/First Author: Bruce M Eglington, University of Saskatchewan, Saskatoon,

Presenter/First Author Email: bruce.eglington@usask.ca

Co-authors: Sally Jane Pehrsson, Geological Survey of Canada Ottawa, Ottawa, Canada; David AD Evans, Yale University, New Haven, CT; David Huston, , , ; Steven Reddy, , ,

Published Material: Some aspects of plate reconstructions are in press but much is new. Some aspects of the database description has been presented but this will focus on new aspects. This presentation has been invited by Evans and Ernst so it will need to incorporate some existing information but will also include new data/fits/interpretations hot off the computer.

Abstract Body: Investigation of the regional geological evolution of the Earth's crust and its mineral deposits is consistently hampered by insufficient information structured to easily compare across time, space and structural domains. IGCP projects 440 (Rodinia supercontinent) and 509 (Nuna supercontinent) provided an effective mechanism to bring together researchers and to compile relevant geological information. IGCP 509 also formally created a number of invaluable datasets, housed in the online DateView and StratDB databases (available from http://sil.usask.ca), including information for geochronology, isotope geochemistry, lithostratigraphy, ore deposits and large igneous provinces. Investigation of information in these databases permits the quantification of global periodicity in Earth evolution since about 3800 Ma, consistent with the formation of several successive supercontinents. At regional scale it is clear that supercontinent amalgamation and disintegration was diachronous. Mineralisation style and location can be shown to be consistent with this behaviour and to fit well with general Phanerozoic settings, so providing additional ways to investigate the spatial distribution of Precambrian crustal blocks. Plate tectonic reconstructions in the

Palaeozoic and Precambrian (pre-seafloor spreading) are just as feasible as Cenozoic to Mesozoic situations but require additional constraints and tests. Modern tools such as GPlates and Paleogis plate reconstruction software which link effectively with GIS-based information, facilitate model development and allow one to test continuously varying time views overlaying multiple datasets. Both younger and older reconstructions are essential to achieving realistic reconstructions. Detailed identification of the domain blocks (plates), including their older subdivisions is a prerequisite for success.
Significant progress in achieving plate reconstructions from the present back to the late Archean is already apparent.

Title: Proterozoic Marine Redox Evolution

Presenter/First Author: Noah J Planavsky, Yale University, Riverside, CA

Presenter/First Author Email: planavsky@gmail.com

Co-authors: Christopher Reinhard, Georgia Tech, Atlanta, GA; Timothy Lyons, University of California-Riverside, Riverside, CA

Abstract Body: There has been extensive debate about marine redox structure in the Proterozoic over the past two decades. We will briefly review this debate and present some new paleoredox work. Given that the Animikie Basin has been essential in shaping our view of the Proterozoic oceans, we will highlight a recent multi-proxy paleoredox study in previously unexplored Paleoproterozoic Animikie Basin drill cores from the Stambaugh Formation in the Paint River Group (Iron River-Crystal Falls district of Michigan). Based on previous tectonic reconstructions and analysis of sedimentary regimes, the Iron River-Crystal Falls sections capture the deepest-water facies of the Animikie Basin. In contrast to previous work, we find evidence for highly variable marine redox conditions—including ferruginous, euxinic, and short-lived oxic conditions—and suggest this variability may be representative of the Proterozoic oceans more broadly. We have been searching for a single redox structure for the Proterozoic oceans. However the hallmark of Proterozoic marine settings may be the lack of a single characteristic redox structure. The Proterozoic oceans are likely defined by strong, short-term redox landscape variability.

Title: An Appalachian-style Multi-terrane Accretion/Collision Model for the Assembly of South China

Presenter/First Author: Shoufa Lin, University of Waterloo, Waterloo, ON

Presenter/First Author Email: shoufa@uwaterloo.ca

Co-authors: Guangfu Xing, 3Nanjing Institute of Geology and Mineral Resources, Nanjing, China; Changqing Yin, Sun Yat-Sen University, Guangzhou, China; Longming Li, , , ; Don Davis, University of Toronto, Toronto, ON, Canada; Bill Davis, Geological Survey of Canada, Ottawa, Canada; Guanghua Chen, , , ; Yang Jiang, , , ; Zhihong Chen, , ,

Abstract Body: South China is traditionally interpreted to have formed by the collision of two blocks, the Yangtze and the Cathaysia. The proposed timing of collision varies from Proterozoic to Mesozoic, corresponding to that of the various tectonothermal events documented in South China. A better understanding of South China is important not only for the assembly of Asia, but also for the reconstruction of supercontinents (e.g., Rodinia).

In this contribution, we propose, as an alternative interpretation, that the evolution of South China involved accretion/collision of multiple terranes (i.e. more than two blocks) and each of the major tectonothermal events corresponds to an accretional/collisional event. The Cathaysia Block has been divided into two parts, West and East, with contrasting histories. New and available age data indicate that the boundary between West and East Cathaysia is not the Zhenghe-Dapu fault as previously thought, but lies ~20 km to its west. In our model, West Cathaysia is a composite terrane formed by amalgamation of multiple terranes/arcs at ~1.0–0.88 Ga. Arc magmatism in the Shuangxiwu, Wuyi and Yunkai areas, metamorphism in the Tianli schist and emplacement of the Xiwan ophiolite were related to the process. West Cathaysia and the Yangtze Block collided at ~825–815 Ma along the NE Jiangxi fault/suture zone, following westward subduction (current coordinate) that generated a ~860–825 Ma arc–back-arc system preserved in the Jiangnan belt. The resulting Yangtze-West Cathaysia continent collided with a postulated continent to the east at ~460–440 Ma, leading to high-grade metamorphism in part of West Cathaysia (the down-going plate) in this “Caledonian”-aged orogen. East Cathaysia, characterized by a ~1.87–1.86 Ga basement and ~250–230 Ma high-grade metamorphism, possibly originated from an “Indosinian” orogen in the Paleo-Tethyan regime to the south. It accreted to the east of West Cathaysia in the Mesozoic, possibly through large-scale strike-slip movement. Before or during the process, the eastern part of the Caledonian-aged orogen and the postulated continent moved away from South China through rifting and/or strike-slip motion. Such a multi-terrane accretion/collision model is similar to what has been proposed for the Appalachian orogen.

Title: Paleomagnetic Insights into the Global Climatic Condition Prior to Sturtian Glaciations: Evidence from the South China

Presenter/First Author: Shihong Zhang, China University of Geosciences Beijing, Beijing,

Presenter/First Author Email: shzhang@cugb.edu.cn

Abstract Body: In some influential models of paleocontinental reconstruction (e.g. Li et al., 2013), the south China block (SCB) was placed in low paleolatitudinal region at ~780 Ma. Huang et al. (2014) recently reported some low values of the chemical index of alteration (CIA) observed from ~780 Ma strata in the SCB and combined their data with the speculation of low paleolatitudinal position of the SCB to suggest that the earth had witnessed multiple climate cooling prior to the Sturtian glaciations. I agree that jointly interpreting of the paleolatitudinal data and CIA data would provide useful constraints to global climatic conditions in deep time. However, the paleolatitudinal positions and tectonic settings of

the SCB in Neoproterozoic are still matters of dispute. Accumulating paleomagnetic data demonstrate that the SCB had experienced an equator-ward drifting during the middle and late Neoproterozoic while the supercontinent Rodinia was breaking up. The SCB was located in very high latitudinal region (> 60° N) at ~820 Ma and reached the Equatorial region at a time close to the Cambrian/Precambrian boundary. The newly obtained paleomagnetic and geochronological results suggest that the SCB was still located at middle to high latitudinal regions (between ~35° and ~55° northern hemisphere) at ~780 Ma (Xiao et al., 2015). The high-latitudinal pre-Cryogenian sedimentary rocks up to thousands meters thick are predominately reddish clastic sandstone, siltstone and shales, suggesting a likely greenhouse climatic condition on the Earth before the Cryogenian Period. These sediments formed in high sedimentary rate rift basins and experienced multiple deposition, erosion and redeposition cycles. The low CIA data from the SCB have no straightforward meaning of global cooling.

Title: A Relic of the Mozambique Ocean in south-east Tanzania

Presenter/First Author: David Robert Mole, University of Western Australa, Perth, WA

Presenter/First Author Email: david.mole@csiro.au

Co-authors: Richard Taylor, Curtin University, Perth, WA, Australia; Peter Kinny, , , ; Stephen J Barnes, CSIRO, Perth, Australia

Abstract Body: The Neoproterozoic geology of East Africa records the events leading up to the formation of Gondwana and subsequently Pangea, and hence understanding the geodynamic history of this area offers a unique insight into supercontinent development and pre-Gondwanan continental growth.

Here, we present new geochemical and geochronological data from the Ntaka region of the Nachingwea district of south-east Tanzania suggesting this area of the Mozambique Belt constitutes an exotic nappe terrane that was part of the Neomozambique Ocean in the Neoproterozoic.

The lithological sequence in the region consists of a 770-720 Ma ‘basement’ of intermediate-felsic paragneiss possibly after volcanogenic sediments which show typical arc-like geochemical signatures. These are intruded by 700-650 Ma amphibolites (±garnet) after mafic-intermediate intrusives that also have arc-like geochemistry. This sequence is then intruded by a set of ca. 670-650 Ma ultramafic, dominantly pyroxenitic sills collectively termed the Ntaka intrusion, which have a much more mantle-like, non-arc origin. The mafic-intermediate intrusives occur synchronous with, and outlast, the ultramafic magmatism, suggesting this event was transient in the context of the overall tectonic regime. The final magmatic event in the terrane is the intrusion of sill-like 640-620 Ma orogenic granites that are coeval with 640-600 Ma upper amphibolite-granulite facies metamorphism.

The broader geodynamic setting consisted of the Congo-Tanzania-Bengweulu Block/Craton to the west and the Azania-Dhawar blocks/craton to the east of the Neomozambique Ocean, both of which contain Archean-Paleoproterozoic detritus. Subsequently, based on the island-arc like geochemical characteristics of the 700-650 Ma mafic intrusive rocks and the lack of detrital zircons >1000 Ma, we suggest that the Ntaka region represents a Neoproterozoic intra-oceanic island arc which was accreted to either East Africa or Azania shortly before full continental collision (the East African Orogeny) at ca. 640-620 Ma. We hypothesise that the short-lived period of ultramafic magmatism at ca. 660 Ma represents a short (ca. 10 Ma?) period during which the island arc intersected a mantle plume ‘hot spot’, resulting in the emplacement of magmas with primary liquid compositions of ca. 15% MgO.

Title: The Large Igneous Provinces Industry Consortium Project: Accomplishments and next steps

Presenter/First Author: Richard E Ernst, Ernst Geosciences, Ottawa, ON

Presenter/First Author Email: Richard.Ernst@ErnstGeosciences.com

Co-authors: Wouter Bleeker, Geological Survey of Canada, Ottawa, ON, Canada; Ulf Söderlund, Lund University, Lund, Sweden; Michael A Hamilton, University of Toronto, Toronto, ON, Canada; Sandra L Kamo, University of Toronto, Toronto, ON, Canada; Kevin Chamberlain, University of Wyoming, Laramie, WY; Paul J Sylvester, Texas Tech University, Lubbock, TX; Michael T D Wingate, Geol. Surv. Western Australia, East Perth, WA, Australia; Sergei A Pisarevsky, University of Western Australia, Crawley, WA, Australia; Brian Cousens, Carleton University, Ottawa, ON, Canada; Pete N Hollings, Lakehead University, Thunder Bay, ON, Canada; Andrew Craig Kerr, Cardiff University, Wales, United Kingdom; Simon M Jowitt, , ,

Published Material: 30% has previously been published, but this represents a new synthesis of previously published and new results

Abstract Body: The Large Igneous Provinces (LIPs) Industry Consortium Project has generated c. 220 U-Pb dates from LIP units (mainly dolerite dykes) across the world, which provided the first robust LIP barcodes for crustal blocks such as West Africa, Siberia, Amazonia, and Sarmatia, led to the discovery of more than 10 Proterozoic LIPs of scale comparable to the Siberian Trap LIP, identified critical LIP barcode matches constraining pre-Pangea supercontinent reconstructions, and provided numerous new targets for paleomagnetic testing of these reconstructions. These results directly benefit academic research and also allow sponsoring mining and oil/gas companies to develop improved exploration strategies by: 1) providing reconstructions that allow known major ore deposits (of any type) to be traced into greenfield areas on formerly adjacent blocks, 2) enabling enhanced targeting within LIPs that are prospective hosts of orthomagmatic deposits (*e.g.*, Ni-Cu-PGEs) or indirectly contribute to other deposit types (*e.g.*, hydrothermal deposits), and 3) contributing to the oil industry by helping to identify and correlate sedimentary basins formed during supercontinent breakup events. The potential influence of the LIPs identified during this project on hydrocarbon exploration also includes the generation of source rocks (via ocean anoxia events caused by oceanic LIPs), the maturation/ overmaturation of hydrocarbons (via a LIP thermal pulse), and by the development of hydrocarbon traps (e.g. beneath sills).

The LIPs Industry Consortium Project (www.supercontinent.org) was funded by a consortium of 6 Industry Sponsors (mining and oil) who provided $1.5 million over 5 years for research into LIPs around the world, focusing on dolerite dyke and sill swarms from LIP events extending back through Proterozoic time. This industry funding was supplemented by a matching NSERC-CRD grant and other funds, enabling a robust complementary program of graduate student research (in geochronology, geochemistry and geophysics) on LIPs.

Co-authors: Kevin Chamberlain, University of Wyoming, Laramie, WY; Ulf Söderlund, Lund University, Lund, Sweden; Michiel 0 de Kock, University of Johannesburg, Auckland Park, South Africa; Tobias Kampmann, , , ; Emilie Larsson, , ,

Published Material: Some of the ID TIMS ages and paleomagnetism of the Westerberg Sill Suite were presented at the 2014 October GSA Meeting in Vancouver, Canada. These results are currently under review. The in situ dating is new material

Abstract Body: The Great Oxygenation Event (GOE) in the Paleoproterozoic coincides with a complex series of glacial episodes preserved in supracrustal successions on the world's cratons. These Paleoproterozoic glacial rocks are bracketed in age between 2.46 and 2.22 Ga, based on the glacial record in the Huronian Supergroup on the Superior Craton in Canada). In southern Africa, the cover successions of the western Kaapvaal Craton preserve possible glacial correlatives of the Huronian Supergroup in the Griqualand West sub-basin of the Transvaal Supergroup. This potential correlative is the glacial diamictites of the Makganyene Formation. The Makganyene Formation is in turn conformably overlain by the Ongeluk Formation, a series of subaqueous mafic volcanic rocks with a putative age of ca. 2.22 Ga. However, both local and global correlations using glacial units of the Transvaal and Huronian supergroups are hampered by a lack of robust well-placed geochronological data. The timing of the Ongeluk Formation itself has been challenged. Here, the sub-volcanic sills of the Ongeluk volcanic rocks have been dated using U-Pb in-situ SIMS analysis on baddeleyite to ca. 2.43 Ga. This has been coupled with ID TIMS dating and paleomagnetism studies on the coeval Westerberg Sill Suite. This suggests that the Ongeluk Formation volcanic rocks, and the immediately underlying Makganyene Formation glacial deposits, are approximately 200 Myr older than generally assumed. These new ages lend support to three glacial epochs around the GOE, of which the first was low-latitude in the Makganyene Formation. The Makganyene diamictites could correlate to diamictites from the Duitsland Formation in the more eastern Transvaal sub-basin of the Transvaal Supergroup, with a significant revision of regional stratigraphic correlations, that is in itself not without challenges. In such a scenario, the Ongeluk volcanic rocks could be correlated with the Bushy Bend volcanics, and not the ≤ 2.25 Ga Hekpoort Formation volcanics. This new magmatic event may be linked with the evolution of the Vaalbara continent, the Kenorland supercontinent, and global environmental changes related to magmatism and weathering in the Paleoproterozoic Era.

Title: Zircon U-Pb Constraints on the Age of the Paleoproterozoic Volcano-Sedimentary Succession in the Alta-Kautokeino Greenstone Belt, Alta, Northern Norway

Presenter/First Author: Fernando Corfu, University of Oslo, Oslo,

Presenter/First Author Email: fernando.corfu@geo.uio.no

Co-authors: Andrey Bekker, University of California Riverside, Riverside, CA; Steffen G Bergh, , , ; Don Davis, University of Toronto, Toronto, ON, Canada

Abstract Body: A succession of Palaeoproterozoic mafic volcanic and interlayered carbonate and siliciclastic sedimentary rocks, the Raipas Group of the Alta-Kautokeino Greenstone Belt (Bergh & Torske 1988), is exposed in the Alta-Kvænangen tectonic window beneath the Caledonian nappes in northern Norway. The Raipas Group unconformably overlies the Archean basement and connects with supracrustal sequences of the Karelian Province. The lower part of the Raipas Group is dominated by basaltic lava flows, in part with coarse massive and pillow lavas. Rhytmic tuffaceous units are common at higher levels and silty layers and dolomite, locally stromatolitic, dominate the middle part. Carbonates in the lower volcanic sequence record the Lomagundi positive C-isotope excursion (>+8‰). The upper part of the Raipas Group consists of clastic sedimentary packages, the Skoadduvarri and Luovusvarri sandstones and dolomites (Gautier et al. 1979). The search for zircon in several tuffaceous layers and lava flows was not successful, except for a basal coarse-grained (gabbroic) lava which yielded typical prismatic to skeletal zircon crystals and fragments. Chemically- and air-abraded zircons yielded near concordant results defining an ID-TIMS U-Pb age of 2150 ± 2 Ma. Detrital zircon from the overlying Luovusvarri sandstones, dated by ICP-MS, yield two dominant groups of ages at 3.1 to 2.7 Ga and 2.1 to 1.8 Ga and sparse ages between 2.5 and 2.1 Ga. In two samples the average ages of the youngest grains are 1925 ±7 Ma and 1922 ±7 Ma. The 2.15 Ga age indicates that the Raipas Group lavas formed during rifting of the Fennoscandian Shield (opening the Kola Ocean) while the overlying sandstones (~1.9 Ga in age) might be foreland basin deposits related to the Lapland-Kola Orogeny (Torske & Bergh 2004; Daly et al. 2006).

Title: A Late Mesoproterozoic Exterior Laurentia–Baltica Margin; Implications for Rodinia Reconstructions

Presenter/First Author: Trond Slagstad, Geological Survey of Norway, Trondheim,

Presenter/First Author Email: trond.slagstad@ngu.no

Co-authors: Nick M W Roberts, NERC Isotope Geosciences Laboratory, Keyworth, NG12, United Kingdom

Abstract Body: The existence of a Precambrian supercontinent - Rodinia - was proposed in the 1970s, when several geologists noted the existence of orogenic belts of similar age (ca. 1.0 Ga) that today are located on different continents. Along with paleomagnetic data, correlating these belts has been the main tool for reconstructing Rodinia. The amalgmation of Laurentia, Baltica and Amazonia, represented by the Grenville, Svecornorwegian and Sunsas orogenies, respectively, is integral in most Rodinia reconstructions. However, this interpretation is not uniquely supported by the paleomagnetic data.

A number of authors have proposed very similar orogenic evolutions in the Grenville and Sveconorwegian Provinces. Although this is broadly correct with respect to timing, recent models for the Sveconorwegian and Grenville Provinces, based on extensive mapping, geochronology and petrology, suggest that rather than forming an eastward continuation of the collisional Grenville Province, the Sveconorwegian remained an active margin throughout the Grenville-Sveconorwegian orogeny. Furthermore, the Sveconorwegian province does not preserve evidence requiring collision with a major landmass. This new interpretation is compatible with the an exterior Laurentia–Baltica margin, imposing an important constraint on Rodinia reconstructions. Correlating orogenic belts based mainly on age data, with only scant knowledge of the tectonic nature of the belt, is inherently risky. This is easilly understood when appreciating the complexity of modern contintental margins, such as the southwest margin of Asia, with tectonic environments ranging from major continent-continent collision zones, zones of major strike-slip movement and extensive and long-lived magmatic arcs. We propose that the Late Mesoproterozoic Laurentia–Baltica margin displayed a similar complexity.

Title: Laurentia – Siberia Connection: An Update with Evidence From Provenance and Magmatic Evolution Studies

Presenter: Robert Rainbird, Geological Survey of Canada, Ottawa, ON

Presenter Email: Rob.Rainbird@NRCan-RNCan.gc.ca

First Author: Andrei K Khudoley, St. Petersburg State University, St. Petersburg,,

First Author Email: akhudoley@gmail.com

First Author Student?: No

Abstract Body: Continental reconstructions that display a connection between Siberia and Laurentia since the amalgamation of Nuna ca. 1.9-1.8 Ga are well supported. Their separation is considered to be mainly between ca. 780 and 720 Ma.

Paleomagnetic data support a north Laurentia – south Siberia connection, but allow for several options, which can be tested by comparing their magmatic events and provenance evolution.

The youngest orogenic belts in the Siberian Craton are ca. 1.9-1.8 Ga. In contrast, eastern Laurentia is defined by the 1.8-1.6 Ga Yavapai and Mazatzal provinces and adjacent ca. 1.45-1.0 Ga Grenville Province. The pre-780 Ma clastic units of northwestern Canada contain distinctive Grenvillian detrital zircons supporting a paleogeographic model whereby extensive river systems transported detritus across Laurentia to its northern margin. However, in Siberia broad distribution of Grenvillian detrital zircons is known only in upper Mesoproterozoic – lower Neoproterozoic successions on the SE margin of the Siberian Craton, and, partly, on the SW margin of Siberia. Such provenance is not recorded in comparable successions located on the northern margin of Siberia.

Proterozoic inliers of the Wernecke and Ogilvie mountains along with Great Bear Lake area host evidence for mafic magmatism at ca. 1.74, 1.67, 1.59, 1.38, 1.27, 0.78 and 0.72 Ga. Mafic magmatic events at 1.75-1.7, 1.67, 1.34 and 0.78-0.72 are recognized in the southern Siberia. In northern Siberia, mafic magmatic events at ca. 1.75, 1.5 and 1.38 Ga are documented, but there is no evidence for younger events.

Provenance and magmatic events studies as well as paleomagnetic data show that north Laurentia – south Siberia connection remains the most viable option. Of concern is the location of Pearya terrane in the early Neoproterozoic. If it was a part of Laurentia, it has no counterpart on the south Siberian margin and a separate landmass between Siberia and Laurentia is required.

Title: Microbial Community Behavior Recorded in Cuspate Microbialites from the Mesoproterozoic Dismal Lakes Group

Presenter/First Author: Julie K Bartley, Gustavus Adolphus College, Saint Peter, MN

Presenter/First Author Email: jbartley@gustavus.edu

Co-authors: Linda C Kah, University of Tennessee, Knoxville, TN; Tracy D Frank, Univ Nebraska, Lincoln, NE

Published Material: The model for microbialite formation was published in the January 2015 issue of *Geobiology* and presented at the 2013 GSA Annual meeting. The speculation about 2-community behaviors is developed more fully in this submission.

Abstract Body: Offshore facies of the Mesoproterozoic Dismal Lakes Group, arctic Canada, preserve microbialites composed of ridge-like vertical supports draped by concave-upward, sub-horizontal elements, resulting in cuspate microbialites with substantial primary void space. These microbialites constitute the lower platform facies of the September Lake reef complex and likely formed in water depths greater than several tens of meters. Morphological and petrographic analyses suggest that structures formed as neutrally buoyant organic mats. Carbonate precipitation within mats was concurrent with growth of the microbial structures and either stabilized or facilitated collapse of otherwise neutrally buoyant forms. Structures were then further stabilized by precipitation of marine herringbone cement.

The two distinct components of these microbialites, vertical supports and horizontal draping laminae, suggest the presence of two distinct microbial communities with different mat-forming behaviors. Similar vertical elements are observed in a variety of modern natural and experimental settings and are associated with motile, filamentous organisms; upward movement typically occurs in response to light or nutrient pressures. In contrast, sub-horizontal laminae more closely resemble mats dominated by non-motile forms.

We suggest that these unusual microbialites are a product of interaction between communities dominated by motile and non-motile microbial members under nutrient-limiting conditions. Mats likely contained a combination of photosynthetic and chemosynthetic communities that either (1) grew across an oxic–anoxic interface, with vertical elements influenced by oxic waters, and draping elements influenced by anoxic conditions; or (2) grew under low-oxygen conditions across a chemical interface, where sulfidic conditions prevailed in the higher vertical elements and ferruginous conditions dominated the lower, horizontal elements. The abundance of coniform stromatolite forms in the Proterozoic—across a variety of depositional environments—may thus reflect a combination of distinct community behavior, combined with elevated carbonate saturation state, together permitting growth and preservation of a diversity of coniform microbialite structures.

Title: Petrology, Structure and Chemostratigraphic Correlation of Chehmit inlier, Tigrai, Northern Ethiopia. Tadele Tesema[1], Mulugeta Alene[1], Nicholas L. Swanson-Hysell[2], Adam C. Maloof[3]

Presenter/First Author: Tadele Tesema Hundessa, Addis Ababa University, Addis Ababa,

Presenter/First Author Email: tadele.tesema@aau.edu.et

Published Material: This work was partly presented at 24th colloquium of African geology that was held in Addis Ababa, Ethiopia from january 8-14, 2013. The study is still undergoing for better understanding of paleo geography and the then earth history from the stratigraphic sequences of Tambien Group.

Abstract Body: Abstract

The Chehmit area is one of the six exposed Neoproterozoic inliers in northern Ethiopia, which consists of both Tsaliet and Tambien Group rocks. The metavolcanics, metavolcanoclastics and phyllite rocks exposed in the area represent the Tsaliet Group whereas the mixed clastic-carbonate metasedimentary rocks constitute the Tambien Group. The ash within the Werii Slate that has been dated at 815 Ma constrain the maximum depositional age of the Tambien Group. An integrated structural, petrological and carbon and oxygen isotope study has been carried out to understand the deformation, metamorphic and Neoproterozoic history of the area. Field structural data demonstrate that there are at least three phases of deformations. Earliest deformation produced minor, steep tight folds and N-S trending, pervasive regional foliation; followed by the formation of major upright folds, and latest brittle structures. Petrographic study of rock samples from the area shows predominantly lower green schist facies metamorphism coeval with the earliest phase of deformation. Stable C and O isotope analysis was carried out on limestones in a stratigraphic section through the Assem Formation in the area. The limestone unit contains an anomalous C-isotope signature that enables local and global correlations with other Neoproterozoic formations. The $\delta^{13}C$ values of limestone in a stratigraphic section through the Assem Formation in the Chehmit area range from -5.8‰ to -2.0‰ with an average value of -3.8‰ while the values of $\delta^{18}O$ range from -7.1‰ to -14.2‰ with an average value of -11.3‰. Although negative carbon isotope excursions in the Neoproterozoic era are often in close stratigraphic relationship with glacial deposits, no glaciation features or erosion surfaces are observed in this unit. Instead, the negative C-isotope excursion is correlated with the Bitter Springs Stage anomaly (found in Australia, NW Canada and Svalbard) which is hypothesized to be the result of inertial interchange true polar wandering. The extended interval of low $\delta^{13}C$ values obtained from the studied limestone indicates a correlation with the Bitter Springs anomaly. Radiometric dating and paleomagnetic studies of the rocks of the Chehmit area can be used to test this correlation.

Title: Petrogenesis of the Cryogenian (850-750 Ma) Imorona-Itsindro Suite, Central Madagascar: Insights into pre-Gondwana Arc Formation Using Zircon Isotopic Proxies

Presenter/First Author: Donnelly Archibald, University of Adelaide, Adelaide, SA

Presenter/First Author Email: donnelly.archibald@adelaide.edu.au

Co-authors: Alan S Collins, University of Adelaide, Adelaide, Australia; John Foden, University of Adelaide, Adelaide, Australia; Justin L Payne, University of Adelaide, Adelaide, Australia; Peter Holden, Australian National University, Canberra, Australia; Bert De Waele, , , ; Theodore Razakamanana, Université de Toliara, Toliara, Madagascar

Abstract Body: Madagascar occupies an important location within the East African Orogen, which involves a collection of Neoproterozoic microcontinents and arc terranes lodged between older cratonic units during the final assembly of the supercontinent Gondwana. The Imorona-Itsindro suite of central Madagascar represents voluminous Cryogenian (850-750 Ma) magmatism with different geochemical characteristics interpreted to signify contemporaneous emplacement in varied tectonic settings. While the age of the magmatic suite is widely accepted, the origin and geochemical nature of magmatism is poorly understood. Arc magma generation is suspected to coincide with oceanic plate subduction during closure of the Mozambique Ocean along the Betsimisaraka Suture in eastern Madagascar. Recently, others have questioned the existence of a Neoproterozoic suture in Madagascar and suggest extension related emplacement into the middle and upper crust through a system of pre-existing fractures. In this comprehensive geochemical study of the Imorona-Itsindro suite, we present new whole rock geochemical data, coupled with microbeam U-Pb, Hf and O zircon isotopic analysis that demonstrates that the suite had several sources from contaminated mantle melts to crustal melts. The spatial variation of these sources is discussed that yields new insights into the origin of this diverse magmatic suite and shed its significance for the closure of the Mozambique Ocean during the amalgamation of Gondwana.

Title: Ediacaran paleomagnetism and paleogeography of Tarim craton

Presenter: David AD Evans, Yale University, New Haven, CT

Presenter Email: david.evans@yale.edu

First Author: Bin Wen, Nanjing University, New Haven, CT

First Author Email: benwen2013@gmail.com

First Author Student?: No

Co-authors: Yongxiang Li, Nanjing University, Nanjing, China

Abstract Body: Tarim craton, western China, is one of the building blocks of Rodinia supercontinent, variously reconstructed on the northern or eastern margins of Australia. If the latter position is correct, then Tarim would form part of the “missing link” between Australia and Laurentia in standard Rodinia models. Precambrian rocks are exposed around the edges of Tarim craton, including our field area in the NW (Aksu-Wushi) region. There, Cryogenian metasedimentary rocks are cut by undated mafic dykes and then unconformably overlain by a sporadically exposed diamictite (Yuermeinak Fm) and cap carbonate, which are then conformably overlain by redbeds and overlying Sugetbrakredbeds and basalts. In northeastern exposures of our study area, these strata appear to have been extensively remagnetized in mid-late Paleozoic time; such remanence directions are similar to those reported previously from the SugetbrakFmin the same area (Zhan et al., 2007Precamb Res 154, 143-158). In southwestern exposures, a two-polarity, N-up/S-down characteristic component is identified from 36 sites. This direction is distinct from all published Phanerozoic results derived from Tarim craton, and it passes a regional fold test (implying a pre-Permian age of remanence) and an inverse baked-contact test on a mafic dyke that may be Carboniferous-Permian in age, based on its remanence direction and prevalence of magmatism of that age in the region. A reversal test using site-level statistics yields a positive C-class rating. Our result is also

substantially different from the recently published Cryogenian pole from the same area (Wen et al., 2013Precamb Res 226, 75-90), implying significant APW / continental motion for Tarim during Cryogenian-early Ediacaran time. Relative to quasi-static Australia, Tarim rotated substantially through that interval, probably related to Rodinia breakup.

Title: Depositional Setting of Algoma-type Banded Iron Formation from the Meadowbank, Meliadine and Musselwhite gold deposits

Presenter/First Author: Blandine Gourcerol, Laurentian University, Sudbury,

Presenter/First Author Email: gourcerol.blandine@gmail.com

Co-authors: Phillips C Thurston, Laurentian University, Sudbury, ON, Canada; Daniel Kontak, Mineral Exploration Research Centre, Sudbury, ON, Canada; Olivier Côté Mantha, , , ; John Biczok, Goldcorp, Thunder Bay, ON, Canada

Published Material: 40% of the material is submitted for an GSC Open File on the TGI-4 researches

Abstract Body: Algoma-type Banded Iron Formations (BIFs) are chemical sedimentary rocks comprised of alternating layers of iron-rich minerals and chert interstratified with bimodal submarine volcanic rocks in Archean greenstone belts. However, the geologic setting for Algoma-type BIF deposition remains equivocal due to the overprinting effects of post-depositional deformation and metamorphism and the absence of modern analogues for comparative studies. Recent studies suggest the abundance of REE+Y in chert bands may reflect the primary BIF geochemical signature and therefore may constrain geological settings favourable for BIF deposition.

In this study, the results of LA ICP-MS on chert at three BIF-hosted gold deposits are presented to assess whether epigenetic gold mineralization is preferentially developed within a particular geochemical type of BIF. The three deposits studied were: (1) Meadowbank deposit (Churchill Province); (2) Meliadine gold district (Churchill Province); and, (3) Musselwhite deposit (Superior Province). The results of this study, which explore rare earth elements (REE) and yttrium as tracers of depositional processes for Algoma-type BIF, suggest that chert bands record: (1) interaction of seawater with Fe-oxyhydroxides, as suggested by heavy rare earth element enrichment coupled with La and Y enrichment; (2) high-temperature (>250 ºC) hydrothermal fluids, as suggested by positive Eu excursions; and (3) hydrogeneous contamination, which is suggested by relatively consistent REE concentrations and a chondritic Y/Ho ratio. Moreover, the pH conditions of the water column at the time of BIF deposition are evaluated using Ce/Ce* as a pH proxy, which suggest acidic seawater conditions associated with positive Ce/Ce* anomalies. This data set does not suggest there is a preferred chemical type of BIF for epigenetic gold mineralization.

Title: IF, GIF, and two BIF in northwest Canada: time-space relationships and depositional environments

Presenter/First Author: Luke Ootes, Northwest Territories Geoscience Office, ,

Presenter/First Author Email: luke_ootes@gov.nt.ca

Co-authors: Kurt Konhauser, University of Alberta, Edmonton, AB, Canada; Rasmus Haugaard, University of Alberta, Edmonton, AB, Canada; Andrey Bekker, University of California Riverside, Riverside, CA; Ernesto Pecoits, University of Alberta, Edmonton, AB, Canada; Natalie Aubet, , ,

Abstract Body: Bedrock exposures in northwest Canada preserve many relevant features critical to understanding Precambrian Earth history. One of these is iron formation (IF), whose physical and chemical attributes uniquely provide details regarding the composition of Precambrian seawater and environmental change. Two distinct types of banded IFs are preserved in the Slave craton. The older was deposited at ca. 2.85 Ga and precipitated on top of fuchsitic quartzite, unconformably overlying basement gneisses. The BIFs are up to 10 m thick and consist of micro- and meso-bands of chert and magnetite. They are generally overlain by massive to pillowed basalt flows or, locally, by pebble conglomerates. The younger BIF type occurs as 5 to 10 m thick beds of interlaminated chert-magnetite-carbonate, with local grunerite and sandstone beds, within ca. 2.62 Ga turbidite packages. These BIFs are preserved across the craton in a southwest to northeast fashion and represent a significant hiatus in turbidite deposition to allow for the chemical precipitation and preservation. The deep-water nature of these Neoarchean BIFs is in stark contrast to the more shallow nature of the Mesoarchean BIFs.

In the East Arm basin, south of the Slave craton, up to 9 m of ca. 1.88 Ga granular IF is preserved within green, grey, and red shales of the Gibraltar Formation in the Great Slave Supergroup. This GIF contains hematite-jasper, and its granular nature, along with ripple marks and local stromatolites, attest to the shallow-water deposition of this iron formation on a marine shelf. The age is similar to that of the Gunflint Iron Formation in the Superior craton, which is also granular and was deposited in a shelf environment. In the northern Mackenzie Mountains, up to 120 m of ca. 700 Ma IF is preserved in the Rapitan Group. It consists of hematite with chert-carbonate nodules and less common individual jasper and hematite beds up to 10 cm thick. The upper exposure of the IF contains granular hematite, perhaps indicating an upward-shallowing depositional environment. Unlike the older IFs, the Rapitan Iron Formation was deposited under glacial conditions of the Sturtian Snowball Earth and represents a return to IF deposition after a 1.15 Ga hiatus.

Title: Detailed Geochemistry and Nd isotopes of a 2.85 Ga old BIF from the Slave Craton: Unraveling the Seawater Sources and Precipitation of Iron and Silica in BIF Formation

Presenter/First Author: Rasmus Haugaard, University of Alberta, Edmonton, AB

Presenter/First Author Email: rasmus@ualberta.ca

Co-authors: Luke Ootes, Northwest Territories Geoscience Office, , Canada; Robert A Creaser, University of Alberta, Edmonton, AB, Canada; Kurt Konhauser, University of Alberta, Edmonton, AB, Canada

Abstract Body: Banded iron formations (BIFs) are metamorphosed chemical sediments that initially precipitated from Precambrian ocean water. The alternating bands of silica and iron contain important information about the composition of seawater at the time of BIF formation, as well as the relative contributions of hydrothermal discharge and continental weathering. In this work we use the combination of geochemistry and Sm-Nd isotopes on a layer-by-layer basis of the ~2.85 Ga old BIF from the Central Slave Cover Group (CSCG). The bulk of the CSCG is composed of oxide BIF underlain by fuchsitic quartzite that unconformably rests on basement gneisses. Seven silica bands and seven iron bands were separated from the BIF. Geochemical analyses show that in all the bands Al_2O_3 is < 1 wt.%, with less in the silica bands (average 0.12 wt.%) relative to the iron bands (average 0.41 wt.%). Highly insoluble elements, such as Ti, Zr, Nb and Th, are elevated in the iron bands relative to the silica bands. Both the total REE concentrations and the shale-normalized REE patterns reveal a systematic difference, with higher REE content and a more elevated LREE patterns for the iron bands. This, together with the higher abundances of insoluble elements, points towards a larger terrigenous input during precipitation of the iron. However, a well-developed Eu anomaly occurs in all the bands suggesting some mixing of high-T hydrothermal fluids with the upper seawater. The iron bands have consistently depleted $e_{Nd}(t)$ values between +1.0 to +2.8 (average of +1.7) reflecting that the dissolved REEs in the source water during ferric iron precipitation may have contained a mixture of submarine hydrothermal fluids and bulk upper seawater dominated by more evolved continental sources. The silica bands, on the other hand, show a higher spread in their $e_{Nd}(t)$ values. Four of the bands have enriched $e_{Nd}(t)$ values of -2.2, -1.2, -0.6 and -0.4 (average of -1.1) and three of the bands have depleted $e_{Nd}(t)$ values of +1.7, +2.4 and +3.4 (average of +2.5). This trend suggests that both evolved and more depleted continental landmasses contributed to the dissolved REE budget of the ambient surface seawaters during silica precipitation.

Title: The Mobility Of Biologically Critical Transition Metals Following Simulated Iron Formation Diagenesis: Zinc and Nickel

Presenter/First Author: Leslie James Robbins, University of Alberta, Edmonton, AB

Presenter/First Author Email: lrobbins@ualberta.ca

Co-authors: Stefan Lalonde, European Institute for Marine Studies, Plouzane, France; Elizabeth Swanner, University of Tübingen, Tübingen, Germany; Merle Eickhoff, , , ; Christopher T Reinhard, California Institute of Technology, Pasadena, CA; Caroline Peacock, University of Leeds, Leeds, United Kingdom; Andreas Kappler, University of Tübingen, Tübingen, Germany; Kurt Konhauser, University of Alberta, Edmonton, AB, Canada

Published Material: These findings have been submitted to, and reviewed by the journal of Chemical Geology. A revised manuscript was recently resubmitted, and is currently being considered for publication.

Abstract Body: Banded Iron Formations (BIF) are iron- and silica-rich chemical precipitates deposited during the Precambrian. They have proven to be a key paleoenvironmental proxy, particularly with regards to the availability of biologically critical elements, such as zinc (Zn) and nickel (Ni), which play key roles in eukaryotic and prokaryotic metalloenzymes, respectively. Recent investigations into the BIF record indicate a stable paleomarine reservoir for Zn, while for Ni a dramatic decline is indicated immediately prior to the great oxidation event. However, what remains cryptic regarding the BIF record is the possible influences of post-depositional effects. Here, we examine the mobility of Zn and Ni from ferric oxyhydroxides, in the absence and presence of organic matter, during simulated pressure-temperature diagenesis (1.2 kbar and 170ºC). Following a two-week diagenetic treatment, that captures the critical mineral transformation from ferrihydrite to hematite, both metals were strongly retained, regardless of the presence of organic matter. Indeed, more than 90% of both metals were retained following diagenesis; hematite was the predominant iron mineral in the non-organic matter experiments, while siderite, magnetite and hematite formed in the carbon-bearing experiments. These results further support the use of BIF for examining the paleomarine trace elements concentrations, and that the authigenic records of Zn and Ni are faithfully recorded in well preserved BIF despite post-depositional alteration.

Title: Did Archean mantle plume events stimulate or limit marine productivity?

Presenter/First Author: Andrey Bekker, University of California Riverside, Riverside, CA

Presenter/First Author Email: andrey.bekker@ucr.edu

Abstract Body: Iron Formations are a hallmark of Archean chemical sedimentation, yet the impact of associated mantle plume events on biological productivity in the oceans is poorly understood. Iron Formations typically have low organic carbon content, but are commonly stratigraphically associated with organic matter-rich shales. Low organic carbon contents in iron formations have been explained by oxidative remineralization of organic matter in presence of co-precipitated iron oxyhydroxides. To understand the impact of mantle plume events on biological productivity in the Archean oceans, it is critical to know what in general controlled organic productivity and burial in the Archean oceans and how high they were.

We approach this question from the perspective of biogeochemical carbon cycle under largely anoxic surface conditions typical for the Archean. Since organic carbon from older sediments would not be oxidized during continental weathering, carbon isotope mass balance requires that carbonate carbon released from older sedimentary successions during continental weathering would also not be utilized for biomass production. As a result, Archean organic productivity and burial were limited and processed only juvenile, mantle-derived carbon. The limitation was likely imposed by a smaller flux of nutrients delivered from the continents under anoxic surface conditions. Mantle plume events that led to deposition of iron formations could have also resulted in a higher flux of nutrients to seawater via submarine hydrothermal processes and acidic weathering conditions, induced by a higher volcanic flux of CO_2 and SO_2 to the atmosphere. We thus suggest that on a geological timescale mantle plume events could have led to enhanced marine productivity, which might explain associated, short-lived oxidation events before the GOE.

Title: Precambrian Secular Evolution of Oceanic Nickel Concentrations

Presenter/First Author: Kurt Konhauser, University of Alberta, Edmonton, AB

Presenter/First Author Email: kurtk@ualberta.ca

Co-authors: Ernesto Pecoits, University of Alberta, Edmonton, AB, Canada; Caroline Peacock, University of Leeds, Leeds, United Kingdom; Leslie James Robbins, University of Alberta, Edmonton, AB, Canada; Andreas Kappler, University of Tübingen, Tübingen, Germany; Stefan Lalonde, European Institute for Marine Studies, Plouzane, France

Abstract Body: Iron formations (IF) preserve a history of Precambrian oceanic elemental abundance that can be exploited to address nutrient limitations on early biological productivity. In 2009 we reported that secular trends in IF Ni/Fe ratios record a reduced flux of Ni to the oceans ca. 2.7 billion years ago, which we attribute to decreased eruption of Ni-rich ultramafic rocks[1]. We determined that dissolved Ni concentrations may have reached ~400 nM throughout much of the Archean, but dropped below ~200 nM by 2.5 Ga and to modern day values (~9 nM) by ~550 Ma. As Ni is a key metal cofactor in several enzymes of methanogens, its decline would have stifled their activity in the ancient oceans and disrupted the supply of biogenic methane. Here we provide an updated compilation of Ni concentrations and Ni/Fe ratios in Precambrian iron formations based on a greatly expanded (>3 fold) dataset. We frame our rock record compilation in the context of new experiments examining the partitioning and mobility of Ni during simulated diagenesis of Ni-doped iron formation mineral precursors, as well as a fresh look at Ni-Fe scaling relationships in IF vs. modern Fe-rich chemical sediments. While its potential effects on atmospheric oxygenation remains to be fully resolved[2], our new results reaffirm the Paleoproterozoic Ni famine, whereby the enzymatic reliance of methanogens on a diminishing supply of volcanic Ni links mantle cooling to the trajectory of Earth surface biogeochemical evolution.

Title: Exploring Relationships Between the Chemical Evolution of the Atmosphere-Ocean System and the Secular Variation in BIF-hosted Gold Deposits

Presenter/First Author: Camille A Partin, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: camille.partin@usask.ca

Abstract Body: As one of the most readily recognized and intriguing chemical sedimentary rock types, banded iron formations (BIFs) also serve as a useful and elegant archive of ocean chemistry. Their apparent secular distribution throughout geologic time has influenced models of evolving ocean chemistry for decades—that more or less stand today, with some important modifications. Recent intensive research concerning chemical changes in BIFs throughout geologic time has greatly expanded our knowledge of changing redox conditions as well as understanding controls on biological evolution. In particular, this work suggests that a dramatic change developed in the Orosirian period (2.05 to 1.8 Ga) resulting in a lower redox state of the atmosphere-ocean system. In contrast to the preceding Siderian and Rhyacian periods (2.5 to 2.05 Ga) that experienced high (modern-like?) oxygen levels, the Orosirian period records a deoxygenation event. There is a notable decrease in the abundance of some trace elements in BIFs, including U, Co, Zn, and Cr, after the end of the Lomagundi Excursion (ca. 2.06 Ga). The same trend is observed in organic matter-rich shales that show a shift in isotopic values and significantly lower trace element abundances. This time interval also coincides with a major peak in orogenic gold deposit occurrences (ca. 2.1 to 1.85 Ga) typically associated with BIFs. While this new model of evolving redox-state of the atmosphere-ocean system has been developing over the last few years, the implications of dynamic oxygen levels in the Proterozoic has not been fully explored. This talk will explore recent advances in our knowledge of the evolving redox state of the Precambrian atmosphere-ocean system, especially in the Orosirian period, and use this to consider ideas regarding controls on secular variations in mineral deposit occurrences.

Title: Petrology and geochemistry of pillow lava bearing volcanic rocks form the Nuvvuagittuq greenstone belt: implications for early crust formation settings

Presenter/First Author: Meghan Moher, University of Ottawa, Ottawa,

Presenter/First Author Email: mmohe072@uottawa.ca

Co-authors: Jonathan O'Neil, University of Ottawa, Ottawa, ON, Canada

Abstract Body: Rare remnants of ≥3.6 Ga supracrustal rocks are the only samples available to study the formation of the primitive crust and the early environments in which it formed. With a possible age of ~4.3 Ga, the Nuvvagittuq Greenstone Belt (NGB) located on the east coast of the Hudson Bay in the Northeastern Superior Province, provides a glance at what these primitive settings may have looked like. The proposed Hadean age of the NGB comes from the irregular ^{142}Nd isotopic compositions of garnet-cummingtonite-biotite layered rocks called the Ujaraaluk unit. Deviation in ^{142}Nd from modern terrestrial mantle can only be produced before 4.0 Ga, while the parent isotope (^{146}Sm) was still actively decaying. The $^{142}Nd/^{144}Nd$ vs. Sm/Nd correlation observed in the Ujaraaluk unit is thus consistent with a pre-4.0 Ga formation age. The Ujaraaluk unit is generally basaltic in composition and divided into three distinct geochemical groups following a stratigraphy reminiscent of volcanic successions found in modern convergent margins. The layered texture of the Ujaraaluk unit however, could be suggestive of a sedimentary origin. Disagreements about the exact formation age of the NGB arise in part from the vague origin of the Ujaraaluk rocks. This research will investigate the petrology and geochemistry of pillow-bearing rocks to the SW and SE of the NGB in order asses their potential genetic link with the Ujaraaluk unit. Preliminary results suggest that these volcanic rocks follow the same chemostratigraphy as the Ujaraaluk unit with samples exhibiting ^{142}Nd deficits falling on the same $^{142}Nd/^{144}Nd$ vs. Sm/Nd Ujarraluk correlation. This will help to better constrain the nature of the protolith of the NGB lithologies, crucial to interpret geochronological results, and provide a better picture of early supracrustal environments.

Title: Petrological and Geochemical Study of Cordierite-Orthoamphibole Rocks from the Nuvvuagittuq Greenstone Belt: Evidence for Seawater Hydrothermal Alteration of Oceanic Crust in the Hadean?

Presenter/First Author: Evelyn Y Abramovitch, University of Ottawa, Ottawa,

Presenter/First Author Email: eabra083@uottawa.ca

Co-authors: Jonathan O'Neil, University of Ottawa, Ottawa, ON, Canada

Abstract Body: With a possible age of ~4.3 Ga, the Nuvvuagittuq Greenstone Belt (NGB) may represent the only remnant of Hadean crust available to study Earth's earliest environments. The NGB is dominated by mafic rocks called the Ujaraaluk unit. The Ujaraaluk preserves a chemostratiraphy ranging from pillow-bearing basaltic rocks at the base of the sequence displaying tholeiitic affinities, to rocks sharing geochemical signatures with modern-day boninites, and basaltic andesites of calc-alkaline affinities at the top. Chemical sediments (banded iron formation) are found at the transition between the tholeiitic and the boninitic basalts. The geochemical stratigraphy in the NGB closely matches what is observed in the modern-day Izu-Bonin-Mariana forearc, suggesting similar petrological processes were involved in its formation. If the igneous age of the NGB is indeed Hadean as suggested by the $^{142}Nd/^{144}Nd$ vs. Sm/Nd correlation observed in the Ujaraaluk unit, it offers the unique opportunity to study the primitive oceanic crust and better understand the Hadean environments in which it formed. This study focusses on the petrology and geochemistry of a specific rock type within the Ujaraaluk unit composed of cordierite-orthoamphibole observed in all three distinct geochemical Ujaraaluk groups. They display high magnesium and low calcium contents consistent with seawater alteration of basaltic crust. Preliminary data show that they exhibit ^{18}O depletion (close to mantle values) with respect to other Ujaraaluk samples [1]. These signatures suggest that the cordierite-orthoamphibole rocks could have been formed in a VMS-type (Volcanogenic Massive Sulfide) hydrothermal system and represent Hadean seawater-altered oceanic crust. This would suggest that VMS-type hydrothermal environments were already present nearly 200 million years after the Earth's formation and can help to further expand our understanding of early crust formation.

Title: Lithogeochemistry and distribution of 4.0–3.4 Ga units of the Acasta Gneiss Complex, NWT, Canada

Presenter/First Author: Jesse Ray Reimink, University of Alberta, Edmonton, AB

Presenter/First Author Email: reiminkjesse@gmail.com

Co-authors: Tom Chacko, University of Alberta, Edmonton, AB, Canada; Richard A Stern, University of Alberta, Edmonton, AB, Canada; Larry Heaman, University of Alberta, Edmonton, AB, Canada

Published Material: A preliminary version of this information was presented in talk form at the Northwest Territories Geoscience Forum, November 2014.

Abstract Body: The Acasta Gneiss Complex (AGC) has long been known to contain rock units with crystallization ages close to 4.0 Ga (Bowring and Williams, 1999; Stern and Bleeker, 1997) making them the oldest known evolved rock units in the world. However, the AGC has experienced a long and complex history with multiple periods of igneous intrusion, deformation and metamorphism. Indeed, previous workers have demonstrated that orthogneisses within the AGC have igneous ages ranging from ~4.03 to ~3.4 Ga (Iizuka *et al*., 2007). This large range in crystallization ages gives us the opportunity to investigate the evolution of Earth's earliest known continental crust through a period of greater than 600 million years.

The geochemical signatures present in some of the oldest rock units are distinct from the TTG suite of granitoids (Reimink *et al.,* 2014), a suite of rocks commonly thought to represent the major contributor to growth of continental crust in the Archean (Moyen and Martin, 2012). Archean TTGs are formed by deep-seated melting of a hydrated basaltic precursor in the presence of significant garnet, potentially in a subduction-like environment while the some of the oldest components of the AGC have geochemical signatures indicating high degrees of fractional crystallization and shallow-level fractionation of plagioclase.

Here we present an updated geologic map of key areas within the Acasta Gneiss Complex in which we delineate units based upon age as well as composition. Recently acquired whole-rock geochemistry, LA-ICPMS zircon U-Pb geochronology and SIMS O-isotope analyses of zircons from a large suite of key samples indicate a significant change in mode of crust formation by 3.6 Ga. These data document a gradual change from a shallow crustal processes generating basaltic to andesitic compositions between 4.0-3.75 Ga, to deep-seated partial melting of hydrated basalt, represented by voluminous Archean TTG intrusion at 3.6 Ga.

Title: The Zircon Hf Isotopic Record of the Acasta Gneiss Complex

Presenter/First Author: Ann Bauer, Massachusetts Institute of Technology, Cambridge, MA

Presenter/First Author Email: annbauer@mit.edu

Co-authors: Samuel A Bowring, Massachusetts Institute of Technology, Cambridge, MA; Jeffrey D. Vervoort, Washington State University, Pullman, WA; Christopher M Fisher, Washington State University, Pullman, WA

Published Material: Goldschmidt (2014) talkAGU (2014) posterThere will be new whole rock Hf and Nd data, new whole rock geochemical data, and new zircon Hf data (about 30% of the zircon Hf data will be new).

Abstract Body: The Acasta Gneiss Complex (AGC) of the Slave Craton in the Northwest Territories, Canada, comprises compositionally and isotopically diverse gneisses with crystallization ages of 3.3 to >4.0 Ga. Whole rock geochemical data and inherited zircons up to 4.2 Ga indicate the involvement of even older crust in their generation[1,2]. The rocks of the AGC have undergone a complex history of metamorphism and deformation[1,3] and, as a consequence, the zircons retain this complex history including inheritance, magmatic and metamorphic overgrowths, recrystallization, and multi-stage Pb loss.

We obtained coupled U-Pb and Lu-Hf in zircon data as well as whole rock compositional and isotopic (Sm-Nd and Lu-Hf) data. The complicated nature of the rocks and minerals has necessitated design of an experimental approach that allows us to obtain accurate and representative isotope compositions. For some samples, our solution and laser analytical approaches yield coherent initial ε_{Hf}, however, some more complicated samples demonstrate variable Hf within individual zircon grains and within gneiss samples and require isotopically distinct components.

Our data are generally consistent with published Hf data from the Acasta Gneiss Complex[4-7] and demonstrate involvement of 4.0 Ga or older crust in younger generations of crust. There are no rocks with zircon Hf isotopic signatures consistent with derivation from a LREE-depleted source; instead, the measured compositions may reflect mixing between a compositionally evolved and relatively unradiogenic reservoir with a reservoir bearing a more radiogenic signature. The simplest interpretation is that these rocks formed in an environment that allowed crustal melting, assimilation and rapid recycling.

Title: Petrological and geochemical investigation of the Eoarchean crust from the Saglek-Hebron Complex, Northern Labrador

Presenter/First Author: Benjamin Wasilewski, University of Ottawa, Gatineau,

Presenter/First Author Email: bwasi082@uottawa.ca

Co-authors: Jonathan O'Neil, University of Ottawa, Ottawa, ON, Canada; Hanika Rizo, Carnegie Institution for Science, Washington, DC

Abstract Body: The Saglek-Hebron Complex is located in Northern Labrador and is part of the Nain Province. The Eoarchean rocks include two suites of supracrustal assemblages, both composed of metavolcanic and metasedimentary lithologies. The oldest suite consists of the Nulliak assemblage which is estimated to be ~3.8 Ga, with Sm-Nd systematics suggesting an older age of ~4.0 Ga [1] for the mantle-derived rocks. Therefore, the Nulliak assemblage represents one of the oldest suites of mantle-derived rocks at the surface of the Earth and could shed light on the formation of the primitive crust and early mantle evolution. The Nulliak unit is intruded by the ~ 3.6 Ga Uivak gneisses, which could be derived from an older mafic component. Supracrustal rocks from the Upernavik assemblage are consistent with a younger emplacement age of ~3.5 Ga. In order to constrain the formation and evolution of the early crust, here we present a preliminary petrological and geochemical study of well-preserved supracrustal rocks from the Nulliak assemblage (Pangertok and Aupaluttok areas) as well as rocks from the younger Upernavik assemblage. These mafic metavolcanic rocks are mainly composed of hornblende + plagioclase ± garnet of variable grain size. Identification of deformed pillow lavas in both supracrustal assemblages and alternation of the mafic metavolcanic rocks with quartz-biotite-garnet schists is consistent with volcano-sedimentary environments of deposition. Preliminary trace and major element data will also help constraining the composition and formation setting of these ancient volcanic rocks. It has been suggested that the Saglek-Hebron Complex may have been related to the well-studied Eoarchean Itsaq Gneiss Complex in Southwest Greenland [2].

Published Material: Some data was presented in at GAC-MAC 2014Bath, O., Hattori, K., Biczok, J., 2014. Young un-metamorphosed sedimentary rock in the North Caribou greenstone belt. *Joint Annual meeting of the Geological Association of Canada and Mineralogical Association of Canada, Fredericton, NB. Abstract*

Abstract Body: This study characterizes the sedimentary rocks in the eastern portion of the North Caribou Greenstone Belt, which hosts the Musselwhite Au deposit. The center of the belt is comprised of siliciclastic rocks of the Eyapamikama Lake Assemblage (ELS) and Zeemal Heaton Lake Assemblage (ZHL). The ZHL is close to the terrane boundary with the Island Lake Domain and the Totogon shear zone. Quartz-rich wackes of the ZHL contain detrital zircon grains of igneous origin (Th/U ~ 0.6) with fine oscillatory zoning. They show a wide range of morphologies and yielded three age populations; 2698-2750, 2844-2903 and 2970-2985 Ma. These rocks show elevated MgO (>1%), Ni (>104 ppm), Cr (>180 ppm) and low REE (>88 ppm) and a relatively undifferentiated signature (Th/Sc: 0.67-0.83, $[Ce]_N/[Yb]_N$: 8.1-19, Cr/Zr: 1.3-2.1). They display εNd(2.7 Ga) of -0.97 to +0.50 and DM model ages of ~2.88 Ga. The data indicates a provenance of surrounding batholiths as well as mafic and 2.7 Ga igneous rocks. These sediments contain X_{sp} (0.246-0.414), X_{alm}(0.378-0.548) garnet and ferro-tschermakite, indicating the peak metamorphism under lower amphibolite facies conditions followed by greenschist retrogression chlorite, epidote and actinolite. Quartz-rich wackes of the ZHL show a gradual decrease in metamorphic grade to the east where garnet composition (X_{sp} ~0.381) indicates peak greenschist facies conditions. The arkosic sediments in the central portion of the belt show one population of detrital zircon ages between 2800-2850 Ma. Zircons display similar morphology and lower Th/U (~0.44). Bulk rocks contain low Mg (<1%), Ni (<24 ppm), and Cr (<50 ppm), relatively high REE (104-166 ppm) and an evolved signature (Th/Sc: 0.8-2.1, $[Ce]_N/[Yb]_N$: 14-21, Cr/Zr: 0.07-0.27). εNd(2.85Ga) of -0.14 to +0.77 and DM model ages of 2.92-2.95 Ga, suggesting a provenance primarily derived from the surrounding batholiths (~2.85Ga). They garnet (X_{grs}0.136-0.196, X_{alm}0.606-0.678, X_{pyr}0.038-0.053). These amphibolite facies sediments show varied compositional zoning of garnet, suggesting protracted history of metamorphism.

Title: Characterizing the Archean rocks of eastern Hall Peninsula, Baffin Island, Nunavut, Canada: An integrated approach using U-Pb and Lu-Hf isotopes

Presenter/First Author: Richard Eric From, University of Manitoba, Winnipeg, MB

Presenter/First Author Email: fromr@myumanitoba.ca

Co-authors: Nicole Rayner, , , ; Qiao Shu, University of Alberta, Edmonton, AB, Canada; Alfredo Camacho, University of Manitoba, Winnipeg, MB, Canada; Graham D Pearson, University of Alberta, Edmonton, AB, Canada

Published Material: The U-Pb SHRIMP geochronology was presented at the Geological Society of America's 2014 annual conference in Vancouver. The format was an oral presentation. The Hf data was briefly mentioned at the end of the presentation but not fully presented.

Abstract Body: Archean rocks of eastern Hall Peninsula, Baffin Island were involved in a period of accretionary tectonism from ca. 1.88 to 1.80 Ga in the Northern Labrador – Baffin Island – West Greenland segment of the Trans-Hudson orogen. Eastern Hall Peninsula lies in the middle of this multiple-stage, three-way collision between the Rae craton, the North Atlantic craton and the Meta Incognita microcontinent with the possible involvement of other microcontinent fragments (e.g. the Aasiaat domain of West Greenland). Consequently, several different interpretations of crustal suture locations are possible and paleo-plate reconstructions of this region have been hindered by the fact that the rocks of eastern Hall Peninsula remain poorly understood. The geologic history of these Archean rocks on eastern Hall Peninsula may hold the key to establishing regional crustal correlations and is also important for the exploration industry with the known presence of diamondiferous kimberlites.

Detailed mapping in a well-exposed study area on east-central Hall Peninsula has highlighted the heterogeneity of this Archean block that was previously thought to be a relatively homogeneous suite of tonalitic to monzogranitic gneiss. Zircon from seven samples from the study area have been analyzed for both U-Pb (Sensitive High Resolution Ion MicroProbe) and Lu-Hf (Laser Ablation Inductively Coupled Plasma Mass Spectroscopy) isotopes in the same spots. The new U-Pb age data bracket the duration of Archean magmatism to ca. 2.99 to 2.72 Ga and document previously unrecognized Archean metamorphism from ca. 2.72 to 2.69 Ga. These Archean magmatic zircons, for the most part, have positive εHf values (+13 to -5) that are typical of magmas that have been derived from the mantle. Hf model ages (T_{DM}) indicate magma derivation from the mantle at ca. 3.00 Ga. One sample with significantly more negative εHf values (-8 to -31) and older T_{DM} ages of ca. 3.50 Ga indicate that it was a melt derived from a re-worked, older crustal source. Additional samples using U-Pb, Lu-Hf and Sm-Nd isotopes will further characterize these Archean rocks and allow comparisons of data from adjacent Archean blocks.

Title: ID-TIMS Geochronology on Precambrian zircons from northern Quebec: treatment, complications and results

Presenter/First Author: Cornelia Roffeis, GEOTOP-UQAM, Montreal,

Presenter/First Author Email: c.roffeis@gmail.com

Co-authors: Yannick Daoudene, University of Quebec at Montreal, Montreal, QC, Canada; Francois Leclerc, Ministry of Natural Resources and Wildlife, Val-d'Or, Canada

Abstract Body: During an ongoing mapping project founded by the ministry of energy and natural resources of Quebec, several plutonic and volcanic samples from areas around Lebel-sur-Quevillon and Chibougamau were selected for ID-TIMS geochronology.

Determination of the Precambrian crystallisation age of these samples has proven difficult due to the metamict nature of the zircons. Nearly all grains show radiation damage. During preliminary analyses it became evident that chemical abrasion leads to better results than zircons treated with air abrasion. The problem was the correct measure of chemical abrasion on such metamict zircons. No systematic study was found on time relations and effects on zircons during the partial dissolution process. One cause might be the variable response of grains from the same sample to the leaching acid. This may be due to microstructures in the zircons, which are invisible during picking. The widely used overnight partial dissolution in HF has proven to be too aggressive for the zircons used in this study. Most of them dissolved, the few remaining ones were very fragile and disintegrated on touch. After experimenting with different dissolution times, six hours was determined as the ideal time, where most of the grains remained largely intact but where the partial dissolution was strong enough to improve concordance. Preliminary analyses of three samples reveal formation ages of 2727 ± 7 Ma for a tonalite in the Holmes Pluton, 2686 ± 5 Ma for the Tonnancourt granite and 2774 ± 26 Ma for a migmatite in the Opatica Subprovince. Special attention was given to the migmatite sample since it shows the oldest age gained from that sampling area so far. Initial data point towards two discordia lines with upper intercepts close to each other, one at 2774 ± 26 Ma formed by grains that appear to be magmatic, the other at 2723 ± 1 Ma formed by strongly rounded, metamorphic looking grains. The interpretation of these two lines is not straight forward. In the easiest explanation it would reveal an intrusive age of 2774 Ma and metamorphism at 2723 Ma, however, discordance due to later events obscures the data. Different stages of magmatic evolution and a much later metamorphic overprint remain possible and will be investigated by further research involving CL images and laser ablation.

Title: Structural geology, geochemistry and geochronology of transpressive deformation zones in the North Caribou greenstone belt, NW Superior

Presenter/First Author: Emilie Gagnon, University of Ottawa, Gatineau, QC

Presenter/First Author Email: egagn023@uottawa.ca

Co-authors: David A Schneider, University of Ottawa, Ottawa, ON, Canada; John Biczok, Goldcorp, Thunder Bay, ON, Canada; Alfredo Camacho, University of Manitoba, Winnipeg, MB, Canada

Published Material: GSA Vancouver 2014: October 19-22, 2014. Session: Deformation Localization throughout the Crust. Title: Relationships between regional metamorphism and transpression in shear zones of the Archean North Caribou greenstone belt, NW Superior Province

Abstract Body: The Archean North Caribou greenstone belt (NCGB), host to the Musselwhite gold deposit, possesses abundant transpressive deformation zones on its northern margins, which appear to have formed under amphibolite facies conditions. Protracted deformation and regional metamorphism are coeval with widespread magmatism and accretion events of the Superior Province, and are responsible for folding the ore-hosting BIF and channeling fluids. The importance of these shear zones in the tectonic evolution of the NCGB and their relationship with metamorphism is equivocal, yet structural analyses support a transpressive system that produced steeply-dipping planar and shallow-plunging linear fabrics that trend broadly parallel to the doubly arcuate shape of the belt. This strongly implicates horizontal tectonism, which is partly in contrast with some currently proposed models for Archean greenstone belts that suggest the formation of shear zones at granite-greenstone contacts is during synchronous vertical and horizontal movement. Moreover, geochemical and microstructural analyses from shear zones in the central part of the belt indicate deformation occurring above 500°C under dry conditions (e.g. Dinnick Lake shear zone), whereas monazite recrystallization seems to record fluid-facilitated deformation in the southern arm (e.g. Markop Lake deformation zone). In situ total-Pb geochronology of small (<100 µm) monazites from high strain zones and K-Ar ages of fabric forming micas were obtained in an attempt to resolve the timing of deformation recorded in shear zones. The ages are consistent with protracted metamorphism and deformation corresponding to the amalgamation of the Superior craton from ca. 2.75 to 2.4 Ga. A strong 2.5-2.4 Ga signature is recorded in many deformation zones and may be a consequence of the regional large igneous provinces throughout the Superior during this period. The heterogeneous nature of deformation during the 400 m.y. tectonothermal evolution of the belt and the high metamorphic grade of the host rock may obscure tectonic signatures, however some structural and geochemical characteristics are consistent with other greenstone belts (e.g. Hemlo, Yilgarn) where vertical and horizontal tectonism may be responsible for channeling fluids.

Title: Tectono-metamorphic evolution of the contact between the Opinaca and La Grande Subprovinces, Superior Province, Quebec: implications for Archean tectonics and regional metallogeny

Presenter/First Author: Antoine Rhéaume Ouellet, Laval University, Québec,

Presenter/First Author Email: antoine.rheaume-ouellet.1@ulaval.ca

Co-authors: Carl Guilmette, Université Laval, Québec, QC, Canada; Jean Goutier, Géologie Québec, Rouyn-Noranda, QC, Canada; François Huot, Laval University, Québec, QC, Canada

Published Material: The project was presented at Québec Mines 2014 (Nov 17-20), in Québec city, in the form of a poster.

Abstract Body: The contact between the Opinaca and La Grande Archean Subprovinces in the Superior Province is host to many of the region's gold showings and deposits. However, the processes leading to their assembly are still poorly understood. The La Grande Subprovince (3.45 - 2.57 Ga) is an assemblage of volcano-sedimentary sequences, tonalitic basement and various instrusions of medium metamorphic grade. It is mainly in tectonic contact to the south with the metasediments of the Opinaca Subprovince, where anatexy is widespread. The individual tectono-metamorphic evolution of both subprovinces is still weakly constrained, with very few quantified metamorphic conditions and ages having been reported. Accordingly, the general tectonic setting for their assembly remains unclear. The present contribution aims at characterizing peak and retrograde metamorphism along two transects intercepting the Opinaca-La Grande contact with the use of thermobarometry, pseudosections and Lu-Hf, Sm-Nd and U-Pb geochronology. The resulting information will be synthetized in the form of pressure-temperature-time (P-T-t) paths, from which information on the geodynamic context can be drawn and confronted to existing models. The two main models proposed for the Opinaca-La Grande assembly (metamorphic core complex versus accretion complex) have important implications for exploration models, but also for tectonic processes that may or may not have been active at such scale during the Archean. Furthermore, the similarity of the Opinaca-La Grande architecture with other metasedimentary-volcanoplutonic successions in the Superior may help draw conclusions for the formation of the Superior and Archean tectonics in general. A better understanding of the tectono-metamorphic evolution of these medium to high-grade metamorphic terranes will likely provide new insights in the metallogeny of gold deposits in such environments.

Title: Structural and Metamorphic Study of the Attic Complex in the Lebel-sur-Quévillon Area, Archean Superior Province, Québec.

Presenter/First Author: Nicolas Revelli, GEOTOP-UQAM, Montréal,

Presenter/First Author Email: nicolas.revelli@gmail.com

Co-authors: Yannick Daoudene, University of Quebec at Montreal, Montreal, QC, Canada; Alain Tremblay, GEOTOP, Montréal, QC, Canada; Hanafi Hammouche, , ,

Abstract Body: Archean cratons mainly consist of TTG-type plutonic terranes and greenstone belts. In the Superior Province of Quebec, the geology of these units is usually well understood and documented, but their tectonic and metamorphic relationships remain debated. For instance, the contact between the Abitibi Greenstone Belt (AGB) and the Opatica plutonic belt (OPB) has been interpreted as a north-dipping Archean subduction zone. Ongoing studies rather suggest that the OPB represents a deeper domain of an AGB-OPB composite crust. Concurrently, several structural domains within the AGB, such as the Attic Complex of the Lebel-sur-Quévillon area, represent larges areas (more than 600 km^2 for the Attic Complex) of TTG intrusions in the core of antiforrnal domes surrounded by more-or-less linear greenstone belts. In the summer of 2014, the northwestern part of the Attic Complex has been studied in detail during a regional mapping program of the Quebec-MRN. In this segment of the Attic Complex, the tonalite of the Holmes Pluton intrudes the mafic volcanic-plutonic rocks of the ca. 2718 Ma Quevillon Group. Both, the Holmes pluton and hosting volcanic rocks show an E-W trending, north-dipping regional schistosity axial-planar to syn-kinematic folds. To the north, the Holmes pluton is bounded by a NW-SE trending subvertical shear zone. The kinematics of this shear zone remains to be clearly determined but a south-directed variation from greenschist- to amphibolite metamorphic grade on both sides of the structure suggests down-faulting of the Quevillon Group relative to the Holmes Pluton. Our preliminary interpretation is that the Holmes Pluton represents a synmetamorphic and syntectonic intrusion. The geological characteristics of the study area are similar to those of the contact zone between the AGB and the OPB. If such a comparison is correct, the structural and metamorphic study of the Attic Complex should permit to better understand the architecture of the Abitibi Archean crust and to investigate the nature of the basement of the AGB.

Title: Insights into Archean greenstone belt evolution: Evidence from compilation of high precision U-Pb zircon data in the southern Abitibi subprovince, Canada

Presenter/First Author: Ben M. Frieman, Colorado School of Mines, Golden,

Presenter/First Author Email: bfrieman@mines.edu

Co-authors: Yvette D Kuiper, Colorado School of Mines, Golden, CO; Nigel M. Kelly, , , ; Thomas Monecke, Colorado School of Mines, Golden, CO

Abstract Body: The geodynamic significance of the chronostratigraphic record in the southern Abitibi subprovince (SAS), which forms part of the Superior Province, was investigated through the compilation of existing high precision U-Pb geochronology data. These data, compiled from the Canadian Geochronology Knowledgebase and other pertinent publications, represent the newest and most complete compilation to date. They reveal that early construction of the SAS was episodic and dominated by ~2750-2695 Ma volcanic and intrusive processes. Composite submarine volcanic packages are heterogeneously distributed throughout the SAS, and were synchronous with construction of spatially restricted composite tonalite-trondhjemite-granodiorite batholiths. Five chronologically distinct volcanic episodes are identified that lasted ~10-15 Myrs each. The episodic volcanism was followed by the deposition of the sedimentary rocks of the ~2695-2680 Ma Porcupine/Pontiac and the ~2680-2670 Ma Timiskaming episodes. The appearance of the sedimentary episodes is synchronous

with granitoid intrusive activity, which may be the result of accretionary tectonic processes.

Compilations of detrital U-Pb zircon grain ages indicate that sedimentary rocks in the SAS were largely derived from local volcanic rocks. However, they also display patterns of provenance that are distinct from one another and contain older (>2750 Ma) secondary detrital age populations that do not occur in SAS supracrustal rocks. These populations are best correlated to ages identified in the adjacent Wabigoon and Opatica subprovinces, or to inheritance from underlying felsic SAS protocrust. However, similarly old zircon ages are identified in the North Caribou, Hudson Bay, or Rivière Arnaud terranes to the north. Overall, the chronostratigraphic progression identified in the SAS is representative of greenstone belts worldwide and reflects large-scale geodynamic processes, which may include subduction-related accretionary tectonic processes.

Title: Evidences of linkage of the Cadillac Larder Lake Fault Zone inherited from preexisting structures, Abitibi Subprovince, Quebec

Presenter/First Author: Pierre Bedeaux, Université du Québec à Chicoutimi, Chicoutimi, QC

Presenter/First Author Email: pierre.bedeaux@gmail.com

Co-authors: Pierre Pilote, Ministère des Ressources Naturelles, Boucherville, Canada; Silvain Rafini, CONSOREM, Chicoutimi, QC, Canada; Réal Daigneault, Centre d'études sur les Ressources minérales (CERM), Chicoutimi, QC, Canada

Abstract Body: The Cadillac Larder Lake Fault Zone (CLLFZ) constitutes a major deformation zone in the southern Abitibi Subprovince ranging from Ontario to Quebec. Numerous deformation events comprising thrusting, extension and strike-slip movements are recorded. In the Quebec portion of the fault, the CLLFZ display different geometries, fabrics and shear sense indicators which lead to subdivide the fault into four segments which are from west to east: 1) Rouyn, 2) Joanna, 3) Malartic and 4) Val-d'Or segments. The fault in these segments is generally E-trending except for the Malartic segment where it is SE-trending. The first event correspond to a N-S shortening and thrusting event displayed by a subvertical E-trending schistosity and dip-parallel stretching lineations present in all 4 segments. An exhumation event displayed by normal shear-sense indicators along with a subhorizontal cleavage is observed in the Timiskaming Group in the Rouyn segment and locally expressed in the Joanna segment. In the Rouyn and Joanna segments where the fault is moderately dipping to the north, a NW-trending cleavage is related to a third event. All segments display the final late dextral strike-slip movement with common shear-sense indicators and subhorizontal stretching lineations but this event is more prominent in the Malartic segment. In this segment, the E-trending main foliation display an anticlockwise angular relationship with bedding planes suggesting an initial architecture already SE-trending. Recording of each deformation event varies through space, as some segments do not express specific deformation event. While dip-parallel stretching lineations are observed in all segments, the Malartic segment and some specific corridors within other fault segment display strike-parallel stretching lineations. The CLLFZ is interpreted to be inherited from the linkage of several early independent discontinuities of different nature during the late strike-slip event.

Title: Progress in Characterizing Regional Metamorphism in the Pontiac Subprovince, Abitibi, Quebec

Presenter/First Author: Nicolas Piette-Lauzière, Laval University, Québec,

Presenter/First Author Email: nicolas.piette-lauziere.1@ulaval.ca

Co-authors: Carl Guilmette, Université Laval, Québec, QC, Canada; Pierre Pilote, Ministère des Ressources Naturelles, Boucherville, Canada; Stephane Perrouty, Western University, London, ON, Canada

Abstract Body: The volcano-sedimentary Pontiac Archean Subprovince is located in the Eastern part of the Superior Province, South of the Cadillac-Larder Lake Fault Zone and the Abitibi Subprovince. Its strong metamorphic gradient has been qualitatively described by many workers, but recent advances in thermodynamic databases now allow a systematic quantification of its geodynamic evolution to be established. The recognition of the the Canadian Malartic world-class gold deposit located in the lower-grade section of the Pontiac also calls for a better understanding of the timing, nature and extent of regional metamorphism in the area, particularly of the timing relationships between deformation and metamorphic recrystallization. This contribution presents preliminary results derived from field and petrographic observations across the biotite-in, garnet-in, staurolite-in and kyanite-in isograds in Pontiac metasediments.

During the summer of 2014, fieldwork has been carried out in collaboration with the MERN South of Val-d'Or and Malartic. Following field observations, the description of metamorphic assemblages in thin sections helped to document mineral textures, infer reactions and assess their relationship with deformation. In the study area, the main stable mineral assemblages, listed from North to South, are biotite-chlorite-muscovite, garnet-biotite-chlorite-muscovite, staurolite-garnet-biotite-muscovite and staurolite-garnet-biotite-muscovite-kyanite. According to available phase diagrams for metapelites, the observed metamorphic gradient would be of the order of 25°C/km with maximum peak conditions in the order of 550°C and 6 kbar (qtz-pl-bt-ms-grt-st-ky). Upcoming multi-equilibria thermobarometry, P-T pseudosections and Lu-Hf Sm-Nd dating of garnet will help further constrain the Pontiac metamorphic evolution. Results will be integrated as precise P-T-t-D paths that will help quantify the Pontiac metamorphic gradient and will suggest an appropriate type of tectonic setting corresponding to its accretion to the Abitibi Subprovince.

Title: Structural Analysis of the Ridout Deformation Zone in the Swayze Greenstone Belt, Ontario

Presenter/First Author: Qihang Wu, University of Waterloo, Waterloo,

Presenter/First Author Email: qihang.wu@uwaterloo.ca

Co-authors: Shoufa Lin, University of Waterloo, Waterloo, ON, Canada

Published Material: 2014 Canadian Tectonic Group MeetingWu, Q. and Lin, S. 2014. Structural and tectonic study of the Ridout shear zone; in Summary of Field Work and Other Activities 2014, Ontario Geological Survey, Open File Report 6300, p.8-1 to 8-5.

Abstract Body: The Swayze Greenstone Belt is the western extension of the mineral-rich Abitibi Greenstone Belt. Despite being separated by the Kenogamissi Batholith, they share similar lithological assemblages and chronological framework. The Ridout Deformation Zone is a crustal-scale structure that transects the Swayze Greenstone Belt. Its structural

evolution and relationship with the gold-prolific Larder Lake-Cadillac Deformation Zone are unclear, but important for both tectonic interpretation and mineral exploartion. Our field and microscopic structural analysis demonstrates that the Ridout Deformation Zone has experienced at least four generations (G_1 to G_4) of deformation. Evidence for G_1 deformation is scarce and it is characterized by local preservation of a penetrative cleavage. G_2 deformation is characterized by S-asymmetry drag folds and crenulation cleavage oriented clockwise to earlier fabrics, and is interpreted to be an oblique shearing with sinistral and N-side-up components. G_3 is characterized by Z-asymmetry drag folds and δ- and σ-type asymmetrical porphyroclasts and quartz boudins, and is interpreted to be a dextral shearing with dominant strike-slip movement. G_4 is characterized by N-S-oriented brittle fractures, interpreted to be associated with regional NNW-SSE-trending faults. Our results are consistent with those of earlier structural studies in the Swayze Greenstone Belt and support that the Ridout Deformation Zone is indeed a regional-scale structure that has experienced multiple phases of reactivation. Contrary to an earlier interpretation, our results show that the Ridout Deformation Zone is similar to the Larder Lake-Cadillac Deformation Zone in terms of kinematic evolution.

Title: Provenance Analysis by Coupled U-Pb, Hf, and O Isotopic Analysis of Detrital Zircon from the Paleoproterozoic Murmac Bay Group, Northern Saskatchewan, Canada

Presenter/First Author: Christine Shiels, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: christine.shiels@usask.ca

Co-authors: Camille A Partin, University of Saskatchewan, Saskatoon, SK, Canada

Abstract Body: The Murmac Bay Group (MBG) is a Paleoproterozoic-aged sedimentary succession deposited on the southern margin of the Rae craton in northwestern SK. There is currently an open question regarding the depositional setting of the upper MBG, whether it may have transitioned from a rift basin (lower MBG) to a passive margin, or an intracratonic or foreland basin setting. The depositional period has recently been constrained through U-Pb dating of detrital zircon grains at <2.33 to <2.17 Ga (160 million years), while constraints from metamorphism suggest a basin lifespan of up to 400 million years. The latter is anomalously long if the Murmac Bay basin is a typical passive margin like today's Atlantic Ocean. The poorly known basin tectonic setting and provenance coupled with the few existing detrital zircon samples from the MBG warrant further study with detrital zircon geochronology. In the first phase of this study, U-Pb detrital zircon and basement geochronological data from previous studies in the region were compiled, and several possible source locations in the surrounding Rae, Hearne, and Slave cratons were identified using the DateView database by comparing peak ages in the detrital zircon data with dated igneous rocks. The proximity and position of the Rae, Slave, and Hearne cratons is debated widely in the literature, but can be addressed using MBG detrital zircon provenance. Coupled U-Pb, Hf and O isotopic provenance analysis is an essential second step, in order to distinguish between possible igneous sediment sources. No previous detrital zircon Hf isotope studies have been conducted on the MBG, but there are existing Hf isotope studies of regional Archean and Proterozoic plutonic rocks, allowing for rigorous testing of specific zircon sources, including the ~2.3 Ga source that is present in nearly all MBG samples and is assumed to be locally sourced from the surrounding Beaverlodge Domain. A source for the youngest (~2.17 Ga) zircon grains found in the MBG remains enigmatic, however candidate sources exist on the Slave craton that can be further resolved using Hf isotopes. New coupled U-Pb, Hf, and O isotopic data will elucidate a possible tectonic setting by distinguishing between local vs. continental derived sources, providing insight into the positions of these cratons during MBG deposition.

Title: Stromatolites from the Lomagundi-Jatuli Isotopic Event Interval

Presenter/First Author: Pavel Medvedev, Russian Academy of Sciences, Petrozavodsk,

Presenter/First Author Email: pavel_medvedev@yahoo.com

Published Material: Medvedev P.V., Chazhengina S.Y., Svetov S.A. Application of Raman spectroscopy and high-precision geochemistry for study of stromatolites. Biogenic-abiogenic interactions in natural and anthropogenic sistem. V International Symposium. Saint Petersburg: VVM Publishing Ltd., 2014, p. 108-110.

Abstract Body: The main biotic event during the 2.2-2.1 Ga carbon isotope excursion is an expansion of cyanobacterial communities that is reflected in geological record by abundance of stromatolites, especially cm-sized buildups (ministromatolites) in the carbonate successions. The Paleoproterozoic ministromatolite assemblages are described on the Fennoscandian shield, in China, India, Northern America and Australia. Stromatolites are mineralized microbial buildups, which vary in morphology, have carbonate composition and characteristic fine lamination. Morphology of the buildups is defined by microbial comunity as well as environmental conditions. Stromatolite formation is a result of complex biogenic and abiogenic processes. Asuming that stromatolites are microbial buildups, it is necessary to prove their biogenic origin. For the purpose there are a number of criteria, one of them is presence of synsedimentary carbonaceous matter within individual laminae. Paleoproterozoic (2.0-2.2 Ga) stromatolites from drill cores of the ICDP Project FAR DEEP were studied by Raman spectroscopy (RS) and ICP mass spectroscopy (LA-ICP MS) methods. Carbonaceous matter (CM) was identified by Raman spectroscopy within individual stromatolites laminae. The Raman spectra for CM in stromatolite samples are consistent with poorly ordered CM. According to Raman data the metamorphic alteration temperatures of CM from studied stromatolites are ca. 400 – 450 °C (greenschist facies). Thus, we can assume that the CM of these stromatolites has the syngenetic origin. Profiling geochemical microsampling of the stromatolites has revealed considerable variations in the concentrations of trace elements induced by the internal heterogenecity of the structures. Many elements display multi-order cycles, which are indicated by variation in the step length between the peaks on the variation curves. Morphological features of the studied Paleoproterozoic stromatolites together with identification of synsedimentary carbonaceous matter by Raman spectroscopy are strong argument for biogenic origin of these carbonate buildups. Precision geochemical analysis of the stromatolite laminae composition links to sedimentary settings and environmental conditions of the microbialite formation.

Title: Is the Williston Basin the site of a Proterozoic accretionary triple junction?

Presenter/First Author: Jennifer N Gifford, St Lawrence University, Canton, NY

Presenter/First Author Email: giff4088@ufl.edu

Co-authors: Paul A Mueller, Univ Florida-Geology Dept, Gainesville, FL; David A Foster, University of Florida, Gainesville, FL

Published Material: I cite data which was published in 1991 by Sims, et al. I also presented a few of my initial geochron ages at the annual GSA meeting in Vancouver, CA in October 2014.

Abstract Body: The Great Falls Tectonic Zone (GFTZ) strikes NE to SW through Montana, and is one of a series of collisional belts, including the north-striking Trans-Hudson Orogen (THO) to the east, that formed during the amalgamation of Laurentia (suturing of the Wyoming, Medicine Hat, and Hearne Provinces). Testing the numerous models for these accretionary belts depends on high quality geochronology in critical areas. One such area is the basement to the Williston Basin (WB), near the presumed juncture of the GFTZ and THO. Poorly constrained Rb-Sr whole-rock model ages, Rb-Sr whole-rock isochrons, and K-Feldspar isochrons using samples from several Deep Test Wells (DTW) that penetrated the WB basement suggested ages from 0.65 Ga to 2.9 Ga. Existing U-Pb geochronology includes only 7 discordant analyses yielding upper intercept ages ranging from 1.7-2.9Ga.

New elemental and isotopic data improve the estimates for protolith ages, thermal history, and petrogenesis of the basement at this critical juncture. Initial geochronology from cores in northeast Wyoming and west-central Montana yield ages of ~2.9 and ~3.0 Ga, while a third sample in northeast Wyoming yielded an age of ~2.6 Ga. These ages overlap with previously reported ages from the Wyoming province and help refine the location of the northern margin of the Wyoming Province and its relation to the THO and GFTZ, respectively. DTW AMJ-6 is located at the presumed intersection of the GFTZ and THO in NW Montana, and a basement sample yielded an age of ~1.8 Ga. DTW MT-3, located in NE Montana, also yielded an U-Pb age of ~1.8 Ga, revealing further influence from the Paleoproterozoic orogenies. These ages overlap with ages reported from both the GFTZ and the THO, confirming the geodynamic problem implied by the high angle intersection of the THO and GFTZ at the location of the WB.

Title: Reassessment of the intersection of the Great Falls Tectonic Zone and the Trans-Hudson Orogen through petrologic and geochronological analysis of Deep Test Well derived sample

Presenter/First Author: Ethan James Matchinski, Saint Lawrence University, Canton, NY

Presenter/First Author Email: ejmatc11@stlawu.edu

Co-authors: Jennifer N Gifford, St Lawrence University, Canton, NY; Paul A Mueller, Univ Florida-Geology Dept, Gainesville, FL; David A Foster, University of Florida, Gainesville, FL

Published Material: References geochronological measurments taken previously, which are cited. Petrographic and geochronological analysis pertaining to sample AMJ-6 are original.

Abstract Body: The Great Falls Tectonic Zone (GFTZ) is a Paleoproterozoic collisional belt, marked by high angle, northeast-southwest striking structures cutting across central to northeastern Montana. The GFTZ joins with the similarly aged, north-south striking collisional belt of the Trans-Hudson Orogen (THO) in the subsurface of the Williston Basin. The GFTZ and THO represent important accretionary events in the ~1.7-1.9 Ga amalgamation of Laurentia; however, our understanding of their role in this event is hampered by limited age control and knowledge of tectonic setting.

Deep Test Wells (DTW) within the Williston Basin basement, near the triple-junction of the GFTZ and THO, provide samples for petrographic and isotopic analysis. Previously published data for this region is restricted to Rb-Sr whole-rock model ages, Rb-Sr whole-rock isochrons, and K-Feldspar isochrons, ranging in age from ~0.65-2.9 Ga. Existing U-Pb geochronology, includes 7 discordant analyses, yielding ages ranging from ~1.7-2.9 Ga. This study intends to refine the current understanding of Williston basement age and magmatism through new U-Pb dating of zircons from DTW AMJ-6 and thorough petrographic analysis.

DTW AMJ-6 comprises amphibolitic migmatite (quartzofeldspathic leucosome) and is near the intersection of the GFTZ and THO in northwestern Montana, where a single basement sample yielded a (U-Pb) age of ~1.8 Ga. Thin-section petrography and zircon U-Pb geochronology of samples from the GFTZ further constrain the protolith ages, thermal history, and petrogenesis of the basement at this cratonic intersection. The age is complimentary to ages in both the GFTZ and the THO, validating affinity of the basement in this region. Further work on samples of DTW MAD-1 and AMJ-6 will provide an opportunity to further refine the composition as well as origin of the basement from the collisional regions of both the GFTZ and THO.

Title: Regional Bedrock Mapping and a Comprehensive Geological History of Hall Peninsula, Baffin Island, Nunavut

Presenter/First Author: Holly Miranda Steenkamp, Canada-Nunavut Geoscience Office, Iqaluit, NU

Presenter/First Author Email: holly.steenkamp@nrcan-rncan.gc.ca

Co-authors: Richard Eric From, University of Manitoba, Winnipeg, MB, Canada; Diane Skipton, University of Ottawa, Ottawa, ON, Canada; Cameron MacKay, University of Saskatchewan, Saskatoon, SK, Canada; C. Gabriel Creason, , ,

Abstract Body: The Hall Peninsula Integrated Geoscience Program began in 2012 and is led by the Canada-Nunavut Geoscience Office in collaboration with the Geological Survey of Canada and seven Canadian universities. Regional bedrock mapping and several thematic studies have been conducted over three field seasons to provide new geological knowledge for this otherwise poorly understood area to help develop more accurate tectonic reconstructions and evaluate economic potential. A comprehensive geological history of Hall Peninsula is summarized based on field observations, geochronology, geochemistry and other analytical results.

Eastern Hall Peninsula is underlain by Archean tonalite to quartz-diorite orthogneiss units ranging in age from 2976 Ma to 2701 Ma with evidence of Archean metamorphism at ca. 2730-2690 Ma. Paleoproterozoic supracrustal and intrusive rocks are exposed on western Hall Peninsula. The supracrustal rocks are dominated by pelitic, psammitic, amphibolite and calc-silicate units containing mostly 2.3-1.9 Ga detritus, and are interpreted as correlative with the Lake Harbour Group of southwestern

Baffin Island. These rocks are thought to have been deposited in a proximal shallow-marine to more distal slope-rise to continental-shelf setting with input of mafic material from a nearby volcanic arc or continental rift. Emplacement of granulite-grade monzogranite to diorite intrusions took place around 1892-1852 Ma. Hall Peninsula records three phases of deformation associated with the Trans-Hudson Orogen that have produced thick-skinned, east-verging fold and thrust structures. Related metamorphism took place at ca. 1850-1830 Ma, at medium pressures (~5-7.5 kbar) and peak temperatures increasing from amphibolite facies in the east (~740 C) to granulite facies in the west (>850 C). Ar/Ar cooling ages and thermal modeling of (U-Th-Sm)/He data indicate an extremely slow, protracted cooling history for Hall Peninsula since the late Paleoproterozoic.

Title: Are the amphibolites the source of contamination of iron-formation at Mount-Wright, Canada?

Presenter/First Author: Joëlle Thiboutot Goyette, University of Quebec at Chicoutimi UQAC, Jonquière,

Presenter/First Author Email: joelle.thiboutot-goyette1@uqac.ca

Co-authors: L.P Bédard, Université du Québec à Chicoutimi, UQAC, Chicoutimi, QC, Canada; Hugues Longuepée, , ,

Abstract Body: The iron deposit of Mount-Wright, Fermont, Canada has been exploited since 1970 for high-quality low-grade iron around 30% Fe. The deposit is located in the Gagnon terrain - in the parautochtone of the Grenville. Mount Wright deposit stratigraphy used is the same as the Labrador Through because River (1983) demonstrated the continuity of the units. The iron formation units in contact with amphibolites show higher contamination in Al, Ti and P. Could the amphibolites be the vector to explain this contamination?

Handheld XRF results show a decreasing Al concentration in iron ore from amphibolite contact (measurement in progress). A microXRF map at the contact of amphibolite and iron formation in thin-section show increasing concentration (over 1 mm towards the contact) in Al, K, Mn, P, Ti while Ca, Fe are decreasing. Trace elements in magnetite in iron formation determined by LA-ICP-MS also show a decrease in Cu, Mg, Al toward the contact with the amphibolite while Zn, Ti and Mn increase. Detailed petrography show Ti exsolution lamella of ilmenite in hematite near the contact of the two units and the presence of rutile in the iron formation while hematite farther from the contact show now ilmenite exsolution. Apatite grain size increases from the iron formation nearing the contact and its proportion increases from 0,5 mm from the contact with amphibolite to 1 mm and more at the contact. The P contamination is explained by the presence of apatite, but at this moment, no direct relationship was established with amphibolite. These observations strongly suggest a contamination from the amphibolites to the iron formation. The igneous or sedimentary nature of the amphibolites is being determined. A magmatic origin of the amphibolite dykes would imply a hydrothermal event associated with their injection. Alternatively, a sedimentary origin would imply that metamorphism has favoured transfer of some elements from the amphibolite to the iron formation.

Title: Characterization of Upper Crustal Electrical Anisotropy in the Precambrian Basement of Northern Alberta, Canada From Magnetotelluric data: Implications for Geothermal Development

Presenter/First Author: Mitch Vagn Liddell, Imperial College London, London,

Presenter/First Author Email: m.liddell14@imperial.ac.uk

Co-authors: Martyn Jonathan Unsworth, University of Alberta, Edmonton, AB, Canada

Published Material: Similar results were presented at the AGU 2013 fall meeting, and at the EMIW 2014 conference in Weimar, Germany.

Abstract Body: The development of engineered geothermal systems (EGS) in the oilsands region near Fort McMurray (FMC) Alberta, requires the characterization of the Precambrian basement rocks. We present the results from magnetotelluric (MT) measurements made in the FMC region that were gathered for this purpose. Large phase tensor skew values (> 10°), as well as out-of-quadrant phases, in MT data are commonly interpreted to indicate an underlying 3-D resistivity structure. Here it is shown that this type of data can also be explained with a 2-D anisotropic model. Initial inversions of the MT data on three profiles showed that a 2-D isotropic analysis was not able to explain the measured MT data. Forward modeling showed that a reasonable fit could be achieved with a resistivity model that included widespread basement anisotropy beginning at a depth of 4 - 5 km with a resistivity ratio of 2000/5 Ωm. Aeromagnetic and core sample data allowed a correlation of the basement rocks in the FMC region with the exposed rocks of the Charles Lake shear zone (CLsz) that outcrops on the Canadian Shield 150 km north. The conducting phase of the anisotropy is most likely to be interconnected graphite films deposited during metamorphism on the igneous basement rocks. Fluid-filled fractures or accumulations of sulphide minerals would have a strong seismic interface to match the resistivity interface, this is not observed. These films are interpreted to be due to interconnected graphite films oriented ~S27°E within the metamorphic basement rocks. This direction is reasonably close to the current minimum stress direction of ~S40°E, which could help guide investigations of fracture propagation needed for EGS development.

Title: Digital litho- and chrono-stratigraphic representation of the Proterozoic geology of Australia

Presenter/First Author: Krisztina Pandur, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: lewendula@gmail.com

Co-authors: Bruce M Eglington, University of Saskatchewan, Saskatoon, Canada; Kevin Michael Ansdell, University of Saskatchewan, Saskatoon, SK, Canada

Abstract Body: A combination of regional time-space correlation charts, geochronology, lithostratigraphic information and palaeogeographic reconstructions provide easy visualization and improved understanding of the geodynamic evolution of any geological region. The Palaeoproterozoic geology of North America and Greenland and of southern Africa has previously been synthesized at domain level for IGCP 509 project "Palaeoproterozoic Supercontinents and Global Evolution" (Eglington et al., 2009, 2013). Similar digital data are not available for Australia, making it difficult to produce relevant direct comparisons of the regions. Neumann & Fraser (2007) summarized available lithostratigraphic and geochronological information from Australia for the period 1900 Ma to 1400 Ma as a basis for regional geodynamic models and to facilitate exploration of the abundance of mineral wealth associated with this time interval. Their time-space correlation diagrams are raster images produced in graphics packages which cannot be queried.

Here, we report on progress to create a digital database of tectonic domains, geological events and lithostratigraphic unit details linked to available GIS maps for the region so as to generate time-space charts and time-slice palaeogeographic reconstructions for comparison with other information in the StratDB and DateView databases (available from http://sil.usask.ca). Our ultimate objective is to achieve a global coverage of quantitative regional geological compilations which assist in achieving a better understanding of Precambrian geological evolution and facilitate investigation of the association of various mineralization styles with the timing of regional metamorphism, igneous activity and orogenic events. The digital charts and maps created are consistent with the most current information added to the master database, are readily updated and all information captured will remain available in a digital format for future researchers.

Title: Newly Discovered Sveconorwegian Batholiths in SW Norway

Presenter/First Author: Nolwenn Coint, Norges Geologiski Undersoekels, Trondheim,

Presenter/First Author Email: n_coint@yahoo.fr

Co-authors: Trond Slagstad, Geological Survey of Norway, Trondheim, Norway; Mogens Marker, , , ; Torkil Røhr, , , ; Nick M W Roberts, NERC Isotope Geosciences Laboratory, Keyworth, NG12, United Kingdom

Published Material: A paper about the first batholith we refer to in the abstract, the Sirdal Magmatic Belt, is currently under review.

Abstract Body: Recent mapping in the Rogaland–Vest-Agder region, SW Norway, revealed the existence of two large granitic batholiths emplaced during the Sveconorwegian orogeny. The first one, the Sirdal Magmatic Belt (SMB) was emplaced between 1070 and 1020 Ma, followed by the Hornblende Biotite Granites (HBG suite) emplaced between 980 and 920 Ma, changing the whole perspective on the regional geology. Previously mapped as high-grade gneisses, the SMB is mainly composed of variably porphyritic biotite granite that cuts granulite-facies rocks, indicating that high-grade metamorphism occurred at a regional scale before the emplacement of the belt. The SW tip of the SMB was metamorphosed later on during the emplacement of the Rogaland Igneous Complex, composed mainly of anorthosite. The later event was accompanied by extensive granitic magmatism and the emplacement of the second batholith (HBG suite). The HBG suite has been mapped as individual plutons, but airborne geophysical data suggest that they are connected in the subsurface and compose one or several batholiths formed around 950 Ma. These new findings do not support the continent-continent collision setting for the Sveconorwegian orogeny, but instead seem to require a long-lived active margin.

Title: Sequence Stratigraphic Correlation and the Age of Diagenesis in the Pandurra Formation, South Australia

Presenter/First Author: Steve Ray Beyer, Queen's University, Kingston,

Presenter/First Author Email: beyer@geol.queensu.ca

Co-authors: T Kurtis Kyser, Queen's University, Kingston, ON, Canada; Paul A Polito, , , ; Garth L Drever, Raven Minerals Corp., Toronto, ON, Canada; James M Marlatt, , ,

Abstract Body: The Mesoproterozoic Pandurra Formation is an unmetamorphosed, relatively flat-lying unit of siliciclastic redbeds up to 1500 metres thick that was deposited on the northeastern Gawler Craton (GC), South Australia. The Pandurra Formation is a key geological unit of the GC, as it records the first major interval of basin formation following GC assembly and is spatially associated with the Olympic Dam IOCG+U deposit, but remains under-studied to-date. We integrate sequence stratigraphy, petrography, stable isotope geochemistry and geochronology in this study to clarify the paleoenvironments of deposition, stratigraphic architecture, and fluid history of the Pandurra Formation.

Detailed cm-scale logging of ten drill core intersections of the Pandurra Formation revealed six lithofacies comprising pebble conglomerate, coarser-grained lithic to quartz arenites and lithic wackes, finer-grained lithic arenites, and siltstone to mudstone that were deposited in braided fluvial and lacustrine paleoenvironments. Facies stacking patterns and the recognition of widespread, sharp, erosive surfaces helped define three unconformity-bounded sedimentary sequences within the Pandurra Formation. The sequences are products of dynamic tectonism and possibly climate changes that influenced facies distribution.

Burial of the Pandurra Formation resulted in quartz cements and hematite followed by white mica and dickite. Stable isotopic ratios of O and H in white mica and dickite suggest that the fluids responsible for diagenetic alteration had components of both seawater and evolved meteoric water at temperatures between 150 and 200°C. White mica give a spectrum of $^{40}Ar/^{39}Ar$ apparent ages ranging from 1536 ±7 Ma to 1249 ±3 Ma, marking diagenesis and reflecting temporal changes in the fluid-conducting capabilities within the basin. The former date is close to 100 m.y. older than a previously-published whole-rock Rb/Sr isochron age of 1424 ± 51 Ma in Pandurra mudstone, thus extending the maximum age of the Pandurra Formation.

Title: Towards Unravelling the Mozambique Ocean Conundrum using a Triumvirate of Zircon Isotopic Proxies on the Ambatolampy Group, Central Madagascar

Presenter/First Author: Donnelly Archibald, University of Adelaide, Adelaide, SA

Presenter/First Author Email: donnelly.archibald@adelaide.edu.au

Co-authors: Alan S Collins, University of Adelaide, Adelaide, Australia; John Foden, University of Adelaide, Adelaide, Australia; Justin L Payne, University of Adelaide, Adelaide, Australia; Richard Taylor, Curtin University, Perth, WA, Australia; Peter Holden, Australian National University, Canberra, Australia; Theodore Razakamanana, Université de Toliara, Toliara, Madagascar; Christopher Clark, Curtin University of Technolog, Perth, WA, Australia

Published Material: Initial findings were presented as a poster at the Gondwana15 Meeting in Madrid, July 2014. The poster was presented by my advisor because I was not able to attend the conference. Since the meeting, our understanding of the data has improved and we have a better understanding of how these rocks relate to similar aged rocks in Madagascar, India and East Africa. The paper is currently under review in the journal "Tectonophysics".

Abstract Body: Madagascar occupies an important location within the East African Orogen, which involves a collection of Neoproterozoic microcontinents and arc terranes lodged between older cratonic units during the final assembly of the supercontinent Gondwana. The detrital zircon record of Proterozoic metasedimentary rock packages within the Antananarivo Domain (the Ambatolampy, Manampotsy, Vondrozo, Itremo and Ikalamavony Groups) are used to identify pre-orogenic tectonic affiliations of the region—affiliations that control interpretations of the evolution of the Mozambique Ocean and the formation of this part of central Gondwana. Here we focus on the Ambatolampy Group, a previously poorly known group of high-grade siliciclastic metasedimentary rocks, and compare these to data from the other sedimentary packages in central Madagascar (the Vondrozo, Sofia, Manampotsy, Itremo, Molo, Ikalamavony, Androyen, Ambodiriana, Iakora and Maha Groups). New U-Pb Sensitive High Resolution Ion Microprobe (SHRIMP) zircon data for the Ambatolampy Group yields detrital age maxima of ~3000 Ma, ~2800-2700 Ma, ~2500 Ma, ~2200- 2100 Ma and ~1800 Ma. The youngest near-concordant detrital zircon age is 1836 ± 25 Ma, which we suggest represents the maximum depositional age of the Ambatolampy Group, in contrast to younger ages reported elsewhere. The detrital spectra are very similar to those from the Itremo Group and we suggest that they correlate with each other. Metamorphic zircons and zircon rims constrain the minimum depositional age to be ~540 Ma; the interpreted age of metamorphism. New d^{18}O data and hafnium isotopic data complement the U-Pb data and provide new constraints on the age, geochemistry and provenance of the metasedimentary rocks. We suggest that central Madagascar contained a Mesoproterozoic (to possibly Tonian) siliciclastic sedimentary basin, within which the Ambatolampy Group, and the Itremo and Maha (and possibly part of the Iakora Groups) were deposited.

Title: A New Model for the Quebecia Terrane of the Central Grenville Province as a Composite Arc Belt

Presenter/First Author: Shannon Vautour, McMaster University, Burlington,

Presenter/First Author Email: vautous@mcmaster.ca

Co-authors: Alan P Dickin, McMaster University, Hamilton, ON, Canada

Abstract Body: After the breakup of Nuna, Laurentia was an active continental margin for a billion years before the assembly of Rodinia. This period of Proterozoic crustal evolution is poorly understood, but much of its geologic history is recorded in crustal terranes of the Grenville Province. The Quebecia Terrane is a 100,000 km^2 Mesoproterozoic arc terrane in the central Grenville Province with T_{DM} model ages ~1.5 Ga, but was shown to contain a few isolated neodymium signatures of Paleoproterozoic crust. A more detailed Nd isotope analysis of orthogneissic samples in the Baie Comeau area of central Quebec has shown the extent and connection between these fragments, showing that they represent one large Paleoproterozoic crustal panel extending longitudinally through the Quebecia terrane. This panel is sandwiched between two large segments of the Quebecia terrane, implying that these segments actually represent two separate arc fragment of the same age that were accreted to the Laurentian margin at the end of the Pinwarian orogeny. It is proposed that through strike-slip tectonics, the Paleoproterozoic panel was detached from the older Makkovikian/Labradorian margin of Laurentia and re-accreted between the northerly and southerly blocks of the Quebecia terrane, forming a 'composite arc belt.' A modern analogue to this process could be the accretion of the western Sumatra block between the east Sumatra and Woyla terrane in Southeast Asia.

Title: Pb Isotope Analysis of Grenville Gneisses: Assessing the Crustal Burial and Exhumation of the Archean Parautochthon in Ontario and Western Quebec

Presenter/First Author: Gabriel Arcuri, McMaster University, Dundas,

Presenter/First Author Email: arcuri.gabe@gmail.com

Co-authors: Alan P Dickin, McMaster University, Hamilton, ON, Canada

Abstract Body: The Grenville Province is a 1 Byr-old orogenic belt in the Canadian Shield that reworked older crustal terranes of Archean to Mesoproterozoic age. As a result, the Grenville Province contains an exhumed section of the Archean Superior Province basement, which allows for a detailed study of its crustal structure. To investigate the burial-uplift history of the crust, whole rock Pb isotope data were determined for several Archean gneisses from across the NW Grenville Province in Ontario and Western Quebec. The high mobility of uranium during regional metamorphism of the continental crust generates stratification in the U/Pb ratio, as uranium is preferentially transported from lower crustal levels into the upper crust. Over geologic time, this process leads to variations in the $^{206}Pb/^{204}Pb$ and $^{207}Pb/^{204}Pb$ ratios of the crust, and hence, Pb isotope mapping acts as a useful tool for determining the exhumation of highly metamorphosed Archean crust. In Ontario, results collected for Archean gneisses shows a strong correlation between the Pb isotope ratio of the crust and the distance SE across the Grenville Front Tectonic Zone. A trend to less radiogenic signatures of the crust across the GFTZ compliments a similar pattern to the Leveck gneiss data from Sudbury that shows a trend to less radiogenic signatures of the crust away from the Sudbury Igneous Complex. The similarity between the unradiogenic signatures of the Grenville gneiss with the Leveck gneiss provides evidence of a progressive exhumation of the Archean basement across the GFTZ with a major ramp exhumed from a crustal depth of >20km. In contrast, the more radiogenic Pb signatures of Grenville gneiss in western Quebec suggest the preservation of Archean upper crust. Large areas of quartzite gneiss in the vicinity support a model for a Paleoproterozoic sedimentary basin that was buried under the Grenvillian allochthon and later exhumed back to the surface, exposing an unconformity over the shallow Archean upper crust.

Title: Tracking the evolution of the Grenville Foreland Basin: detrital mineral dates from the Sleat and Torridon groups, Scotland

Presenter/First Author: Maarten Krabbendam, British Geological Survey Edinburgh, Edinburgh,

Presenter/First Author Email: mkrab@bgs.ac.uk

Co-authors: Helen Bonsor, , , ; Matthew SA Horstwood, British Geological Survey Keyworth, Nottinghamshire, United Kingdom

Abstract Body: The Grenville Orogen, instrumental in the assembly of Rodinia, lacks a clear foreland basin in its type area in eastern Canada. However, Early Neoproterozoic siliciclastic rocks in Northern Scotland are now interpreted as remnants of a proximal Grenville Foreland Basin. Analysis of sedimentology and detrital minerals from the Torridon and underlying Sleat group (previously regarded as different in source and setting), constrain the evolution of this basin.

The Sleat Group, ~3500 m of shallow marine deposits, is overlain via a low-angle unconformity by the Torridon/Morar groups, which comprise > 8000 m of braided river to shallow marine deposits in a basin of large but unknown size.

Youngest U-Pb zircon dates in all samples from both groups all show similar late Grenvillian ages. Key older age components, however, vary in proportion throughout the sequence. The lower Sleat Group deposits show a dominant cluster of ~ 1750 Ma (?Rhinnian source), whereas in the Torridon group ~1650 Ma ages (?Trans Labradorian) become increasingly significant, as are age clusters between 1500 – 1100 Ma (Pinwarre – Elzevirian to early Grenvillian). These changes likely reflect uplift and erosion of different basement complexes within the Grenville Orogen. There is no difference in source across the Sleat/Torridon unconformity. Detrital rutile in the Torridon Group show similar pattern, except for an enigmatic 1900 Ma cluster.

The detrital mineral data and sedimentology tentatively suggest: i) early deposition in a narrow marine basin (lower Sleat Group), sourced from the Irish-Scottish sector of the Grenville Orogen, with orogen-normal fill; ii) within the Sleat Group a gradual switch to more distal sources from the Canadian Grenville orogen, via axial transport ; iii) across the Sleat-Torridon boundary a sudden switch from underfilled to overfilled deposition, but with no change in provenance. This latter deposition represents a major denudation event of the Grenville Orogen.

Title: Archaean unstable stagnant lid tectonics

Presenter/First Author: Jean H J Bedard, Geological Survey of Canada, Quebec, QC

Presenter/First Author Email: jbedard@nrcan.gc.ca

Co-authors: Tim E Johnson, Curtin University, Perth, WA, Australia; Craig O'Neill, Macquarie University, Sydney, Australia; Lyal Harris, INRS-ETE, Québec, QC, Canada

Published Material: Two figs were previously published by C O'Neill & T Johnson, the rest is mostly new.

Abstract Body: It has been proposed that the early Archaean Earth was in an unstable stagnant lid mode, with non-cratonic areas dominated by oceanic ‘plateau’ type crust. Numerical models of convection under a thick conductive mafic to ultramafic crustal layer imply frequent basal delamination of garnetiferous rocks; with rapid recycling of subaqueously erupted lava into the mantle. The unstable sub-crustal convection pattern would prevent development of a sub-oceanic lithospheric mantle layer (SOLM); in contrast with the modern Earth where a SOLM forms gradually as oceanic lithosphere drifts away from the ridge axis thermal anomaly. The absence of a thick, cold, stiff, dense SOLM beneath Archaean oceanic crust removes the principal driving force for subduction. Archaean continental drift as a result of mantle traction on the sub-continental lithospheric mantle root would produce broad, ‘soft’ mafic accretionary orogens. Partial subcretion and anatexis of oceanic crust beneath the continental leading edge would produce voluminous syn-tectonic TTGs. Bédard & Harris 2014 (Geology) proposed that the S.Superior craton was disaggregated by a Neoarchaean mantle overturn; followed by reassembly of detached ribbon-continents and intervening oceanic tracts when the N.Superior block drifted south. Numerical modelling of global mantle convection on an unstable stagnant lid planet implies frequent early whole-mantle overturn events so as to evacuate mantle heat buildups. Modeling results imply that overturns would cease due to the progressive decay of radiogenic heat, and would then have been replaced by a mobile lid plate tectonic mode. Global mantle overturn events can explain synchronous tectono-magmatic pulses on different cratons. Areas of high vertical flux during overturns would create unusually thick crust and would be favored sites of craton genesis or reworking. Vigorous mantle flow would drive faster continental drift and could also correspond to phases of enhanced tectonism.

Title: Implications from geophysical data for the structural and tectonic evolution of the Superior and Yilgarn cratons

Presenter/First Author: Lyal B. Harris, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec, QC

Presenter/First Author Email: lyal_harris@ete.inrs.ca

Co-authors: Jean H J Bedard, Geological Survey of Canada, Quebec, QC, Canada

Published Material: Whilst all information for the Yilgarn is new and unpublished, and not presented elsewhere, some images for the Superior craton to be used for introduction only were included in recent articles: Bédard, J.H. & Harris, L.B. (2014) Neoarchean disaggregation and reassembly of the Superior Craton. Geology, doi: 10.1130/G35770.1 & Harris, L.B., Bédard, J.H. (2014a) Crustal evolution and deformation in a non-plate tectonic Archaean Earth: Comparisons with Venus. In: Dilek Y, Furnes H (Eds), Evolution of Archean Crust and Early Life, Modern Approaches in Solid Earth Sciences 7, Springer, Chapter 9, 215-288.

Abstract Body: Gravity, aeromagnetic and seismic tomographic data for the Superior and Yilgarn cratons suggest that: (i) Some terrane boundaries defined from geological, geochemical and geochronological data and aeromagnetic interpretation of upper crustal features of the Superior craton do not correspond to margins of disparate, lithospheric-scale blocks. Early terrane boundaries preserved in the deep crust and upper mantle at high angles to mapped terrane boundaries and to greenstone belts in the upper crust are identified. Many “terranes” represent reassembled fragments previously derived from disaggregation of older (proto)cratons. (ii) Long wavelength aeromagnetic, bouguer gravity and pseudogravity data portray regional domes at deep crustal levels in both cratons, even in areas dominated by linear greenstone belts and transcurrent shear zones in the upper crust. Differences in shear zone geometries in the Superior craton indicate decoupling between the upper and mid- to lower crust, although shear zones at all crustal levels are compatible with the same inferred bulk shortening. (iii) Most large mineral deposits occur on margins of paleo-rifts preserved in the upper mantle and above deep crustal structures and/or on rims of deep domes at a high angle to greenstone belts for which there is little upper crustal expression. (iv) Broad regional ductile shear zones develop prior to formation of the mapped discrete ductile to brittle-ductile shear and faults. On deep

reflection seismic profiles (i) dipping reflectors cutting the upper mantle and lower crust are interpreted to represent mantle and lower crustal imbricates formed during bulk shortening and not fossil subduction zones, and (ii) both cratons preserve an early extensional and not a thrust/accretionary architecture. Some adjacent blocks differing in age and metamorphism in both cratons (eg. Abitibi-Opatica, Narryer-Youanmi) display basement-cover relationships and are not tectonically juxtaposed exotic terranes. Many observations are incompatible with previous, actualistic, subduction/arc accretion models, and shortening associated with regional folding and shearing in both the Superior and Yilgarn cratons is interpreted as the result of cratonic mobilism. Outcomes provide a new framework and approach for mineral exploration.

Title: Komatiite Volcanism: Lithospheric Controls on the Earth's Hottest Melts and Links to Crustal Growth in the Archean

Presenter/First Author: David Robert Mole, University of Western Australa, Perth, WA

Presenter/First Author Email: david.mole@csiro.au

Co-authors: Marco Fiorentini, University of Western Australia, Crawley, WA, Australia; Nicolas Thebaud, University of Western Australa, Perth, WA, Australia; Campbell McCuaig, University of Western Australia, Crawley, WA, Australia; Kevin F Cassidy, , , ; Chris L Kirkland, Geological Survey of Western Australia, Perth, Australia; Sandra Romano, , , ; Michael Doublier, , , ; Elena A. Belousova, Macquarie University, Sydney, Australia; Stephen J Barnes, CSIRO, Perth, Australia

Published Material: These findings were reported in the Proceedings of the National Academy of Sciences in July 2014, issue 111 (28), pages 10083-10088.

Abstract Body: Major periods of komatiite activity, possibly on the scale of Phanerozoic large igneous provinces (LIPs), occurred in the Archean Yilgarn Craton of Western Australia in two regions during two distinct periods. The oldest known deposits (3.0-2.8 Ga) occur in the south of the Southern Cross Domain (SCD). The youngest (~2.7 Ga) are predominantly found in the Kalgoorlie Terrane (KT). This study aimed to investigate whether variations in lithospheric architecture could explain the location and timing of komatiite magmatism. An integrated program of U-Pb and Lu-Hf analyses were performed on granitoids and felsic volcanics from the south-central Yilgarn Craton, Western Australia. These data have been plotted as time-resolved Lu-Hf maps which record the changing architecture of the craton in space and time.

The 3.1-2.8 Ga Lu-Hf time-slice shows that the south-central Yilgarn lithosphere (encompassing the Forrestania, Lake Johnston and Ravensthorpe greenstone belts) was relatively juvenile (εHf>0) at this time. The region to the north (central SCD), encompassing the Marda greenstone belt, shows an evolved signature (εHf<0). The greenstone belts formed over juvenile crust contain thick komatiite sequences which comprise high Mg lavas, thick cumulate zones and channelized flows, indicative of rapid, voluminous emplacement of extremely primitive magma (Barnes 2006a, 2006b). In contrast, the Marda greenstones are dominated by a thick, mafic succession, with minimal komatiite.

The younger, 2.8-2.6 Ga time-slice indicates that the west Yilgarn has cratonised into a more homogenous, evolved terrane (Youanmi Terrane; YT), whereas the KT has a juvenile signature. This contrast forms an isotopic discontinuity (paleo-craton margin?) between the two terranes, and results in a ~700 km, N-S trending belt of komatiites on the juvenile (KT) side of the isotopic boundary. These komatiites represent some of the hottest magmas ever erupted on Earth (Fo_{ol}92-94). In contrast, there is no known coeval mafic-ultramafic volcanism in the YT.

These results not only explain the timing and location of major komatiite eruptions but also why some regions do not have significant komatiite sequences at all. They also indicate that the evolution of the lithosphere and its subsequent architecture form a major control on komatiite volcanism.

Title: Crustal shortening, pop-down tectonics, fluid channelling and ore transfers within hot lithospheres – implications for Precambrian Cratons

Presenter/First Author: Denis Gapais, Géosciences Rennes, université de Rennes 1, Rennes,

Presenter/First Author Email: Denis.Gapais@univ-rennes1.fr

Co-authors: Justine Jaguin, CREGU, Université de Nancy, Nancy, France; Philippe Boulvais, Géosciences Rennes, université de Rennes 1, Rennes, France; Florence Cagnard, , ,

Published Material: Part of the abstract was presented in private conferences, and also at the GSA meeting in Denver in 2013. The presentation will include new data acquired since this time

Abstract Body: Field and experimental works dedicated to deformation modes of hot lithospheres in compressive regimes show major differences compared to modern orogenic belts (Gapais et al., 2014, Tectonophysics 618, 102–106). These works led to a new tectonic model marked by compression-induced downward motions of pop-downs of upper-crustals that pile up along vertical deformation zones. Downward motion of upper-crustals does not require any gravity-induced processes as potentially attached to sagduction of heavy greenstones. The first-order requirement is just a hot and weak lithosphere with a ductile lithospheric mantle (fig. 1). In such a context, pop-downs of upper crust pile up along vertical deformation zones potentially connected with the underlying ductile mantle. These zones are marked by high strains, steeply dipping foliations and steeply plunging stretching lineations. These zones are particularly favourable for circulations of fluids of various origins from surface to mantle and for long-lived fluid-rock interactions (Fig. 1).

We present field examples showing structural features arguing that pop-down tectonics may be a key for various ore concentrations in various crustal levels within ancient hot deformation belts of various ages, from Archaean to Palaeoproterozoic.

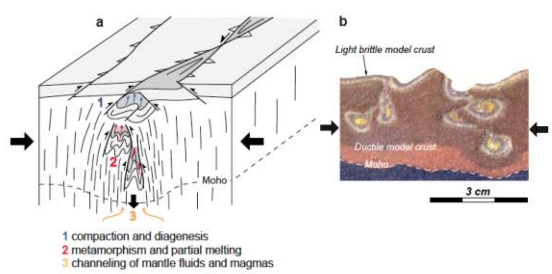

Fig.1. (a) Model of compression of a hot lithosphere where piling-up of upper crustal pop-downs may favour interactions between crustal deformation, fluid transfers, and potential ore deposits. (b) Analogue model of shortened weak continental lithosphere showing piling-up of upper-crustal pop-downs within underlying weak crust (Gapais et al., 2014, Tectonophysics 618, 102–106).

Wu, M.L. et al., 2013. Zircon U-Pb geochronology and Hf isotopes of major lithologies from the Yishui Terrane: Implications for the crustal evolution of the Eastern Block, North China Craton. *Lithos 170–171, 164-178.*

Abstract Body: The Archean basement rocks are widely exposed as several metamorphic complexes in the Eastern Block of the North China Craton, consisting predominantly of granitoid gneisses with minor mafic and felsic supracrustal rocks and charnockites. The timing of crustal growth and tectonic setting of the Eastern Block have been hotly debated. This study presents new zircon U-Pb and Lu-Hf data from major Archean basement complexes in eastern China to better understand the Archean crustal evolution of the Eastern Block of the North China Craton. Magmatic zircon U-Pb data have revealed an intensive magmatism at 2.6-2.5 Ga immediately followed by a large-scale tectonothermal event at ~2.5 Ga over the Eastern Block. In some complexes, multi-stage magmatism of ~2.9 Ga, ~2.7 Ga and 2.6-2.5 Ga have been reported, followed by the ~2.50 Ga widespread metamorphism and local metamorphism at ~1.9-1.8 Ga. Zircon Lu-Hf isotopic data have revealed that the Neoarchean magmatic zircons have positive $\varepsilon_{Hf}(t)$ values with depleted mantle model ages peak at 2.8-2.7 Ga. These suggest the Eastern Block underwent a major juvenile crustal growth at 2.8-2.7 Ga and then experienced a strong crustal reworking event at 2.6-2.5 Ga. Integrated with previous petrological, metamorphic and structural data, it is concluded that the Neoarchean is an important crustal growth period in the Eastern Block and the end-Neoarchean widespread tectonothermal event is possibly related to the intrusion and underplating of magmas originated from a mantle plume.

Title: Tectonic and metamorphic setting of orogenic gold deposits in an Archean greenstone belt: implication of $^{40}Ar/^{39}Ar$ dating in the SE Superior province

Presenter/First Author: Yannick Daoudene, University of Quebec at Montreal, Montreal, QC

Presenter/First Author Email: daoudene@gmail.com

Co-authors: Alain Tremblay, GEOTOP, Montréal, QC, Canada; Gilles Ruffet, Géosciences Rennes, UMR CNRS 6118, Université Rennes 1, Rennes, France; Francois Leclerc, Ministry of Natural Resources and Wildlife, Val-d'Or, Canada; Jean Goutier, Géologie Québec, Rouyn-Noranda, QC, Canada

Abstract Body: Our metamorphic ages data are consistent with those of adjacent areas of the Superior province, suggesting that the peak and duration of metamorphism might have been coeval over a large region as expected for vertical tectonic models. Available geochronological data for orogenic gold occurrences in the AGB further suggest that most of the auriferous quartz-tourmaline veins and hosting shear zones were formed late during the regional structural evolution.

Title: Structural Analysis of the Archean France River Shear Zone and Related Gold Mineralization, Chibougamau, Superior Province, Québec.

Presenter/First Author: Christine Vezina, University of Quebec at Montreal UQAM, Montreal,

Presenter/First Author Email: christine_vezina@hotmail.com

Co-authors: Yannick Daoudene, University of Quebec at Montreal, Montreal, QC, Canada; Alain Tremblay, GEOTOP, Montréal, QC, Canada; Francois Leclerc, Ministry of Natural Resources and Wildlife, Val-d'Or, Canada

Abstract Body: The Chibougamau mining camp (CMC), located in the northeastern part of the Archean Abitibi greenstone belt, has been the second largest mining district in Quebec from 1955 to 2008 (60,09 Mt of ore which produced 994 802 t Cu, 160 t Au and 102 t Ag). Known for its Cu-Au vein deposits, the CMC hosts shear zones related, gold-bearing veins in volcanic and sedimentary rocks metamorphosed to greenschist-facies. Existing regional studies have demonstrated the spatial relationships between such type of Au deposits and regional E-W-trending shear zones without, however, providing precise chronological relationships. This study evaluates the relative timing of regional deformations and gold-bearing quartz veins emplacement through a detailed structural analysis of a typical shear zone of the CMC, the France River shear zone, which hosts gold-rich veins in the Monexco property, located 30 km northeast of Chibougamau. The France River shear-zone, approximately 450 metres-wide, shows an anastomosing pattern of deformation corridors and it is characterized by folds, a penetrative schistosity S2, and a nearly down-dip mineral and stretching lineation L2. Subsequently, the shear zone was affected by a strike-slip D3 deformation characterized by a more localized crenulation clivage and a sub-horizontal stretching lineation L3. Shear bands and rotation of extension veins suggesting dextral motions are the main kinematic indicators associated with the D3 deformation.

The structural and metallogenic evolution of the France River shear zone can be interpreted in a continuous deformation model. The D2 deformation is associated with north-south directed compressive stress that generated regional folds and faults. The localization of D2 deformation resulted in the development of discrete shear zones, that facilitated the emplacement of dykes and sills of quartz-feldspar porphyry and gabbro. These intrusions predated a dextral strike-slip D3 deformation that is restrained to the France River deformation corridor. «Late» quartz veins cut across all lithologies and are variably affected by D2 and D3, suggesting that the bulk of the gold mineralization is late- D2/syn-D3.

Title: Revised geology, U-Pb dating and new interpretations of the relationships between the Malartic - Louvicourt - Piché - Cadillac Groups and the Larder Lake-Cadillac Fault Zone, Abitibi Subprovince, Quebec

Presenter/First Author: Pierre Pilote, Ministère des Ressources Naturelles, Boucherville,

Presenter/First Author Email: pierre.pilote@mern.gouv.qc.ca

Co-authors: Réal Daigneault, Centre d'études sur les Ressources minérales (CERM), Chicoutimi, QC, Canada; Jean David, GEOTOP, Montréal, QC, Canada; Vicki McNicoll, Geological Survey of Canada, Ottawa, Canada, ON, Canada

Abstract Body: The Larder Lake - Cadillac Fault Zone (LLCFZ) is one of the most important structures with respect to gold mineralization in the Abitibi Subprovince (AS). It typically juxtaposes rocks of various compositions and ages. In the Rouyn-Noranda area for example, the fault juxtaposes Timiskaming-aged rocks (the Granada Formation, a fluviatil sequence, formed between 2680 and 2670 Ma) and Cadillac Group rocks (CG - a turbiditic sequence composed of wacke, siltstone and shale, formed between 2690 and 2680 Ma). In the Malartic area, U-Pb dating of two samples from a conglomeratic unit of the CG yielded Timiskaming ages (<2678 and < 2676 Ma). These new results reveal that Timiskaming-aged rocks extend further to the east than previously recognized and that this younger sedimentary facies can be contained within the older CG package. The new ages illustrate the complexity of these basins, exhumation of nearby lithologies and the localized, episodic nature of the sedimentation.

The LLCFZ has been historically correlated and associated with a talc-chlorite-serpentine schist corridor, which varies in thickness from less than 100 m to more than 1500 m, and has been named the Piché Group (PG). Although discontinuous along its length the PG, which is composed of variably deformed and carbonatized ultramafic/mafic volcanic rocks, can be observed from east of Louvicourt to Rouyn-Noranda (> 150 km). The origin of the PG is still debatable. It could represent (1) a single homogenous stratigraphic volcanic unit, (2) a composite assemblage, or (3) a tectonically emplaced sliver. However, a new U-Pb age from a tonalitic dyke crosscutting the ultramafic rocks at the Buckshot pit near Malartic yielded an age of 2710 Ma and is proposed to be correlative with the base of the Malartic Group (MG), supporting the sliver hypothesis.

A newly recognized sudsidiary structure to the LLCFZ is the Rivière Héva Fault. This large scale fault (> 80 km) duplicates the lower part of MG and could explain the presence of younger Héva Fm volcanic rocks (2700 Ma) juxtaposed to the Dubuisson Fm (2708 Ma).

With respect to metallogenic and geodynamic models, the LLCFZ and its various subsidiary segments are of tremendous importance. They have affected the various styles and timing of gold mineralization as well as the global architecture of the southern part of the AS.

Title: Review of Stratigraphy and Metallogenic Context of the Bartlett, Halliday and Shaw Domes, Western Abitibi Greenstone Belt, Ontario, Canada

Presenter/First Author: Sonia Préfontaine, Ontario Geological Survey, Sudbury,

Presenter/First Author Email: sonia.prefontaine@ontario.ca

Co-authors: Michel Houlé, Geological Survey of Canada, Québec, QC, Canada

Published Material: Part of the finding have been written up as a Summary of Field work, an Ontario Geological Survey publication.

Abstract Body: The Timmins area, located in the western Abitibi greenstone belt (WAGB), is known for its Au and Ni endowment. The Porcupine-Destor deformation zone (PDDZ), an Au-bearing structure, cuts the Timmins geology into the Timmins gold camp and the Shaw Dome, located north and south of the PDDZ respectively. The Shaw Dome consists of 2 volcanic episodes: 1) 2734–2724 Ma (Deloro) and Ni-rich 2710–2704 Ma (Tisdale).

The Bartlett and the Halliday domes, located southwest of Shaw Dome, were previously thought to be the stratigraphic continuation of Shaw Dome. However, recent geological mapping and geochronology has improved our knowledge of the stratigraphy and metallogenic context of the area. The geology in the Bartlett Dome correlates to the Shaw Dome, based on similar lithologies, geochemical affinities and geochronology. In contrast, new geochronology in the Halliday dome has revealed 2720-2710 Ma (Kidd-Munro) volcanic rocks and younger volcanic and sedimentary rocks (ca. 2689 Ma- Porcupine) thus making the Halliday Dome distinct from the Shaw and the Bartlett domes. In addition, komatiitic rocks displaying pepperitic contacts occur in the younger Porcupine sedimentary rocks. These new findings are significant since they are the first clear recognition in the WAGB of: 1) Kidd Munro episode rocks south of the PDDZ and 2) komatiitic magmatism coeval with Porcupine sedimentary rocks.

Recognition of Kidd-Munro age rocks in the Halliday dome increases its VMS mineralization potential as similar age rocks host the giant Kidd-Creek Cu-Zn Mine. Also, the presence of komatiites of Porcupine age creates a previously unrecognized target for Ni-mineralization in the WAGB. Furthermore, Au potential should not be neglected in this area. The Larder Lake-Cadillac deformation zone is an important Au structure in the WAGB and its potential extension west of Matachewan is poorly constrained. However, recent mapping suggests a possible westward extension of the deformation zone passing between the Halliday and the Bartlett domes where strong deformation corridors and several Au occurrences are present. These new results highlight knowledge gaps in our understanding of the architecture and evolution of the WAGB, thus further investigations are still warranted.

Title: Geochemical Fingerprints of Maximum Flooding Surfaces in the ca. 850 Ma Upper Fifteenmile Group, Yukon Reflect the Iron Shuttle

Presenter/First Author: Timothy Gibson, McGill University, Montreal, QC

Presenter/First Author Email: timothy.gibson@mcgill.ca

Co-authors: Marcus Kunzmann, McGill University, Montreal, QC, Canada; Galen P Halverson, McGill University, Montreal, QC, Canada

Abstract Body: We have performed a multi-proxy geochemical study ($\delta^{13}C$, $\delta^{56}Fe$, major and trace elements) spanning three maximum flooding surfaces within the ca. 850 Ma, mixed carbonate-shale Reefal Assemblage in Yukon, northwestern Canada, in order to evaluate the role of relative sea level fluctuations on redox sensitive geochemical proxies. The maximum flooding (MF) intervals are characterized by very fine-grained and finely laminated mudstones with relative high %TOC and low Fe_T/Al. The transition above the MF intervals, which reflects shoaling at the beginning of the highstand systems tract (HST), shows a sharp decline in %TOC, rise in Fe_T/Al, and spikes in redox sensitive trace metal concentrations, most notably U. Iron isotope compositions are inversely correlated with Fe_T/Al across this transition, with a sharp decline in $\delta^{56}Fe$

corresponding to an increase in Fe_T/Al. We interpret these patterns to record the influence of the benthic iron shuttle, whereby ^{56}Fe-depleted iron is removed from mudstones (rendering them ^{56}Fe-enriched) during sea level maxima, when high relative sea level, low sedimentation rates, and high organic carbon flux result in anoxic conditions at the sediment-water interface. As these conditions retreat and dissipate during the HST, a return to oxic bottom waters results in an accumulation of ^{56}Fe-depleted iron and trace metals released from anoxic sediments immediately downslope. These results and our interpretation have multiple implications for the redox state of early Neoproterozoic seawater and the application of redox proxies in ancient organic-rich sediments. First, it is evident that at least during period of high sea level, anoxic conditions prevailed below the surface mixed layer on continental shelves. Second, fluctuations in relative sea level under these conditions generates large variations in redox proxies which do not directly reflect changes in the redox state of the global ocean. Finally, the iron shuttle, driven by dissimilatory iron reduction, was vigorous in the early Neoproterozoic, and while it may have resulted primarily in downslope transport of iron, this mobilized iron would have also diffused upslope, where it was removed under oxic conditions of the surface ocean.

Title: A δ^{26}Mg Record of the Paleozoic Oceans

Presenter/First Author: Sarina Cotroneo, University of Ottawa, Ottawa, ON

Presenter/First Author Email: sarinaec@gmail.com

Co-authors: Ian Douglas Clark, University of Ottawa, Ottawa, ON, Canada

Published Material: Background information on the site from which the cores were taken has been published, however the focus of the presentation will be on new (unpublished) δ^{26}Mg data.

Abstract Body: The prospect of storing nuclear waste in the deep geosphere (ie. 600-800 m below ground surface (mbgs)) has generated considerable interest in the provenance and movement of deep crustal fluids in the Michigan Basin, where the construction of a deep geologic repository (DGR) for radioactive waste has been proposed. This waste management strategy seeks to isolate radioactive waste from the biosphere on geologic timescales, which demands a detailed understanding of the pore waters in low-permeability environments. A halite-mineralized Ordovician carbonate aquiclude is the proposed host of the DGR. The associated pore waters are a post-dolomitic brine of evaporated Silurian seawater, which has resided in the aquiclude for more than 260 m.y.[1]. Cores reaching depths of 861 mbgs, and spanning Cambrian to Devonian strata taken from a Bruce Power nuclear site near Kincardine, Ontario, have already been used to investigate several geochemical and isotopic tracers at this site. Mg isotopes are an emerging tool in the investigation of dolomite formation, magnesium cycling, and may be useful in the investigation of past and continental weathering fluxes. This study employs Ca (δ^{44}Ca) and Mg (δ^{26}Mg) isotopes measured by MC-ICP-MS to trace the movement of dolomitization fluids through Devonian, Silurian, and Orovician carbonates. The first segment of this research focuses on the δ^{26}Mg of dolostones throughout the core to establish a baseline expectation of the δ^{26}Mg of the pore waters if they are primary, while generating a record of δ^{26}Mg of the oceans through the Paleozoic and investigating dolomite formation in deep time.

Title: The utility of chromium isotopes as a redox tracer

Presenter/First Author: Christopher Reinhard, Georgia Tech, Atlanta, GA

Presenter/First Author Email: chris.reinhard@eas.gatech.edu

Co-authors: Noah Planavsky, Yale University, New Haven

Published Material: EPSL, v407, p9Science, v346, p635

Abstract Body: Advances in mass spectrometry allowing for the routine and precise measurement of metal stable isotope distributions in natural materials have revolutionized geochemistry. In particular, transition metal isotope systems have provided unique insight into the chemical evolution of Earth's ocean-atmosphere system on a range of timescales. However, the oceanic isotope mass balance of a given trace element and the fidelity of signal transmission into the sedimentary record are typically governed by a complex array of syn- and post-depositional processes. As a result, the ultimate utility of a metal isotope system is context-dependent and often quite different from that initially anticipated. This talk will focus on the chromium (Cr) isotope system as both a paleoceanographic proxy and a potential 'paleobarometer' for atmospheric pO_2 levels. Some recent applications of Cr isotopes to ancient sedimentary rocks and modern marine sediments will be discussed, along with data from a range of high- and low-temperature systems that help to constrain processes that do and do not induce significant stable Cr isotope fractionation near Earth's surface. In addition, the primary gaps and current frontiers in our understanding of modern Cr isotope mass balance at Earth's surface and how it has evolved with time will be highlighted.

Title: Regional Climate Projections using Effective Climate Sensitivities

Presenter/First Author: Raphaël Hébert, McGill University, Montreal, QC

Presenter/First Author Email: raphael.hebert@mail.mcgill.ca

Co-authors: Shaun Lovejoy, McGill University, Montreal, QC, Canada; Anne de Vernal, University of Quebec at Montreal UQAM, Montréal, QC, Canada

Abstract Body: The relationship between temperature and anthropogenic forcings (especially CO_2), is so strong that the decomposition of climate variability into the sum of a deterministic anthropogenic component and a stochastic natural variability component turns out to be quite accurate. It was recently shown that the anthropogenic component can be well estimated by using the actual (historical) CO_2 radiative forcing as a linear surrogate for all the anthropogenic effects (regressing the global temperature against the logarithm base 2 of the global CO_2). The constant of proportionality is the "effective climate sensitivity" (i.e. the actual sensitivity to a historical CO_2 doubling). Alternatively, using instead the estimated equivalent CO_2^{EQ}, leads to nearly identical results with the sensitivities increased by a factor 1.08. For global annual temperatures, the residuals (the natural variability) is ±0.109K which is very close to GCM estimates of natural variability. This means that over the period 1880-2013, the global mean temperature is given to within an error of only ±0.109K once the global mean CO_2 is known. This provides a robust empirically based method for projecting global temperatures into the future using various Representative Concentration Pathways (RCP's).

In this presentation, we extend this method from global to regional effective sensitivities and regional projections at 5ºx5º resolution. We used local series of monthly gridded historical temperature records: HadCRUT4,

NASA Goddard Institute for Space Studies and NOAA National Climatic Data Center. To validate the method, we perform hindcasts for the period 1993-2013 comparing them with GCM hindcasts (the CMIP5 models). Our hindcasts are comparable or better than the CMIP multimodel mean hindcast. Our approach is based on observations and implies only a small number of parameters and assumptions, providing results which are completely independent from those obtained through GCMs, it can thus be used for benchmarking. This allows us to establish long term regional empirical projections of expected anthropogenic warming up to the IPCC target period 2081-2100, following the Representative Concentration Pathways, RCP, scenarios and we compare our projections with those from CMIP5.

Title: Scaling linear Inverse Models (SLIM) for regional climate forecasting and the development of Global Macroweather Models

Presenter: Lenin del Rio Amador, McGill University, Montreal, QC

Presenter Email: lenindelrio@gmail.com

First Author: Shaun Lovejoy, McGill University, Montreal, QC

Co-authors: Raphaël Hébert, McGill University, Montreal, QC, Canada

Abstract Body: By using slightly different initial conditions, and exploiting the sensitive dependence on initial conditions, GCM's generate a statistical ensemble of future states. The high frequency "weather' is essentially treated as a source of noise. This has lead to attempts to directly generate the noise and the low frequencies that they force using stochastic models, the most well known are the linear inverse models (LIM). These have been presented as a benchmark for decadal surface temperature forecasts. For annual, global hindcasts, LIM skills superior to those of GCM's have been reported. Nevertheless, the exponential decorrelation in time of the LIM models is not only quite unrealistic (the true decorrelations are power laws), but also – as a consequence - limits its useful forecast horizon to roughly 1-3 years: We show that it enormously underestimates the memory of the system.

In this work we make a scaling analogue of the LIM: Scaling Linear Inverse Modelling (SLIM) that exploits the power law (scaling) behavior in time of the temperature field and consequently, make use of the long history dependence of the data to improve the skill. When applied to macroweather time scale range (from 10 days to 100 years) this allows us to achieve much better skills. The SLIM model is the predictive component of a new Global Macroweather Model (GMM) currently under development at McGill.

The prototype SLIM divides the planet into 10º x 10º regions from -70º to 70º latitude and analyzes the temperature series for each region. As a first step, we removed the anthropogenic component of each time series based on its sensitivity to equivalent CO_2 concentration for the last 130 years, the residue is our estimate of the natural variability that SLIM predicts. The parameters of the model can be obtained directly from the actual data. We report maps of theoretical skill predicted by the model and we compare it with actual skill based on hindcasts for some regions of interest. A comparison between our results and previous results using LIM or other GCM's is also shown. We also studied the interconnection between different regions and how they can mutually affect the corresponding predictability.

Title: Holocene Labrador Current strength reconstructed from sediment sortable silt proxy

Presenter/First Author: Harunur Rashid, Memorial University of Newfoundland Grenfell, Corner Brook, NL

Presenter/First Author Email: hrashid@grenfell.mun.ca

Co-authors: David Piper, Bedford Institute of Oceanography, Dartmouth, NS, Canada; Kelly M Best, The Ohio State University, Columbus, OH; Francky Saint-Ange, Geological Survey of Canada-Atlantic, Dartmouth, NS, Canada

Abstract Body: Variability in the Atlantic meridional overturning circulation results from changes in the sea-surface conditions. During the early to mid-Holocene period, weakening of deep water formation in the North Atlantic has been partly attributed to the fluctuation of freshwater discharge to the Labrador Sea but direct evidence for this linkage is lacking. Furthermore, a recent study has shown no evidence of only temperature and salinity link between Labrador and Nordic seas for the mid to late Holocene period, implying that the subpolar gyres were not influenced by the Labrador Sea input but rather by a decrease in wind stress (Thornalley et al., 2009). Previous studies have been hampered by the lack of a high-resolution proxy for the flux of cold, low saline water from the Labrador Current. Here we present such a high resolution sediment proxy for variations in the strength of the Labrador Current for the Holocene from two northwestern Labrador Shelf cores. We compare variations in paleo-current strength inferred from the sortable-silt in conjunction with other paleoclimate proxies. Our data suggest that there were two prominent weakening of the Labrador Current strength centered at 8.4 ka and 7.8 ka which were accompanied by high detrital carbonate and notable changes in sediment geochemical tracers. The Labrador Current was strong between 7.6 ka and 3.5 ka with minor fluctuation in its strength. Furthermore, an enigmatic increase in the Labrador Current strength, which was not accompanied by any changes in the sediment geochemistry, was also observed at 3.4 ka. High sortable-silt values can result either by reworking off the adjacent sediments on the shallow shelf or by a very strong Labrador Current. If there was a large sediment input from the Labrador Shelf, the concentration of ice-rafted detritus would be diluted, which is not the case as the concentration of ice-rafted detritus increases from ~5.4 ka to the present. We therefore suggest that the sortable-silt data appear to represent variations in the Labrador Current strength.

Title: North Atlantic temperature seasonality throughout the Holocene: isotopic evidence from micromilled bivalves

Presenter: Bruce M Eglington, University of Saskatchewan, Saskatoon,

Presenter Email: bruce.eglington@usask.ca

First Author: Sandra Timsic, University of Saskatchewan, Saskatoon, SK

First Author Email: sandra.timsic@usask.ca

First Author Student?: No

Co-authors: William Paul Patterson, University of Saskatchewan, Saskatoon, SK, Canada

Published Material: Poster presentations at Goldschmidt in 2012 (preliminary conclusions) and Arctic Science Workshop in 2010 (early part of the record). Manuscript is currently in review.

Abstract Body: We provide the first record of Holocene temperature seasonality for the North Atlantic, a climatically important region with significant transregional effects. Bivalves are particularly valuable proxies because growth bands of their shells archive high-resolution records of temporally discrete environmental information. High-resolution sampling enables reconstruction of variability of seasonal high and low temperatures, and therefore changes in seasonality—one of the most significant climatic variables that influences marine and terrestrial ecosystems. Thirty-five well-preserved aragonitic bivalves were extracted from a giant marine piston core in NW Iceland and sequentially sampled concordant with growth banding using a computer-controlled micromilling device. Carbonate aliquots were subsequently analyzed for $\delta^{18}O_{(CaCO3)}$ values to obtain snapshots of ambient seawater temperatures at a sub-monthly resolution. Previous research on this core observed significant variations in seasonal temperature over the last two millennia (Patterson *et al*., 2010). Here, we extend this seasonality record back to ~10,650 cal yr BP. Our temperature record is compared to other climate records around Iceland to produce a multi-proxy reconstruction of Holocene climate variability. Our data suggest that the Early Holocene (10,650 to 7,600 cal yr BP) exhibited the most persistently warm summers, with maximum summer temperatures ~2°C higher, and with greater seasonality than during the subsequent cooler Neoglacial period (7,000 to 4,750 cal yr BP). Our results indicate that the Neoglacial period was a relatively stable cold period, with the lowest summer maximum temperatures, as well as the lowest seasonality during the Holocene. Sporadic warm periods and increased seasonality are observed in the record after 4,500 cal yr BP, when maximum summer temperatures reached between ~7 and 9.5°C. The highest reconstructed temperatures of the entire record occurred during the Roman Warm Period centered at ~2,000 cal yr BP.

Title: Hydro-climate of Subtropical North America since Last Glacial Maximum and Variations in the Dynamics of Atlantic and Pacific Moistures

Presenter/First Author: Priyadarsi D. Roy, Universidad Nacional Autonoma de Mexico, Mexico Df,

Presenter/First Author Email: p_debajyotiroy@yahoo.com

Co-authors: Axel Rivero-Navarrete, Posgrado en Ciencias de la Tierra, Mexico City, Mexico; Claudia Magali Chávez Lara, UNAM National Autonomous University of Mexico, Iztapalapa, Mexico; Norma Lucina Hernández Juárez, Facultad de Ciencias, Mexico City, Mexico; Rufino Lozano-Santacruz, Instituto de Geología, Mexico City, Mexico; Nayeli Lopez-Balbiaux, USAI, Facultad de Quimica, Mexico City, Mexico

Published Material: A part was presented in AGU Fall meeting 2015 and a part of this is in review in Quaternary Research

Abstract Body: Modern day hydro-climate of subtropical North America (i.e. southern USA and northern Mexico) is controlled by the moisture sourced from both Atlantic and Pacific Oceans in the forms of summer as well as winter precipitations. Over the late last glacial and deglaciation, the dynamics of moisture from Pacific are better studied and geographical coverages of summer and winter precipitations are reconstructed by using several proxy records of continental deposits from southwestern USA and northwestern Mexico (Barron et al., 2012; Lyle et al., 2012; Kirby et al., 2013; Roy et al., 2013). The lack of records from northeastern Mexico and southeastern USA was a major hindrance for the reconstruction of dynamics of the moisture flow sourced from Atlantic. However, there is more paleoclimatic information from the eastern part of subtropical North America in the last decade (Grimm et al., 2003; Tripsanas et al., 2013; Feng et al., 2014). We present two different millennial-scale paleohydrological records from the northeastern and northwestern Mexico in order to reconstruct the dynamics of moisture sourced from both Atlantic and Pacific since the Last Glacial Maximum (LGM). Santiaguillo Basin located near the Pacific received more runoff during LGM and the amount of runoff decreased during deglaciation. The runoff record of El Potosi Basin located near the Atlantic is opposite of the Santiaguillo record and indicates more runoff during the deglaciation. The runoff into Santiaguillo over the Holocene was comparable with the proxy values of deglaciation, whereas El Potosi received less runoff during Holocene compared to the deglaciation. However both the sites registered reduced amount of runoff during the cooler Younger Dryas and Heinrich Stadial 1. Information about the variations in salinity, aeolian activity, productivity and source of productivity are reconstructed using multi-element concentrations, total organic carbon and C/N relation. A spatio-temporal reconstruction of the Atlantic moisture will be presented by comparing the paleohydrological information from northeastern Mexico with proxy records from Texas, Gulf of Mexico and Florida.

Title: Paleolimnological evidence of global spread of hypoxia in freshwaters caused by local anthropogenic pressures

Presenter/First Author: Jean-Philippe Jenny, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Québec,

Presenter/First Author Email: jphilippe.jenny@gmail.com

Abstract Body: The recent development of seasonal or persistent hypoxia in many lakes and coastal environments around the world severely stresses ecosystems, causing a decline of fisheries, a loss of biodiversity, and an alteration of food webs, including mass mortality of fauna. In marine environments, global instrumental surveys showed that the number of hypoxic coastal sites exponentially increased since the 1950s. In lakes, however, long-term instrumental monitoring surveys remain limited, preventing a global reconstruction of hypoxia's dynamic and pinpointing long-term causes of these changes on the continents. Nevertheless, hypoxic conditions are recorded in lakes when varve sediments start to be preserved once thresholds in oxygen-depleted conditions are crossed. Here, we compiled the time when varves started to be preserved in lakes over the last 300 years from 365 sites across the world as an indication of the global evolution of hypoxia on continents, and compared these data with anthropogenic and environmental variables compiled for each of these 365 watersheds. Additional sites in Europe were included in the study to reconstruct changes during the Holocene epoch. Our results show that continental hypoxia started spreading worldwide before AD 1900, mainly because of local growth in population density, human footprint and land uses, leading to eutrophication. No significant correlation was found with changes in precipitation or temperature. Hypoxia in continental realm spread about 50 years prior to marine environments. Finally, no sign of general return to past well-oxygenated conditions are observed despite implementation of local restoration programs and implementation of policies limiting nutrients yields since several decades in Europe and North America. This highlights the low resilience of lacustrine systems in the context of the added likely stress due to global warming and population increase.

Title: Non-Pollen Palynomorph Records of Natural (Climate-Driven) and Cultural Eutrophication

Presenter/First Author: Francine M G McCarthy, Brock Univ, St Catharines, ON

Presenter/First Author Email: fmccarthy@brocku.ca

Co-authors: Matea Drljepan, Western University, London, ON, Canada; Olena Volik, University of Waterloo, Toronto, Canada; Andrea Krueger, Brock Univ, St Catharines, ON, Canada; Donya Danesh, Queen's University, Kingston, ON, Canada; Nicholas Riddick, Brock Univ, St Catharines, ON, Canada; Caitlyn Garner, Brock Univ, St Catharines, ON, Canada

Abstract Body: Algal palynomorphs (*e.g. Pediastrum*, dinoflagellate cysts, desmids, *Botryococcus*) in lake sediments from eastern North America record Holocene variations in nutrient availability. Eutrophication promotes the preservation of organic-walled planktonic microfossils while inhibiting benthic organisms (through BOD-induced bottom water anoxia) and corroding mineralized microfossils (through lowered pH in sediments due to organic acids). Non-pollen palynomorph (NPP) analysis is thus ideally suited to studies of eutrophication. Increases in algal biomass and changes in NPP assemblages (and decreases in biodiversity) identify both natural and cultural eutrophication in cores from Sluice Pond, Massachussetts and Lake Simcoe, Ontario. Natural, climate-driven, increases in nutrient availability are associated with Holocene warming, particularly with the lowstand during the hemlock decline. Cultural eutrophication is associated with impact of indigenous North Americans as well as European colonists, clearly evident in cores from Honey Harbour (Lake Huron) and Crawford Lake, Ontario.

Because these microfossils are present in slides prepared for pollen analysis, the main impediment to the exploitation of non-pollen palynomorphs (NPP) in paleolimnological studies appears to be relatively poorly understood taxonomy and ecology. Ongoing studies aim to remedy increase awareness of these microfossils and of their relation to the algal biomass that produced them, as well as investigating the effects of taphonomy on NPP assemblages; oxidation, for instance, selectively destroys more susceptible taxa, both *in-situ* and during acetolysis treatment. Pollen analysts are urged to pay attention to the valuable "by-products" in their slides, and to avoid acetolysis where possible, in order to obtain the maximum benefit from palynological preparations.

Title: Identifying Regional Hotspots of Biodiversity Change Over the Past ~150 Years: Beta-diversity of Diatom Assemblages from ~400 US Lakes

Presenter/First Author: Amanda Winegardner, McGill University, Montreal,

Presenter/First Author Email: amanda.winegardner@mail.mcgill.ca

Co-authors: Beatrix E Beisner, , , ; Irene Gregory-Eaves, McGill University, Montreal, QC, Canada

Published Material: I presented a preliminary report on this project at the 2014 annual meeting of the Quebec Centre for Biodiversity Science. This presentation will include updated and more thorough results.

Abstract Body: There is growing acceptance that, over the past ~200 years, humans have fundamentally changed the functioning of the Earth's key processes. However, at present it is less clear how diversity has been altered over this period. Here we use the USEPA National Lake Assessment program, an open access database containing data from over 1000 lakes, including lake sediment records (~400 lakes), to explore questions of regional aquatic diversity change. The focus of this project therefore, is to compare diatom assemblages from pre-industrial (where possible) or baseline sediments, to those found in modern (2007) sediments, generating estimates of beta-diversity. Our specific objectives are to: (1) Quantify patterns in latitudinal richness across lakes and regions with different disturbance histories, testing the hypothesis that latitude as a weaker effect on diatom (alpha) diversity in modern sediments relative to pre-1850 sediments, (2) Map diatom beta-diversity through both time (bottom and surface sediment core samples) and space (between lakes), creating a visual depiction of beta-diversity hot spots across the US, and (3) Relate landscape-level anthropogenic changes/trends to diatom diversity and beta-diversity as well as functional diversity, with a particular focus on alterations that influence lakeshore condition. We have found longitudinal richness patterns with both pre-industrial and modern sediments as well as regional differences in beta-diversity. Additionally, high beta-diversity is more related to species replacement through time or across a landscape than species loss. This work will contribute to an understanding of how landscape-scale changes affect diatom (plankton) alpha and beta diversity across the US, through the combination of both long-term monitoring and paleolimnogical data.

Title: Low-frequency Variability in the North and South Saskatchewan Rivers over the Past Millennium

Presenter/First Author: Jeannine-Marie St-Jacques, University of Regina, Regina, SK

Presenter/First Author Email: jmcheval@sympatico.ca

Co-authors: David Sauchyn, Prairie Adaptation Research Collaborative (PARC), Regina, SK, Canada; James Dickenson, Prairie Adaptation Research Collaborative (PARC), Regina, SK, Canada; Edward R Cook, Lamont -Doherty Earth Observatory, Palisades, NY

Abstract Body: The Canadian province of Alberta faces significant water challenges driven by an expanding population, accelerating economic growth, and the interaction between economic development and a changing climate. Nowhere in Canada are these issues more pressing than in semi-arid southern Alberta, where water supplies are under serious pressure and scrutiny. This region is known today for its highly variable hydroclimate. The instrumental record is only of centennial length and there is accumulating evidence suggesting that Euro-Canadians settled the region during a relatively wet period. This makes accurate proxy-reconstructions of paleo-flows extremely important in order for water managers to have a realistic idea of what is possible for already scarce surface water supplies under a changing climate due to global warming. We present reconstructions of the South and North Saskatchewan Rivers which are based upon treering series standardized by signal-free, regional curve standardization. With novel signal-free, regional curve standardization, treering series are processed in an unbiased manner to conserve low-frequency multi-centennial variability. Our reconstruction includes a *Pinus flexilis* treering chronology that begins in AD 549.

Preliminary results show river flows with a large amount of low-frequency variability, with a wet 20th century, dry Little Ice Age and a generally moist Medieval Warm Period. However, this region experienced an extremely dry half century beginning in the AD 1150s; a time period which researchers are finding to have been one of the most extreme megadroughts in western North America. The high amount of low-frequency variance observed in the reconstructed river flows would prove very challenging to water managers.

Title: Application of Biochemical modeling in Paleoclimatic reconstructions from tree ring cellulose isotope data

Presenter/First Author: Trina Bose, Physical Research Laboratory, Ahmedabad,

Presenter/First Author Email: trinabose@yahoo.com

Co-authors: Supriyo Chakraborty, , , ; R. Ramesh, Physcial Research Laboratoy, Ahmadabad, India; Saikat Sengupta, Indian Institute of Tropical Teteorology, Pune, Maharashtra, India; Hemant P Borgaonkar, Indian Institute of Tropical Teteorology, Pune, Maharashtra, India

Abstract Body: Present scenario of climate change has lead to the requirement of detail knowledge of the climate system, long term climate change, its different components and their interactions [1,2]. One of the primary sources of climatic variability information in recent past are the tree ring cellulose isotope datasets due to their stable temporal resolution[3,4,5]. However the reconstructions produced from such data have variable dependabilities due to their site and species specificness in terms of parameter reconstructed and the calibration[1]. There are myriad reasons of statistical regressions having limited correlation with instrumental data, e.g. nearest meteorological station data might be hundreds of kms away. In some cases correlation are higher due to complex statistics applied but this does not remove the site specific characteristics of these analyses.
Cellulose formation in all of the trees is mostly the same basic physiochemical process as they all undergo C3 metabolic process. This process and resultant isotopic fractionation have been modeled from experimental information on live trees[6,7,8]. Evans[9] used these relations as forward models to determine isotopic values of wood cellulose. Managave et al[10] tested similar forward models for a trial and error interpretation of the unknown inputs. Although some papers e.g.[11] identified some processes in long term data, but no process based reconstructions were given till now.
Among many benefits of process based reconstruction models, the primary is that the parameter being reconstructed and their dependabilities will stay constant in time and space. This will make the resultant reconstructions more easily interpreted in terms of observed physical processes in present and their variabilities in the past.
In presence of basic meteorological data i.e. temperature and humidity estimates,
the pCO2 has been reconstructed from carbon isotope data from tree ring cellulose[12]. The processes involving oxygen and hydrogen isotope fractionations provide information about humidity, temperature and source water isotopic compositions. Some of these process based fractionation models along with resultant reconstructions from them will be discussed.

Published Material: I presented parts of these findings at the AGU Fall Meeting in 2014.

Abstract Body: Twelve temperature-depth profiles (>1500 m) located in Eastern to Central Canada were studied to determine the ground surface temperature histories (GSTH) for the Last Glacial Cycle (LGC) and afterwards. The GSTHs were inferred by inversion. At three locations (Sudbury, Manitouwadge, and Thompson) with multiple boreholes, simultaneous inversion was used to illustrate regional trends. For all studied sites, the results indicate that ground surface temperatures throughout the LGC that range from -1.4-2.5°C, near the pressure melting point of ice. These ground surface temperatures are representative of the basal temperatures of the Laurentide Ice Sheet, which covered the region throughout the LGC. These temperatures allow for the possibility of basal flow and fast flowing ice streams, which have also been inferred from geomorphological data and are consistent with modeling efforts. Regional variations in basal temperatures are observed. A warming following the retreat of the ice sheet is noted at ~5-7.5 ka in all the GSTH reconstructions and is attributed to the Holocene Climatic Optimum. Only a portion of the sampled sites are suitable for studies of recent climate. These sites display

signs of a cold period from 200-500 yrs BP, corresponding to the little ice age.

Title: Environmental DNA preserved in lake sediments: Calibrating a new tool for biodiversity science

Presenter/First Author: Joanna Gauthier, McGill University, Montreal,

Presenter/First Author Email: joanna.gauthier@mail.mcgill.ca

Co-authors: David Walsh, Concordia University, Montreal, QC, Canada; Daniel Selbie, , , ; Isabelle Domaizon, 4Institut National de la Recherche Agronomique, CARRTEL, Thonon-les-Bains, France; Irene Gregory-Eaves, McGill University, Montreal, QC, Canada

Abstract Body: Biodiversity losses are a major cause of global change and could lead to significant alterations in aquatic ecosystems. Therefore, there is an urgent need to quantify biodiversity from aquatic ecosystems. Applying molecular methods to environmental DNA (eDNA) has the potential to greatly advance aquatic biodiversity science as these methods may allow for a more efficient and reproducible quantifications of biodiversity. These methods have proven to be effective in detecting endangered and invasive vertebrate and invertebrate species in water. In paleolimnology, eDNA utilization has the potential to widen the range of possible target taxa. However, more calibration is needed to elucidate the advantages and the limitations of using molecular tools in paleolimnology. The objectives of this project are then (1) to evaluate to the degree to which eDNA from sediment extracts preserve the biological dynamics apparent in the water column, and (2) to quantify the congruence between molecular approaches and traditional tools to identify taxa. To address these objectives, water samples are collected and sediment traps are deployed on a monthly basis in Cultus Lake, British Columbia. Diatoms are targeted in this study because they are adequately preserved in lake sediments and are then a suitable candidate for the calibration purpose. In addition, sockeye salmon are also studied to explore the potential of molecular methods to detect species without diagnostic features preserved in lake sediments. This study will provide great insights of the limitations and the advantages to use molecular methods to reconstruct past community dynamics.

Title: Testate amoeba assemblages of southern Patagonian peat bogs record drastic 20th century shifts: unprecedented climate change or increased UV-B radiation?

Presenter/First Author: Simon van Bellen, University of Aberdeen, Aberdeen,

Presenter/First Author Email: simonvanbellen@gmail.com

Co-authors: Dmitri Mauquoy, University of Aberdeen, Aberdeen, United Kingdom; Richard J. Payne, , , ; Thomas P Roland, University of Southampton, UK, Southampton, United Kingdom; Tim Daley, Plymouth University, Plymouth, PL4, United Kingdom; Paul Douglas Michael Hughes, University of Southampton, Southampton, United Kingdom; N Loader, Swansea University, Swansea, United Kingdom; F. Alayne Street-Perrott, , , ; Emma M. Rice, , , ; Veronica A. Pancotto, , ,

Published Material: We have published the testate amoeba transfer function in Journal of Quaternary Science (2014) 29: 463-474. Here we will present new, yet unpublished reconstructions.

Abstract Body: The ombrotrophic peat bogs of southern Patagonia are located within the southern westerly wind (SWW) belt, the position of which is the dominant mechanism of climate variability in this region. We have sampled cores from peat bogs to reconstruct water table depths during the last 2000 years and aim to relate past fluctuations in water table depth to shifts in regional climate in general and the position and intensity of the SWW in particular.

Cores were extracted from peat bogs located along a longitudinal transect across Tierra del Fuego. We reconstructed local water table depths based upon quantitative analyses of testate amoeba (TA) assemblages. These unicellular organisms live at the surface of humid ecosystems and create shells ('tests') that are generally well preserved in peat and their relative presence is closely linked to the local position of the water table. We therefore constructed a transfer function that allows for the quantitative reconstruction of past water table depths from historical assemblages. This transfer function has predictive ability, but relatively high prediction errors given the wide range of sampled water tables in excess of 100 cm. Statistical analyses of TA assemblages were performed to explore spatio-temporal patterns and relationships with climate and environmental variables.

Although water table depth remained the main environmental variable in explaining fossil TA assemblages, sensitivity to environmental factors varied between sites. During the last 2000 years, bogs recorded slightly wetter conditions between ~500-1000 AD, and drier conditions during the LIA. However, the sharpest change in both amoeba assemblages and reconstructed water table depths, suggesting important drying, was found during the 20th century. Given other evidence from previous publications and considering the regional climatic context, this shift, replicated at several sites, may have been forced by a decrease in precipitation. Nevertheless, we cannot exclude the influence of increasing UV-B radiation resulting from the local degradation of the ozone layer since the late 1970s. This may have affected and possibly still affects living TA

assemblages in the southern Patagonian region.

Title: Recent afforestation of the Johnville Peat Bog, southern Québec, Canada, investigated using dendroecological and paleoecological techniques

Presenter/First Author: Matthew C. Peros, Bishop's University, Sherbrooke, QC

Presenter/First Author Email: mperos@ubishops.ca

Co-authors: Julien Vachon, , ,

Abstract Body: Recent dendroecological and paleoecological investigations at the Johnville Peat Bog, in southern Québec, Canada, have provided insight into the evolution of ombrotrophic bogs (those that receive all precipitation and mineral input from the atmosphere) as well as their response to human impacts, such as drainage. Many peat bogs in eastern North America experienced afforestation during the 20th century due to factors such as fire or landuse changes. The Johnville Peat Bog also underwent afforestation during the 20th century, possibly related to its drainage for agricultural purposes. The purpose of this study is to examine how Picea mariana (black spruce) responded to this drainage in terms of both its spatial distribution and its annual growth. Eighty black spruce trees, in different areas of the bog, and 20 hemlock trees (Tsuga canadensis), around the margin of the bog, were cored to determine the minimum age of the trees and also their rates of annual growth. The results show that the most rapid expansion of black spruce occurred in the area of the bog close to the area of drainage and that trees in other areas of the bog were relatively unaffected. Annual growth rates were determined by scanning and measuring the rings using WinDENDRO software, but showed more equivocal results. This study indicates that tree growth in ombrotrophic bogs is complex but that there is potential for using tree rings from these systems to infer hydroclimatic variability.

Title: Peat bog as geochemical archives of atmospheric dust deposition in eastern Canada: a multi-proxy approach

Presenter/First Author: Steve Pratte, GEOTOP-UQAM, Montreal, QC

Presenter/First Author Email: pratte.steve@gmail.com

Co-authors: Michelle Garneau, GEOTOP-UQAM, Montréal, QC, Canada; François De Vleeschouwer, EcoLab, Auzeville Tolosane, France

Abstract Body: Atmospheric mineral dust plays an important role in the Earth's climate through parameters such as atmospheric radiation, cloud properties and biogeochemical cycles. While variations in dust deposition during the Holocene are not of the same magnitude as those occurring on a glacial-interglacial scale, the complex spatial and temporal variability in climate during this period was important enough to affect dust production and transport. Ombrotrophic peatlands (bogs) have proven to be valuable archives of atmospheric dust deposition as their accumulation rate over the Holocene are rarely matched by other archives.

Two peat bogs, located on the North Shore region, eastern Canada, were sampled to investigate dust deposition/palaeowinds in north eastern North America over the mid and late Holocene. Here we present geochemical (major and trace elements, Pb and Nd isotopes) records combined with ash content, particle size, plant macrofossils and bulk density for both cores. The distribution of lithogenic element (REE, Ti, Sc) concentrations within the cores show periods of increased dust deposition at Baie and IDH. The range of dust deposition varies from 0.5 to 4 g m^{-2} yr^{-1} in the Baie bog and from 0.1 to 2.7 g m^{-2} yr^{-1} in the IDH bog respectively. The higher dust fluxes in the Baie bog were recorded from 100-600 and 1000-1500 cal yr BP, originating either from greater wind intensity or drier climatic conditions. The most significant episode of dust deposition at IDH occur around 3.8 yr cal BP with a maximum of 2.1 g m^{-2} yr^{-1}. Both cores record higher dust fluxes during the last century which suggests an anthropogenic impact on the dust cycle in the region. Before the 19th century (1850AD), the stable Pb isotopes ratios ($^{206}Pb/^{207}Pb$) in the Baie bog range between 1.188 and 1.215, which corresponds to the value of the Canadian Shield. Neodymium isotopes analyses (on going) will allow to identify potential change in dust source which might not be recorded by stable Pb isotopes.

Title: Late Holocene climate of coastal Labrador: subseasonal evidence from stable isotope values of tree-rings

Presenter: Bruce M Eglington, University of Saskatchewan, Saskatoon,

Presenter Email: bruce.eglington@usask.ca

First Author: Sandra Timsic, University of Saskatchewan, Saskatoon, SK

First Author Email: sandra.timsic@usask.ca

First Author Student?: No

Co-authors: William Paul Patterson, University of Saskatchewan, Saskatoon, SK, Canada

Published Material: Manuscript is under review.

Abstract Body: Three centuries of subannual/annual climate data were retrieved from the $\delta^{18}O$ and $\delta^{13}C$ values of tree-ring cellulose in the temperature-sensitive region of central-coastal Labrador, Canada, situated near the northernmost boundary of the boreal forest. A large cookie of a white spruce (*Picea glauca*) tree was micromilled using a custom-made computer-controlled micromilling device to retrieve multiple samples per year and/or early and late wood that were subsequently analyzed for $\delta^{18}O_{cellulose}$ and $\delta^{13}C_{cellulose}$ values. The coastal Labrador/Nunatsiavut region is a climatically dynamic region that is significantly influenced by ocean-atmosphere interactions and thus has exceptional potential for studying both, terrestrial and marine climate variability, and their interactions. $\delta^{18}O_{cellulose}$ values were calibrated to the mean-annual temperature (°C), while $\delta^{13}C_{cellulose}$ values were interpreted to represent long-term water budgets. We found a good agreement between reconstructed mean-annual temperatures and major climatic trends and events, including multidecadal warm and cold climate episodes, historical meteorological measurements collected by the Moravian missionaries, modern mean-annual temperatures and salinity anomalies in the NW North Atlantic Ocean, as well as cooling trends induced by major volcanic eruptions such as Lakagígar in 1783-84, Tambora in 1815, and Krakatoa in 1883. Persistent cold intervals are found from 1790 to 1810, 1875 to 1895, and 1950 to 1970, while the warmest intervals are found during the mid-18th and 19th centuries. A sharp increase in Suess corrected $\delta^{13}C_{cellulose}$ values since the 1960s is possibly related to moisture stress induced by the persistent positive North Atlantic Oscillation (NAO) phase. Moreover, continuous transform wavelet analysis was used to analyze $\delta^{18}O_{cellulose}$ and $\delta^{13}C_{cellulose}$ periodicities and suggest that their interannual and multidecadal periodicities are similar to those of the NAO.

Title: A Time-transgressive Two-phased Hypsithermal Warm Period Across the Boreal Region of Northwest Ontario: A Multiproxy Study From Deep-water and Near-shore Cores

Presenter/First Author: Brian F Cumming, Queen's University, Kingston, ON

Presenter/First Author Email: cummingb@queensu.ca

Co-authors: Donya Danesh, Queen's University, Kingston, ON, Canada; Kathleen R Laird, Queen''s University, Kingston, ON, Canada; Moumita Karmakar, , ,

Published Material: The pollen that will be presented has not been published or submitted. The information on changes in water levels from the nearshore core was just published in The Holocene (2015) Vol. 25. It is the time-transgressive nature of the change in the pollen and the linkage to the hydrological balance of these lakes that is unique, which together provides evidence for two-phased climatic optimum, or Hypsithermal Period.

Abstract Body: Climate warming is expected to have major effects on boreal ecosystems situated near the prairie-forest boundary in central North America. To investigate the impact of past climate change on boreal ecosystems in northwest Ontario over the Holocene, we developed a network of deep-water and near-shore cores from three headwater lakes that spanned a distance of over 250-km from boreal regions near the forest-prairie boundary to spruce-dominated forests to the east (i.e. northwest of Kenora to north-east of Sioux Lookout). Center cores were used to reconstruct large-scale changes in climate based on changes in pollen assemblages in the cores. The lake closest to the forest-prairie boundary exhibited a prolonged period of early-to-mid Holocene aridity, as indicated by a decline in spruce and increases in shrubs and grasses, from approximately 10,000 to 3,000 cal yr BP. Sites located further into the boreal forest had a much shorter period of enhanced aridity that extended from approximately 8,500 to 4,500 cal yr BP. We used near-shore sediment cores to track changes in water levels in these three lakes over the Holocene based on changes in diatom assemblages to reconstruct past water balance. In all cores, planktonic diatom assemblages increased during the later phase of the Hypsithermal Period (as indicated by the pollen), with changes in the lake closest to the forest-prairie boundary showing the longest and most pronounced changes. Taken together, this study supports a two-phased Hypsithermal Period: a warm-dry phase followed by a warm-wet phase. Further, the extent of the Hypsithermal was substantially longer closer to the forest-prairie boundary, with an earlier onset and later termination, in comparison to the sites that are today well within the boreal region. This study also suggests that high water levels in northwest Ontario have occurred only over the last four-to-five thousand years, and that many boreal lakes were more productive during the Hypsithermal Period.

Title: Documentary Data Rescue In Canada: Daily Temperature Records For The St-Lawrence Valley In The Past 270 Years

Presenter/First Author: Victoria Slonosky, Organization Not Listed, Montreal,

Presenter/First Author Email: victoria.slonosky@mail.mcgill.ca

Published Material: Some of this work has been presented in a seminar at McGill Univsersity and at the 7th ACRE meeting. The methodology used (which will be very briefly explained for purposes of clarity) was published in 2014.

Abstract Body: Daily weather observations in Montreal and Québec City from the mid-1700s until the end of the 19th century have been digitized by a crowd-source citizen science data rescue project. Sub-daily (typically two or three observations per day) temperature readings from 14 different sources were assessed for quality using observational frequency techniques by comparing the historical observations with modern hourly data. A series of regression models were constructed and validated to estimate historical daily minimum and maximum temperature from the sub-daily historical measurements. The reconstructed minimum and maximum temperatures were used to compile a single series of daily minimum and maximum temperatures for the St-Lawrence Valley region between 1742 and 2010, with nearly continuous observations from 1798 to 2010. These daily temperatures were analyzed for changes and variability over the past two and half centuries. Cold conditions prevailed in the 1810s, 1830s and 1880s, while warm summers were observed in 1808, 1825, and 1955. Documentary evidence also suggests warm summers and frequent drought in the mid-18th century, with the hot and dry summer of 1754 described in particular detail. While there are warming tendencies in minimum temperatures, especially in winter with no very cold winters since the 1930s, little change over the century time scale is seen in maximum temperatures. Climatic indicators such as heat wave and cold spell counts suggest considerable decadal scale variability over the past 200 years.

Title: Impact of Holocene Climate Variability on Arctic Vegetation

Presenter/First Author: Konrad J Gajewski, University of Ottawa, Ottawa, ON

Presenter/First Author Email: gajewski@uottawa.ca

Abstract Body: Using all available postglacial pollen data from across the Canadian Arctic and around Greenland, the regional vegetation history was studied in the context of Holocene climate variability. Pollen records from several islands in the Canadian Arctic Archipelago show that most taxa arrived immediately after local deglaciation, in spite of the apparent obstacles to dispersal. The fossil pollen records were compared to modern samples from the Arctic to determine if the vegetation during the early to mid-Holocene warm period resembled the modern vegetation. Most Holocene pollen samples find analogues in the modern data, although the values of squared chord distance (SQD), which defines similarity between fossil and modern data, tend to be larger in samples older than 5000 cal yr

BP. Plant production, as measured by pollen influx tended to be greater during warmer periods.

Title: The paleoecological record of gray birch (*Betula populifolia*) in eastern North America

Presenter/First Author: Martin Lavoie, Laval University, Québec,

Presenter/First Author Email: martin.lavoie@cen.ulaval.ca

Co-authors: Patricia Beauregard, , , ; Stéphanie Pellerin, , ,

Abstract Body: Gray birch (*Betula populifolia* Marshall) is a tree species native to North America, with a continuous distribution range extending east to west from Novia Scotia to southern Ontario, and south to New Jersey and Pennsylvania. It is a fast-growing, short-lived pioneer species that prefers poor, dry soils. Present notably on abandoned fields, the species can colonize diverse habitats. Little paleoecological information about the postglacial dynamic of gray birch is available, largely due to the fact that it is virtually impossible to identify its pollen in pollen assemblages. In order to document its past presence, we examined all sites within and beyond the species' current distribution range in eastern North America that have been subjected to macrofossil analyses. Periods during which the species was present were estimated based on available ^{14}C data. In total, more than 20 sites with gray birch remains were inventoried. The first occurrences date from the Late Glacial and Early Holocene. Gray birch was present during the period when the first forests formed, and fires were more frequent than they are today. Few sites show a long continuous presence of gray birch in macroremains assemblages during the Holocene. These sites are situated in pine barrens where fires seem to have always been frequent. Several ombrotrophic peatlands are characterized by gray birch establishment during approximately the last hundred years, very probably due to drier hydrological conditions in response to anthropic activities (agriculture, urbanization), conditions that favor the species' expansion.

Title: Radiocarbon Dates in Québec: Analyzing Paleopopulations and Environmental Change

Presenter/First Author: Michelle A. Chaput, University of Ottawa, Ottawa, ON

Presenter/First Author Email: mchap036@uottawa.ca

Co-authors: Konrad J Gajewski, University of Ottawa, Ottawa, ON, Canada

Abstract Body: The extent to which North American paleopopulations influenced the environment and contributed to global atmospheric change remains unknown, partly due to a lack of data concerning population densities. The analysis of archaeological radiocarbon dates is one way of obtaining paleopopulation densities since the frequency of dates can be interpreted as being proportional to the number of people living around a site. The Canadian Archaeological Radiocarbon Database (CARD) contains more than 35,000 radiocarbon dates derived from cultural and paleoecological material spanning the last 25,000 years. These data form the basis of our study of past human-ecosystem-climate dynamics.

A first step in the analysis of any database is to identify problematic data, which can occur due to many causes, including contamination by older or younger carbon and stratigraphic problems. To obtain an accurate representation of human impact on North American ecosystems, these dates must be identified and corrected, and additional dates must be obtained for locations with insufficient data. The issue of taphonomic loss must then be addressed such that the true human population density is revealed. Although shown to provide reasonable results at a continental scale, more work is needed to determine at what point the "dates as data" approach is applicable at regional scales.

Six hundred and sixty two CARD dates from Québec spanning 13,000 years were analyzed as a function of ecoregion. Most dates are located in coastal regions, along the St. Lawrence River, or are associated with resource development projects. All ecoregions display a similar trend in the frequency of dates, which generally increases towards the present, with the exception of a sharp increase between 1,000 and 3,000 cal BP. Further analyses will reveal whether the sharp increase in date frequency is a result of taphonomic loss or population growth. Humans appear to have settled all ecoregions following the retreat of the Laurentide Glacier. One site in coastal northern Québec, where glacial ice remained until approximately 7,000 years ago, had a clearly anomalous date (8,428 cal BP). The uneven spatial distribution of sites, a consequence of archaeological activity, also needs to be considered when mapping past population distributions.

Title: Space-time Millenial-Scale Evolution of Vegetation and Climate Gradients in Boreal and Mixed Forests of Western Québec since 9000 years

Presenter/First Author: Bianca Fréchette, GEOTOP-UQAM, Montréal, QC

Presenter/First Author Email: frechette.bianca@uqam.ca

Co-authors: Pierre Grondin, Ministère des Ressources Naturelles, Québec, Canada; Martin Lavoie, Laval University, Québec, Canada; Pierre JH Richard, , ,

Abstract Body: Millenial-scale changes in vegetation gradients and climate conditions were reconstructed in more than 25 lacustrine cores of the boreal and mixed forests, in western Québec, based on the modern analogue technique applied to pollen assemblages. The modern database used includes 1010 sites from eastern Canada, east of 100°W. Pollen assemblages of surface samples and modern climate conditions are available in the database and a cluster (*K*-means) analysis applied to surface pollen assemblages helped in assessing the modern vegetation of the sites. The reconstructed vegetation types are illustrated on maps and postglacial changes in vegetation gradients are evidenced. The reconstructed climate parameters include July temperature, annual precipitation and summer sunshine. Here, the reconstruction of summer sunshine is used to document large-scale atmospheric circulation patterns. Although climate reconstructions from individual sites indicate some local differences, there are generally consistent features on a regional scale including a progressive 1°C decrease in July temperature since 9000 cal BP, a progressive 150mm/yr increase in annual precipitation and a 3% decrease in summer sunshine. Data also indicate notable climate and vegetation changes at 5000 cal BP. In western Québec, climate was warmer and drier than today before 5000 cal BP and the dominant westward winds were stronger. This climate transition is tentatively attributed to a weakening of atmospheric circulation. Maps of paleo-vegetation point to west to east gradients before 5000 cal BP and to more diversified vegetation. Thermophilous trees were then more abundant than today in forests of western Québec. Reconstructed vegetation also illustrates that modern latitudinal gradients were attained lately at ca. 3500 cal BP. Coniferous trees abundance then increased in vegetation landscapes and modern boreal forest established in western Québec.

Title: Impact of the Little Ice Age cooling and recent climate change on peatland vegetation and peat accumulation dynamics in northeastern Alberta, Canada

Presenter/First Author: Gabriel Magnan, GEOTOP-UQAM, Montreal, QC

Presenter/First Author Email: magnangabriel@gmail.com

Co-authors: Simon van Bellen, University of Aberdeen, Aberdeen, United Kingdom; William Shotyk, University of Alberta, Edmonton, AB, Canada; Claudio Zaccone, University of Foggia, Foggia, Italy; Catherine La Farge, University of Alberta, Edmonton, AB, Canada; Michelle Garneau, GEOTOP-UQAM, Montréal, QC, Canada

Abstract Body: Northern peatlands are one of the most important terrestrial sinks of organic carbon (C) and these ecosystems are highly sensitive to human activities and climate change. This study aims at understanding how the climate changes over the last 1000 years have affected peatland vegetation and peat accumulation dynamics in the boreal region of northern Alberta. The past changes in vegetation communities were reconstructed using high-resolution plant macrofossil analyses from multiple peat bogs located at the southern limit of permafrost peatland distribution in the Fort McMurray region (56-57° N). Our data show important changes in peatland vegetation and peat accumulation dynamics that coincide with the Little Ice age cooling period (~AD1600-1850) and the subsequent climate warming. In all the peatlands, the plant macrofossil data suggest a synchronous period of permafrost aggradation characterised by dry ombrotrophic conditions, increased peat decay and high abundance of ericaceous shrubs and black spruce (*Picea mariana*). In most sites, this period was followed by permafrost thawing characterised by a short-term local shift towards wetter minerotrophic conditions (*Sphagnum* sect. *Cuspidata*) and a decline in black spruce on the peatland. Finally, we have observed a subsequent shift to a relatively stable presence of *Sphagnum* sect. *Acutifolia* (e.g. *Sphagnum fuscum*) which indicates the establishment of relatively dry ombrotrophic conditions in all the peatlands. Our data suggest that the recent climate change has been particularly favourable to *Sphagnum* growth and peat accumulation in northeastern Alberta.

Title: Holocene Paleohydrological Changes in the Southern Bay of Biscay: New Insights from Planktonic Microfossil Assemblages

Presenter/First Author: Marie-Camille Gasparotto, GEOTOP-UQAM, Montréal,

Presenter/First Author Email: mcamille.gasparotto@gmail.com

Co-authors: Sandra Brocheray, , , ; Frédérique Eynaud, , , ; Linda Rossignol, , , ; Marion Péral, , , ; Fabienne Marret, Univ of Liverpool, Liverpool, United Kingdom; Yannick Mary, , , ; Marie-Hélène Castéra, , , ; Sébastien Zaragosi, , , ; Michel Cremer, , ,

Published Material: M.-C. Gasparotto, S. Brocheray, F. Eynaud, L. Rossignol, M. Péral, F. Marret, Y. Mary, M.-H. Castéra, S. Zaragosi, M. Cremer, Holocene paleohydrological changes in the southern Bay of Biscay: new implements from planktonic microfossil assemblages., Poster for the XIVth International Symposium on Oceanography of the Bay of Biscay (ISOBAY 14), June 11-13, 2014, Bordeaux (France)

Abstract Body: The Bay of Biscay is a region where significant shifts related to the North Atlantic Oscillation variation occur, a mechanism that is considered to be a major internal forcing for the climate variation during the Holocene, but still not too well constrained in this region. A core (PP10-07, 43°40.63'N; 02°13.69'W, water depth of 1472 m and 2004 cm long) collected at Capbreton canyon, with an exceptional sedimentation rate has enabled to recover a continuous and undisturbed Holocene climate signal, with a decadal to secular resolution. The present study was focused on studying cysts of dinoflagellates (dinocysts) with the aim to quantitatively reconstruct surface hydrological paleo-parameters and paleo-productivity, and therefore highlighting the Holocene signal of oceanographic changes in this area of the North East Atlantic. The ecological significance of the analysed dinocyst assemblages, besides showing evidence of high biodiversity, does not indicate any important movement of water masses. Most of the identified species are cosmopolitan and adapted to a wide range of surface temperature and salinity. These species are typical from the North Eastern Atlantic subtropical to temperate bioclimatic assemblages, with especially high occurrences of the intra-neritic species such as *Lingulodinium machaerophorum*, together with the cosmopolitan *Operculodinium centrocarpum* and *Spiniferites ramosus*. However, the quantitative reconstruction of the surface hydrological parameters and paleo-productivity through modern analogue technique derived from transfer functions highlights changes in temperature significantly differing from both the current average temperatures and the temperature signal given by foraminiferal data. Moreover, a relation between temperature variations and productivity at some times was observed, which could be as much associated with a cold or warm episode. Coupled to the detailed investigations made on the sedimentary context of the deposits, these palynological data derived from dinocyst assemblages allow us, for the first time in the Capbreton canyon area, to: (1) test the reliability of the marine palynological flora record in this atypical sedimentological environment, and (2) tentatively draw a coherent paleoceanographical pattern along the Holocene.

Title: Anthropogenic carbon release rate unprecedented throughout the Cenozoic

Presenter/First Author: Richard E Zeebe, University of Hawaii at Manoa, Honolulu, HI

Presenter/First Author Email: zeebe@hawaii.edu

Co-authors: Andy John Ridgwell, University of Bristol, Bristol, BS8, United Kingdom; James C Zachos, University of California Santa Cruz, Santa Cruz, CA

Abstract Body: Carbon release rates from anthropogenic sources have reached a record high of about 10 Pg C/y in 2013. Due to uncertainties in climate system feedbacks, the impact of the rapid carbon release on ocean biogeochemistry and future climate change is difficult predict. Geological analogues from past climate episodes are therefore urgently sought after to guide future climate change assessment. Based on data and models of various past eras and climate episodes, this presentation will provide a paleo-perspective on the magnitude and rate of anthropogenic CO2 emissions, including effects on seawater chemistry, carbonate mineral dissolution, and ocean biogeochemical cycles. Given currently available records, we demonstrate that the present anthropogenic carbon release rate is unprecedented throughout the Cenozoic (past 66 million years). Our results have important implications for our ability to use past analogues to predict future changes, including constraints on climate sensitivity, ocean acidification, and impacts on marine and terrestrial ecosystems.

Title: THE PAST AND FUTURE DYNAMICS OF ECOSYSTEM COMBUSTION AND CLIMATE

Presenter/First Author: Richard Paul Guyette, University of Missouri Columbia, Columbia, MO

Presenter/First Author Email: guyetter@missouri.edu

Co-authors: Michael C Stambaugh, University of Missouri-Columbi, Columbia, MO; Daniel C Dey, , ,

Published Material: Partially presented at Great Plains Drought Conference, Omaha, Nebraska.Parts of this presentation in scientific Journals: Forest Science and Ecosystems

Abstract Body: Society is confronted with the effects of climate change on fire in ecosystems. Bringing paleo data and ecosystem processes into the future will increase the strength of estimating future conditions. We develop and calibrate an ecosystem combustion model (PC2FM[1]) with pre-climate change fire data, abiotic atmospheric variables (temperature K, H_2O, and O_2), and biotic variables (proxy reactant concentration) for predicting fire intervals and probability. We demonstrate a method for estimating changes in fire probability based on temperature and precipitation output from global climate models (GCMs). We calculated change in fire frequency and probabilities from the difference between current and future climates and map climate forced percent changes in fire probability under GCMs. Future fire probability estimates increased in cooler northern and high elevation regions, but decreased slightly in some hotter and drier regions. Our approach's greatest strength may be reliance on only climate data and the basic principles of physical chemistry.

Title: Stability of the AMOC depends on the background climate

Presenter/First Author: Aixue Hu, National Center for Atmospheric Research, Boulder, CO

Presenter/First Author Email: ahu@ucar.edu

Co-authors: Gerald A Meehl, National Center for Atmospheric Research, Boulder, CO; Ayako Abe-Ouchi, University of Tokyo, Bunkyo-ku, Japan

Abstract Body: Atlantic Meridional Overturning Circulation (AMOC) is an important global scale oceanic circulation which contributes significantly to the global heat balance. Previous theoretical and modeling studies suggest that the stability of this circulation can affect the regional and global climate and may be the primary cause of the abrupt climate change event in the ice core records. Here we use two version of the Community Climate System Model (CCSM3 and CCSM4) to study the hysteresis of the AMOC under present day and mid-glacial conditions with two ensembles for each background condition. This is the first time that we clearly demonstrate the AMOC's hysteresis not only depending on the background climate but also depending on the status of the Bering Strait. With an open Bering Strait, the AMOC strength is only determined by the strength of the external haline or thermal forcing, not the background climate, and does not have hysteresis behavior. However, with a closed Bering Strait, the AMOC could collapse/restart suddenly and induces abrupt climate change events regardless the background climates. Further, the width of the AMOC hysteresis loop is affected by the background climates with a much narrower width under glacial conditions, suggesting that with a closed Bering Strait, the AMOC is much more sensitive to the freshwater perturbation in the subpolar North Atlantic than under present day condition. For the future warmer climate with an open Bering Strait, the AMOC could collapse due to strong greenhouse gas effect, but would restart as soon as the greenhouse gas forcing weakens, indicating the absence of the AMOC hysteresis. We conclude that the AMOC is possibly mono-stable under present day condition with an open Bering Strait, and multiple stable under glacial condition when Bering Strait is closed.

Title: Pliocene Climates and the Pliocene Model Intercomparison Project

Presenter/First Author: Mark A. Chandler, CCSR / NASA GISS, Madison, WI

Presenter/First Author Email: mchandler1@gmail.com

Co-authors: Alan M Haywood, University of Leeds, Leeds, United Kingdom; Harry J Dowsett, USGS, Baltimore, MD; Aisling M Dolan, University of Leeds, Leeds, LS2, United Kingdom; David B Rowley, University of Chicago, Chicago, IL; Ayako Abe-Ouchi, University of Tokyo, Bunkyo-ku, Japan; Bette L Otto-Bliesner, National Center for Atmospheric Research, Boulder, CO; Dan John Lunt, University of Bristol, Bristol, United Kingdom; Ulrich Salzmann, Northumbria University, Newcastle-Upon-Tyne, United Kingdom

Published Material: Similar material will be presented by the same group of authors at the April 2015 EGU. Little overlap in participation is expected, thus the dual presentations.

Abstract Body: The mid-Pliocene Warm Period probably bears a closer resemblance to the CMIP5 RCP8.5 scenario than any other well-studied geologic interval (see Masson-Delmotte et al., 2013, Box 5.1). Marine and terrestrial data point to high-latitude temperature amplification, decreases in sea ice and land ice, higher sea levels, and poleward expansion of warm climate biomes. But uncertainty remains regarding how nearly representative mid-Pliocene regional climates and processes are of Earth's future climate. The Mid-Pliocene CO2 level was 350-450 ppm, higher than pre-industrial, but far lower than projections for even the mid-21st century. Yet sea level rise was probably much greater than will occur in the coming century. The IPCC 5th assessment points to significant melting of Greenland and West Antarctic ice sheets, plus some ice loss from East Antarctica, during the Pliocene. This, along with other geologic evidence, yields *high confidence* that sea level was above present, with 20 meters being an upper bound. An additional disparity between Pliocene and future climate simulations exists in the North Atlantic, where warming surpasses all other regions during the Pliocene but lags in RCP8.5. The next phase of model-model-data comparisons, designated PlioMIP-2, will attempt to address some of these uncertainties.

PlioMIP Phase 1 (2008-2014) resulted in the most complete analysis to date of Pliocene climate, including: detailed analyses of ocean circulation and monsoon behavior, an examination of large-scale global climate features and the ability of models to reproduce regional climates reconstructed from marine and terrestrial paleodata. We will highlight some of the PlioMIP-1 results before discussing the new PlioMIP-2 experiment design. PlioMIP-2 will incorporate significant updates to the paleogeographic boundary conditions, including a new land/sea mask, topography, bathymetry, and the Greenland and Antarctic ice-sheets. Within the PlioMIP-2 framework modelling groups will also have the option of using dynamic global vegetation models. Finally, the long-term partnership with the USGS Pliocene Research Interpretation and Synoptic Mapping Project (PRISM4), will give PlioMIP-2 participants access to an expanded, high-resolution data set of marine proxy records designed to aid data/model comparisons.

Title: Volcanoes and Water Vapor Feedback in the Past and Implications for the Future

Presenter/First Author: Allegra N LeGrande, NASA Goddard Institute for Space Studies, New York, NY

Presenter/First Author Email: allegra.n.legrande@nasa.gov

Co-authors: Kostas Tsigaridis, Columbia University of New York, Palisades, NY; Susanne Bauer, NASA Goddard Institute for Space Studies, New York, NY; Gavin A Schmidt, NASA Goddard Institute for Space Studies, New York, NY

Abstract Body: The 1991 eruption of Mt. Pinatubo has long been used as a key forcing to assess the skill of GMCs in simulating feedbacks associated with tropospheric water vapor, radiation and dynamics. In particular, tropospheric water vapor decreases significantly after the eruption, magnifying the directly-induced surface cooling. In contrast, stratospheric water vapor increases in response to volcanic eruptions. Previous work has speculated that the climate response to historical volcanic eruptions, such as Krakatoa in 1883, may have in fact been mitigated by the direct addition of water vapor into the stratosphere.

We will describe in detail the water vapor response to volcanic eruptions over the last millennium to the present. We have tested two versions of the GISS-E2 model, one in which volcanic aerosol distribution and properties are prescribed, and another where we use prognostic model of aerosol microphysics (MATRIX) and model physics to produce a distribution consistent with direct emissions of volcanic output. Where possible, especially for the 1815 Tambora eruption (one of the largest and well constrained eruptions of the last millennium), we assess the skill of the model in simulating the appropriate sized temperature response to the volcanic forcing.

We find that in contrast to the prescribed-aerosol version, the stratospheric water vapor feedback in the MATRIX version of the model is much longer lasting. In addition, additional water vapor injection to the stratosphere in the MATRIX version does not attenuate the climate response, rather expedites the chemistry to convert the emissions to aerosols. We assess the impact that these contrasting responses could have on our ability to simulate future climate change – not only in response to volcanic forcing, but any strong global radiative perturbation, including greenhouse gases.

Title: Using the Paleo-Record to Constrain Future Arctic Climate Change from Global Climate Models

Presenter/First Author: Bruno Tremblay, McGill University, Montreal, QC

Presenter/First Author Email: bruno.tremblay@mcgill.ca

Co-authors: David B Huard, David Huard Solutions, Quebec City, QC, Canada; Gavin A Schmidt, NASA Goddard Institute for Space Studies, New York, NY; Anne de Vernal, University of Quebec at Montreal UQAM, Montréal, QC, Canada

Abstract Body: The Coupled Model Intercomparison Project, Phase 5 (CMIP5), include historical simulations from the 20th century, future climate simulations following different Representative Concentration Pathways (RCPs) for the 21st Century and beyond, and, for the first time in CMIP, three sets of paleo-climate simulations of the recent past for which more paleo-proxi-data exist. We use simulations of the Mid- Holocene (MH) climate (6K BP) from General Circulation Models participating in CMIP5 to constrain future projections of Arctic climate change by the same models. During the Mid-Holocene, the Arctic received approximately 50 W/m2 more solar radiation at the top of the atmosphere during summer, a similar increase to what is projected from greenhouse gas forcing for the middle of the 21st century. The constraint in our analysis arise from a measure of the ability of GCMs to hindcast MH climate using a suite of both land paleo-records – which are much more abundant for high latitudes than ocean proxy - and ocean paleo-record. Results show that GCMs with skill at simulating the MH climate and today's climate give more realistic future projections of the sea ice decline in forced climate simulations of the 21st century participating in the IPCC-AR5.

Title: Using scaling fluctuation analysis to determine the accuracy of climate records and multiproxy reconstructions and the return periods of climate events

Presenter/First Author: Shaun Lovejoy, McGill University, Montreal, QC

Presenter/First Author Email: lovejoy@physics.mcgill.ca

Published Material: The return period part (in the coclusion of the talk) has appeared in GRL last summer, but the rest has not been published.

Abstract Body: There has been much debate about the reliability of climate records and multiproxy reconstructions. There are now half a dozen global scale climate records and a dozen or so multiproxy reconstructions, each based on somewhat different data and different methodologies. We argue that a) we can only have high levels of confidence when there is substantive agreement between them, b) due to numerous sources of bias, that the most difficult problem is accurate rendition of the low frequencies. Using three instrumental records and a reanalysis and nine last millenium multiproxy reconstructions, we therefore determined the variabilities as functions of time scale as well as

the differences between series as functions of time scale using fluctuation analysis (based on easy to understand and interpret Haar wavelets).

Although due to increased temporal averaging, we might naively expect the discrepancies between records to diminish with scale, on the contrary we find that for the global temperature over the range 1 month to one hundred years, that the RMS fluctuations in the differences are constant at around ±0.03K. While this is sufficient for many purposes, it cannot be easily accounted for - we discuss various hypotheses. An analogous analysis of the multiproxies shows a) an improvement of the more recent ones (post 2003) with respect to the older ones, b) agreement to within about ±0.05 K for scales below a century, but rapidly rising at longer time scales. We conclude that for centennial scale studies of pre-industrial statistics (including the determination of return times for natural temperate fluctuations and statistical hypothesis testing), that the data and multiproxies are sufficiently accurate. However, this may not be true of the multicentennial, and longer scale variability.

Title: Wandering, uplifting, and eroding continents: impact on silicate weathering and carbon cycle

Presenter/First Author: Yves Godderis, GET CNRS, Toulouse,

Presenter/First Author Email: yves.godderis@get.obs-mip.fr

Co-authors: Yannick Donnadieu, LSCE Laboratoire des Sciences du Climat et de l'Environnement, Gif-Sur-Yvette Cedex, France; Sebastien Carretier, IRD Institute for Research and Development, Marseille Cedex 02, France; Galen P Halverson, McGill University, Montreal, QC, Canada

Abstract Body: The geological evolution of the carbon cycle is pending on many complex processes. Among them, continental silicate weathering is known to be a controling factor of first importance, able to modulate the atmospheric CO2 and the Earth climate. But this process is itself a function of many processes. Specifically, the role of mountain uplift and basaltic weathering has been particularly discussed in the recent years. But much less attention has been paid to the role of continental drift, which modulates the climate over large regions, and hence the CO2 consumption by silicate weathering.

Here we discuss the combined effects on the Earth climate of two major continental reorganizations: one in the late Neoproterozoic and the other in the late Paleozoic. The investigation tool is the coupled carbon-climate numerical model GEOCLIM. In the first case, the tectonic context is the dislocation of the Rodinia super continent, with the onset of many highly weatherable large igneous provinces, all processes leading to a global cooling. In the second case, antagonistic forcings (the equatorial hercynian range promoting weathering and the Pangea assembly inhibiting weathering through aridification) produces first a global cooling from 330 to 290 Ma. This cooling is concomittant with the Late Paleozoic Ice Age. Then the demise of the range and the rising aridity allows CO2 to rise to high level in the late Permian, ending the glacial episode.

In both case, the scenarios are in agreement with the strontium isotopic ratio evolution, which traces the relative contribution of the weathering of various lithologies to the global strontium and carbon budgets.

Title: Continental Magmatic Arcs as Drivers of Neoproterozoic and Phanerozoic Icehouse-Greenhouse Transitions

Presenter/First Author: Ryan McKenzie, Yale University, New Haven, CT

Presenter/First Author Email: ryan.mckenzie@yale.edu

Co-authors: Brian K Horton, University of Texas at Austin, Austin, TX; Daniel F Stockli, University of Texas, Austin, TX; Shannon E Loomis, University of Texas at Austin, Austin, TX

Published Material: Similar results were presented in a poster at the GSA annual meeting

Abstract Body: Tectonic outgassing from volcanic and metamorphic degassing contributes the major CO_2 flux to the atmosphere, whereas silicate weathering and organic matter burial draws down CO_2 on multimillion-year timescales. Variation in silicate weathering is generally consider the dominant controller of atmospheric pCO_2 and shifts in global climate regimes. Recent studies, however, postulate that continental arc magmatic systems in particular may play the major role in pCO_2 variation. Here we present a compilation of ~120,000 new and published single grain detrital zircon U-Pb age-dates acquired from globally dispersed siliciclastic sedimentary rocks with depositional ages that span the last ~720 million years. Globally, age distributions are skewed towards relatively young detrital zircon populations during periods of greenhouse climates, e.g., the Cambrian, Jurassic, and Cretaceous, whereas age distributions during the Cryogenian and Permian icehouse climates are broader with relatively low concentrations of young grains. These shifts in the relative abundance of young zircon grains indicate that continental volcanic arcs were spatially extensive during greenhouse climates and spatially reduced during icehouse climates. Based on this relationship, we propose that major shifts in atmospheric pCO_2 have been principally controlled by the continental arc volcanic flux, which drove major icehouse-greenhouse transitions from the Cryogenian to the modern.

Title: Coupled tectonic-ocean-atmosphere-weathering-pCO_2 feedback as a trigger for Eocene-Oligocene Antarctic glaciation

Presenter/First Author: Genevieve Elsworth, McGill University, Montreal, QC

Presenter/First Author Email: genevieve.elsworth@gmail.com

Co-authors: Eric D Galbraith, McGill University, Montreal, QC, Canada; Galen P Halverson, McGill University, Montreal, QC, Canada

Published Material: 2013 AGU Fall Meeting

Abstract Body: Rapid emplacement of the Antarctic ice sheet spanning the Eocene-Oligocene Transition (EOT) was initially attributed to thermal isolation of Antarctica due to tectonic widening of Southern Ocean gateways, but in recent years it has been more frequently attributed to atmospheric pCO_2 drawdown. A combination of geochemical evidence and modeling results suggest the possibility that a series of Earth system feedbacks actually linked these two mechanisms together by reducing atmospheric pCO_2 in response to an initial tectonic change and thereby triggering Antarctic glaciation. Large vertical gradients in benthic foraminiferal $\delta^{13}C$ in the Southern Ocean, evident from ODP Sites 689 [*Diester-Haass and Zahn*, 1996] and 1090 [*Pusz et al*., 2011], suggest that strong stratification of the Southern Ocean developed during an ~2 million year interval of the latest Eocene. We suggest that during this time, the deepening of Southern Ocean gateways prevented southward geostrophic transport of saline subtropical water to high southern latitudes, causing

the North Atlantic to salinify in compensation, and thereby strengthening the Atlantic Meridional Overturning Circulation. The consequent effects of changes in ocean heat transport, amplified by radiative cloud feedbacks, would have resulted in a warming of the northern hemisphere relative to the southern hemisphere [*Yang et al*., 2013], consistent with temperature reconstructions [*Plancq et al*., 2014; *Zanazzi et al*., 2007]. Because the northern hemisphere contains more land area, the interhemispheric temperature shift would have accelerated the global rate of silicate weathering, providing a mechanism for the drawdown of atmospheric pCO_2 and global cooling during the latest Eocene. The decline of atmospheric pCO_2 below a certain threshold would have enabled rapid growth of the Antarctic ice sheet across the EOT, with the subsequent formation of cold, dense waters ventilating the Southern Ocean and subsequently eliminating the vertical benthic foraminiferal $\delta^{13}C$ gradient. This series of Earth system feedbacks – initiated by the tectonic deepening of Southern Ocean gateways and culminating in atmospheric pCO_2 drawdown driven by silicate weathering – reconcile competing hypotheses for the mechanisms responsible for onset of Antarctic glaciation during the EOT.

Title: Testing for supply-limited and kinetic-limited chemical erosion in field measurements of regolith production and chemical depletion

Presenter/First Author: Ken Ferrier, Harvard University, Cambridge, MA

Presenter/First Author Email: ken.ferrier@gmail.com

Co-authors: Clifford S Riebe, University of Wyoming, Laramie, WY; William Jesse Hahm, University of Wyoming, Laramie, WY

Published Material: I spoke on a similar subject at the AGU 2014 Fall Meeting. These results have not been published anywhere.

Abstract Body: Understanding the controls on silicate weathering rates is of wide interest because silicate weathering influences nutrient supply, landscape evolution, and Earth's long-term climate. Some studies have suggested that silicate weathering rates are proportional to rates of mineral supply to the regolith, a condition known as supply-limited chemical erosion. Because this condition implies that silicate weathering rates should be strongly coupled to regolith production rates, and because regolith production rates are strongly coupled to rock uplift rates, this also implies that silicate weathering rates (and hence climate, via the carbon cycle) should be strongly coupled to tectonics over long timescales. Although theoretical considerations suggest that silicate weathering rates should scale with supply rates, it has been difficult to test whether chemical erosion rates are in fact supply-limited at any given field site. One obstacle is that the quantities that are most frequently used to test for supply limitation (i.e., rates of denudation and chemical erosion in regolith-based studies, and fluxes of sediment and solutes in river-based studies) are spuriously correlated, which complicates attempts to quantify effects of one variable on the other. Here we discuss a statistical method for testing for supply-limited chemical erosion, and we apply it to a number of published datasets. Our results suggest that chemical erosion rates in most of these datasets depend more strongly on supply rates than on dissolution kinetics, but they also suggest that the uncertainties in many datasets are too large to conclude whether regolith chemical erosion is or is not supply-limited. These analyses suggest that new measurements across a wide range of supply rates will be needed to quantify the strength of the coupling between chemical erosion and mineral supply, and, ultimately, to test hypotheses about the influence of tectonics on the long-term evolution of Earth's climate.

Title: The Importance of Terrestrial Weathering for Climate System Modelling on Extended Timescales: A Study with the UVic ESCM

Presenter/First Author: Marc-Olivier Brault, McGill University, Montreal, QC

Presenter/First Author Email: marc-olivier.brault@mail.mcgill.ca

Co-authors: Lawrence A Mysak, McGill University, Montreal, QC, Canada; Damon Matthews, Concordia University, Montreal, QC, Canada; Christopher T Simmons, McGill University, Montreal, QC, Canada

Abstract Body: The chemical erosion of carbonate and silicate rocks is a key process in the global carbon cycle and, through its coupling with calcium carbonate deposition in the ocean, is the primary sink of carbon on geologic timescales. The dynamic interdependence of terrestrial weathering rates with atmospheric temperature and carbon dioxide concentrations is crucial to the regulation of Earth's climate over multi-millennial timescales. However any attempts to develop a modeling context for terrestrial weathering as part of a dynamic climate system are limited, mostly because of the difficulty in adapting the long timescales of the implied negative feedback mechanism with those of the atmosphere and ocean, the latter typically operating on timescales several orders of magnitude lower than the former. As a result we still have but a rudimentary understanding of the chemical weathering feedback mechanism and its effects on ocean biogeochemistry.

Much of the earlier work on this topic is based on box-model approaches, abandoning spatial variability for the sake of computational efficiency and the possibility to investigate the impact of weathering on climate change over time frames much longer than those allowed by traditional climate system models. Only one such attempt [Meissner et al., 2012, Global Biogeochemical Cycles 26] has been made with the University of Victoria Earth System Climate Model (UVic model), to investigate the role of weathering as a dynamic component of the global carbon cycle. Using a land map which takes into account a number of different rock lithologies as well as changes in sea level, and an empirical model of the temperature and NPP dependency of weathering rates for the different rock types, we introduce a two-dimensional representation of weathering processes into the carbon cycle component of the UVic model. Taking the last deglacial period (c. 21000BP to 13000BP) as a contextual timeframe, we compare results between our 2-D version of the weathering feedback mechanism and a simulation using only the box-model parameterizations of Meissner et al. [2012]. In doing so we hope to assess the importance of two dimensional factors (i.e., changes in sea level and rock type distribution) within the weathering negative feedback mechanism.

Title: Global carbon burial in deep-sea sediment across the last glacial cycle based on a comprehensive sediment proxy database.

Presenter/First Author: Olivier antonin Cartapanis, McGill University, Montreal, QC

Presenter/First Author Email: oliviercartapanis@yahoo.fr

Co-authors: Eric D Galbraith, McGill University, Montreal, QC, Canada; Daniele Bianchi, McGill University, Montreal, QC, Canada

Abstract Body: The ultimate fate of most carbon released from the solid Earth through volcanoes (and now human activity) is as organic carbon and carbonate minerals in marine sediments. As such, the marine burial of carbon exerts a strong control on long-term climate, via its impact on CO2,

and modulated by the silicate weathering feedback. But the sensitivity of these fluxes and feedbacks to climate remains uncertain.

Here, we sought to evaluate and quantify past changes in the organic carbon and carbonate burial in deep-sea sediment over the last glacial cycle, taking advantage of a comprehensive global marine sediment proxy database we have built. Our strategy consists of three consecutive steps. First, to produce a global map of modern burial in the sediment. Second, to subdivide the ocean into provinces with consistent biogeochemical properties. Third, to modulate the modern burial in each province over time, according to the mean changes in burial rates calculated using sediment cores from the same province.

Our results suggest a significant change in global deep-sea organic carbon burial over glacial interglacial timescales, with a peak in organic carbon burial during glacial maxima, that represent 150-175% of interglacial burial rates (±25%). In contrast, despite regional heterogeneity, preliminary results do not suggest consistent and significant variations of the global burial of carbonates in the deep-sea over glacial/interglacial timescales and during glacial termination. Rather, the increase of carbonate burial in the Atlantic during the deglaciation was compensated by a decrease in the Pacific and Indian Ocean. Considering the large burial flux of carbonate on continental shelves that has existed throughout the Holocene, which was essentially absent during glacial maxima, implies that the total carbonate burial has been substantially greater in the Holocene. Given the relatively short timescale of carbonate compensation (a few thousand years) this suggests that silicate weathering rates were also substantially larger during the Holocene.

Title: Searching for an extinction event at the end of the Earth

Presenter/First Author: Peter William Crockford, McGill University, Montreal, QC

Presenter/First Author Email: peter.crockford@mail.mcgill.ca

Co-authors: Grant M Cox, McGill University, Montreal, QC, Canada; Galen P Halverson, McGill University, Montreal, QC, Canada; Boswell A Wing, McGill University, Montreal, QC, Canada

Abstract Body: Disentangling the events surrounding the K-Pg extinction remains hotly debated with specific questions unanswered about the kill mechanism of both terrestrial and aquatic species, and the response of the marine environment to these events. Evidence has been presented that shows surface water foraminifera being severely impacted, however it is still unclear if global primary production was significantly affected. Novel isotopic techniques emerging are providing new insights to the geologic record, specifically Zn isotopes are showing promise as a proxy for paleo-productivity. Here we present new data from IODP core 577A, currently located approximately 2000 km east of Japan, spanning events before, during and after the K-Pg transition. Our novel approach first explores seawater eNd, and $^{87/86}$Sr isotope ratios to observe any perturbations over this period. Preliminary eNd, results show a primitive signal, with an average value of -2.5, that may be a possible result of Deccan volcanism, which interestingly $^{87/86}$Sr values display a delayed response. Exploring possible impacts on global productivity, d^{66}Zn values indicate that despite the dramatic events unfolding, seawater isotope ratios recorded in carbonates deposited on the other side of the Earth saw no significant changes in these isotope ratios.

Title: PEER NGA-East Overview: Development of a Ground Motion Characterization Model and Ground Motion Prediction Equations for Central and Eastern North America

Presenter/First Author: Christine A. Goulet, University of California Berkeley, Los Angeles, CA

Presenter/First Author Email: goulet@berkeley.edu

Co-authors: Yousef Bozorgnia, University of California Berkeley, Berkeley, CA; Norman A Abrahamson, Pacific Gas and Electric Company, San Francisco, CA

Published Material: Partial findings of this study has been previously presented in NGA-East workshops (Berkeley, CA), which were made public and accessible online. Other progress reports on NGA-East have been presented at various meetings, such as SSA meetings and hazard workshops hosted by the USGS (multiple US locations).

Abstract Body: The Next Generation Attenuation project for Central and Eastern North America (NGA-East) is a large multi-disciplinary project tasked to develop a new ground motion characterization (GMC) model for the Central and Eastern North-America (CENA) region. The GMC model consists in a set of ground motion prediction equations (GMPEs) for median and standard deviation of ground motions and their associated weights, combined into logic-trees for use in probabilistic seismic hazard analyses (PSHA). NGA-East faced many technical challenges, most of them related to the relatively small number of earthquake recordings available for CENA. To address this shortcoming, the project relied on ground motion simulations to supplement the available data. Other important scientific issues were addressed through targeted research projects on topics such as the regionalization of seismic source, path and attenuation of motions, the treatment of variability and uncertainties and on the evaluation of site effects. Seven working groups were formed to cover the complexity and breadth of topics in the NGA-East project, each focused on a specific technical area. Through its multi-year span, NGA-East developed a comprehensive database of ground motion records, numerous interim products for the quantification of ground motions in CENA as well as new GMPEs. An overview of the project is presented, followed by highlights on latest progress, notably on the development of new GMPEs and their integration into the GMC model.

Youngs (2014), "PEER NGA-East Database", Pacific Earthquake Engineering Research Center, PEER Report 2014/09.

Abstract Body: We summarize the attributes of a comprehensive ground motion database developed for the Central and Eastern North America (CENA) region. The database was developed as part of the Next Generation Attenuation Project for CENA (NGA-East), a large multi-disciplinary project coordinated by the Pacific Earthquake Engineering Research center (PEER).The NGA-East database includes the two- and three-component ground-motion recordings from numerous selected events (M ≥ 2.5, distances up to 1500 km) recorded since 1988. The final database contains over 9,600 records from 81 earthquake events and 1379 recording stations. The NGA-East database constitutes the largest database of processed recorded ground motions from Stable Continental Regions (SRCs). The motivation behind the development of the empirical database is the same as for other NGA projects (NGA-West1 and NGA-West2), which is to be used, along with other information and data, for the development of ground motion prediction equations (GMPEs). The NGA-East ground motion database, similar to those from the NGA-West projects, includes pseudo-spectral acceleration (PSA) for the 5%-damped elastic oscillators with periods ranging from 0.007 to 10 sec. Additionally, the NGA-East database includes Fourier amplitude spectra (FAS) of the processed ground motions. The NGA-East database therefore consists of three groups of complementary products: the summary file referred to as the flatfile, which contains metadata, ground motion information and intensity measures on a record-per-record basis, the time series (acceleration, velocity, and displacement), and the corresponding Fourier spectra files. The NGA-East database products will also be made available to the public through the PEER online ground motion tool. An overview of the NGA-East database attributes and development is presented.

Title: Ground-Motion Prediction Equation Development Using Random Vibration Theory, Bayesian Regression, and Finite Fault Simulations: The PEER NGA-East Example

Presenter/First Author: Justin Chow Hollenback, University of California Berkeley, Berkeley, CA

Presenter/First Author Email: jhollenback@berkeley.edu

Co-authors: Nicolas Martin Kuehn, University of Potsdam, Potsdam, Germany; Christine A. Goulet, University of California Berkeley, Los Angeles, CA; Norm A Abrahamson, , ,

Abstract Body: Central and eastern North America (CENA) presents a challenging problem in regards to ground-motion modeling as there is a lack of data in areas critical to engineering design. The two cases where data is both sparse and necessary are for large magnitude and short source-to-site distance. Here, we present a methodology used to develop ground-motion prediction equations (GMPEs) for pseudo spectral acceleration (PSA) that utilizes both finite fault simulations and regionalized data from around the world. This methodology allowed us to produce several alternative models for predicting PSA all the way up to magnitude 8.2. Since there is little to no useable amplitude data in CENA for magnitude greater than 6.0 many alternative models are necessary to capture the epistemic uncertainty of the median prediction. This methodology was implemented for development of GMPEs as part of the Pacific Earthquake Engineering Research center (PEER) NGA-East Project.

There are two other relatively uncommon steps taken to develop these alternative models: the majority of the model development is performed on the Fourier Amplitude Spectrum (FAS) of acceleration, and a Bayesian inference scheme was used to estimate both fixed and random effects of the GMPE. In general, GMPEs for PSA are developed using PSA values themselves. However, working in FAS space allowed for better integration of the finite fault simulations and other seismological models for extrapolation. Using the Bayesian inference scheme allowed for the integration of data from regions thought to have different seismological properties. The hierarchical nature of the model accounts for regional difference in how ground motions scale with distance. The way in which our model was set up inherently assumes that the scaling of ground motion with magnitude is similar across regions. The methodology enabled us to produce alternative median GMPEs in CENA that behave reasonably well up to magnitude 8.2.

Title: A Hybrid Empirical Ground Motion Prediction Model for Eastern North America

Presenter/First Author: Shahram Pezeshk, Lettis Consultants International, Inc, Boulder, CO

Presenter/First Author Email: spezeshk@memphis.edu

Co-authors: Arash Zandieh, Lettis Consultants International, Inc, Boulder, CO; Kenneth W Campbell, , Beaverton, OR; Behrooz Tavakoli, , ,

Published Material: Pacific Engineering Research Center NGA-East

Abstract Body: A hybrid empirical method (HEM) is utilized to develop two new ground-motion prediction equations (GMPEs) for Eastern North America (ENA) using five new NGA-West2 GMPEs developed by the Pacific Earthquake Engineering Research center (Bozorgnia *et al.,* 2014). The two new GMPEs are derived for a moment magnitude (**M**) range of 4 to 8 and shortest distances to the fault rupture (R_{RUP}) as far as 1000 km. The GMPEs are developed for the 5%-damped pseudo-acceleration response spectra and the peak ground acceleration (PGA) for hard-rock sites with V_{S30} = 3000 m/sec.

Seismological parameters for ENA are adopted from the most recent research and published information in ENA (Yenier and Atkinson, 2015a; Chapman, *et al.,* 2014; Boore and Thompson, 2015; Hashash, *et al.,* 2014). Seismological parameters for western North America (WNA) are adopted from a study by Zandieh and Pezeshk (2015) in which they performed a set of point-source inversions to match the median NGA-West2 GMPEs for **M** ≤ 6.0, R_{RUP} ≤ 200 km, V_{S30} = 760 m/sec, strike-slip faulting, and sediment-depth parameters equal to the default values recommended by each of the NGA-West2 developers.

The two new sets of ENA GMPEs are based on two approaches: (1) using HEM to model magnitude scaling over the entire range of magnitudes; and (2) using HEM to model magnitude scaling for **M** ≤ 6.0 and using the magnitude-scaling predicted by the NGA-West2 GMPEs for **M** > 6.0.

The new GMPEs can be used as an alternative to those developed for ENA by other methods (e.g., stochastic and numerical simulation).

Title: A Preliminary Model of Site Amplification for use in Ground-Motion Modeling in Southern Ontario

Presenter/First Author: Sebastian Christopher Braganza, University of Western Ontario, London,

Presenter/First Author Email: sbragan@uwo.ca

Co-authors: Hadi Ghofrani, University of Western Ontario, London, ON, Canada; Gail Marie Atkinson, University of Western Ontario, London, ON, Canada

Abstract Body: A critical component in the understanding and interpretation of earthquake ground motions is the role that site effects play. In southern Ontario, Canada, the soil layers which overlie glaciated bedrock produce strong and highly variable site responses. We use horizontal-to-vertical (H/V) response spectral ratios as the indicator variable by which to characterize the salient characteristics of site response in southern Ontario. We show that site response can be modeled using two key descriptive variables that are readily obtainable: (i) peak resonant frequency (f_{peak}), as determined from H/V or soil depth; and (ii) overall soil type (or stiffness). We use these variables to create a preliminary model of site amplification across southern Ontario that can be used in the development of ground-motion prediction equations (GMPEs) and in real-time interactive ground-motion (IGM) map applications.

The key to the site characterization is the relationship between f_{peak} and drift thickness (depth to bedrock), which we derive using H/V data from earthquakes in the region, combined with a detailed digital drift thickness map available online from the Ontario Geological Survey (OGS). The OGS map also provides information on soil type, which is correlated with peak amplitudes (A_{peak}) of response. H/V spectral shapes may be associated with four main soil categories, which in decreasing order of stiffness are: bedrock, till, sand/clay, and organic soil/fill. The value of A_{peak} increases as stiffness decreases. We model site response by defining a generic site amplification curve, which is dependent only on f_{peak} and soil category. The generic curve enables an estimate of site amplification to be made over the entire frequency band from 0.1 to 20 Hz, knowing just the site depth and type. These site amplification curves can be applied in the development of regional GMPEs, and in the construction of robust near-real-time IGMs.

Title: An ENA Empirical GMPE based on the NGA East Database and Intensity Observations

Presenter/First Author: Chris H Cramer, University of Memphis, Memphis, TN

Presenter/First Author Email: ccramer@memphis.edu

Co-authors: Md. Nayeem Al Noman, , , ; Philip Ogweno, , ,

Abstract Body: We have developed an empirical GMPE for Eastern North America (ENA). Our GMPE is based on the two-stage regression approach of Joyner and Boore (1993, 1994). This approach provides both within event and between event variability along with event and site terms. Besides ground motion observations from the latest NGA East flatfile, we included ground motion observations from the 1976 M6.8 Gazli and 2001 M7.6 Bhuj earthquakes plus intensities converted to ground motion estimates for the M>6 ENA historical 1811-1812 New Madrid, 1886 Charleston SC, 1925 Charlevoix, and 1929 Grand Banks earthquakes. We fit linear regressions to median $\log_{10}$ ground motions vs. Modified Mercali Intensity (MMI). Community Internet intensity (CII) observations (Did You Feel It?) have been corrected to MMI using the approach suggested by Hough (2014). We have applied a magnitude correction based on residuals, which corrects for the effect of shifting source spectral corner frequency with magnitude. The magnitude correction (an increase in estimated ground motion with increasing magnitude) is more pronounced at longer periods, as expected. Magnitudes for historical events were taken from Cramer and Boyd (2014) for the 1811-1812 and 1886 M7 earthquakes and from Bent (1992, 1995) for the 1925 and 1929 earthquakes. Our empirical GMPEs are for 23 periods, including PGA and PGV. Empirical observations were restricted to mid-continent crustal regions, avoiding Gulf Coast and western US Q regions for both earthquakes and recording stations. Site conditions were modeled with a Vs30 term using NGA East provided Vs30 estimates at each site. The reference Vs30 is 760 m/s. Geometrical spreading is modeled by a single term due to the limited observations at distances less than 50 km. We included a magnitude-dependent geometrical spreading term to help model magnitude saturation at large magnitudes. Alternative terms are also provided for focal mechanism type (reverse, strike-slip, and undefined).

Title: Regionally-Adjustable Generic Ground-Motion Prediction Equation: Application to Central and Eastern North America

Presenter/First Author: Emrah Yenier, University of Western Ontario, London, ON

Presenter/First Author Email: emrah.yenier@gmail.com

Co-authors: Gail Marie Atkinson, University of Western Ontario, London, ON, Canada

Published Material: This study is currently under review in the Bulletin of the Seismological Society of America. The findings of this study has been previously presented in the NGA-East Workshop in October 2014, in Berkeley, CA.

Abstract Body: We develop a generic ground-motion prediction equation (GMPE) that can be adjusted for use in any region by modifying a few key model parameters. The basis of the GMPE is an equivalent point-source simulation model whose parameters have been calibrated to empirical data in California, in such a way as to determine the decoupled effects of basic source and attenuation parameters on ground motion amplitudes. We formulate the generic GMPE as a function of magnitude, distance, stress parameter, geometrical spreading rate and anelastic attenuation coefficient. This provides a fully adjustable predictive model, allowing users to calibrate its parameters using observed motions in the target region. We also include an empirical calibration factor to account for residual effects that are different and/or missing in simulations compared to observed motions in the target region. As an example application, we show how the generic GMPE can be adjusted for use in central and eastern North America (CENA), and calibrated with the NGA-East database. We provide median predictions of ground motions in CENA for average horizontal-component peak ground motions and 5%-damped pseudo spectral acceleration, for magnitudes **M**3 to **M**8 and distance up to 600 km.

Title: Estimation of Moment Magnitude and Stress Parameter from ShakeMap Ground-Motion Parameters for Real-Time Applications

Presenter/First Author: Behzad Hassani, Western University, London, ON

Presenter/First Author Email: behhassani@gmail.com

Co-authors: Gail Marie Atkinson, University of Western Ontario, London, ON, Canada

Abstract Body: For many applications ranging from real-time ShakeMaps to the development of ground-motion prediction equations (GMPEs) it is useful to have estimates of moment magnitude and stress parameter; these parameters control the low-frequency and high-frequency amplitudes of shaking, respectively. In many regions of low to moderate seismicity, such as eastern North America (ENA), estimates are required for the small to moderate events that happen several times per year. Such events may not be very damaging but rapid information on the amplitudes of shaking is required to inform the public, and government or regulatory officials as appropriate.

We describe a method to determine moment magnitude and stress parameter from ShakeMap ground motion parameters (5%-damped pseudo spectral acceleration [PSA] at 1s, peak ground acceleration [PGA] or PSA at 0.1s), suitable for regions having a sparse network, in the immediate aftermath of a small to moderate earthquake. The methodology is based on relating ShakeMap parameters to source and attenuation parameters within the context of a stochastic point-source model, in order to provide an event-specific GMPE that will reliably predict amplitudes across the region. An example application is provided for southern Ontario. Here, we initially develop a simulation-guided regional generic GMPE model based on the available database. Then, using the estimated regional attenuation and source parameters, we obtain simple equations to express ShakeMaps parameters as a function of magnitude and distance. Using these equations alongside ShakeMap parameters enable us to estimate moment magnitude and stress parameter in real-time, in order to provide reliable event-specific GMPEs. The event-specific GMPE are then used to provide robust, calibrated ShakeMaps that are fully consistent with ground-motion observations.

Title: Scenario Shakemaps for Use in Earthquake Risk Studies in Montreal

Presenter/First Author: Hadi Ghofrani, University of Western Ontario, London, ON

Presenter/First Author Email: ghofrani_hadi@yahoo.com

Co-authors: Gail Marie Atkinson, University of Western Ontario, London, ON, Canada; Luc Chouinard, McGill University, Beaconsfield, Canada; Philippe Rosset, McGill University, Montreal, QC, Canada; Kristy French Tiampo, University of Western Ontario, London, ON, Canada

Published Material: The findings of this study has already been submitted for publication in the Canadian Journal of Civil Engineering on 20-Nov-2014 and it is under review.

Abstract Body: Montreal ranks second after Vancouver among Canadian urban areas in terms of seismic risk. A recent research analysis estimated that, for a 2% in 50 years scenario event, roughly 5% of the building stock would be damaged; this might result in direct economic losses of around 1.5 billion dollars and projected casualties of 500 people injured or killed. In a different insurance industry study, total losses were estimated to be as much as $61 billion for the Quebec province in case of a larger earthquake scenario in the Saguenay area. Scenario studies to date have been based on primitive data for the soil conditions and limited consideration of likely event locations and ground motions; these parameter could greatly affect the outcome in a large event. We develop a set of scenario shakemaps for Montreal using forecasts of most-likely earthquake locations, combined with recent ground motion modeling validated with local recorded data and microzonation information on site amplification, to assess the expected motions for realistic scenario shaking. The target probability level for the scenarios is near the 2%/50 yr ground motions, as used for design of new structures in Montreal according to the National Building Code of Canada (NBCC 2010). The shakemaps provide the expected ground-shaking intensity distribution patterns by considering the occurrence of a scenario (a given magnitude event) at various likely locations in the region. The results of this study may be used as new input to improved seismic risk studies in this region.

Published Material: These results will also be reported at the April 2015 Seismological Society of America meeting in Pasadena, Calif.

Abstract Body: Seismic and liquefaction hazard maps, that include the effects of local geology, have been completed for the greater St. Louis urban area. Geological, geophysical, and geotechnical information for the 29 quadrangles of the study area were provided by the Illinois State Geological Survey, the Missouri Geological Survey, and the Missouri University of Science and Technology. This information includes maps of surface geology and bedrock depth, and reference shear-wave velocity profiles and liquefaction probability curves keyed to the surface geology. Maps were generated using the approach of Cramer et al. (2004, 2006, 2008, 2014), and were based on the 2014 update of the USGS national seismic hazard model (Petersen et al., 2014), including source models, attenuation relations, and weights. The seismic and liquefaction hazard

maps were developed on a 0.005 degree (500 m) grid for peak ground acceleration (PGA), and 0.1, 0.2, 0.3, 0.5, 1.0, and 2.0 s spectral acceleration (Sa). Liquefaction hazard maps are for Liquefaction Potential Index (LPI) values exceeding 5 and 12. Both probabilistic and scenario hazard maps have been created, with the probabilistic maps being generated using the fully probabilistic methodology of Cramer (2003, 2014) and Cramer et al. (2008). Scenario hazard maps include results for a repeat of a M7.5 earthquake on the northern segment of the New Madrid seismic zone and a hypothetical M5.8 earthquake beneath downtown St. Louis. Probabilistic seismic and liquefaction hazard maps show moderate (0.1 – 0.25 g PGA) shaking hazard and low (LPI > 5 below 30% probability for the uplands) to high (LPI > 5 above 60% for Missouri River flood plain) liquefaction hazard in the St. Louis area.

Title: Sensitivity analysis of Eastern Canada High Resolution Seismic Hazard Maps to the Ground Motion Prediction Equations

Presenter/First Author: Yelena Yevgenyevna Kropivnitskaya, University of Western Ontario, London, ON

Presenter/First Author Email: yelena.kro@gmail.com

Co-authors: Kristy French Tiampo, University of Western Ontario, London, ON, Canada; Jinhui Qin, University of Western Ontario, London, ON, Canada; Michael Bauer, University of Western Ontario, London, ON, Canada

Abstract Body: Eastern Canada has been known as a region, where detailed source characteristics and wave propagation properties of particular active fault sources are generally unavailable. However, several generations of the source zones models, earthquake occurrence patterns and ground motion relations have been developed to quantify seismic hazard characteristics in the region. The variety of proposed models increases the resulting level of uncertainty and results in potential error in the decision making process, related policies and standards. As a result, there is a strong interest in the sensitivity analysis of hazard maps as they relate to the main input parameters for seismicity rates and ground motion prediction equations (GMPEs) in order of total possible uncertainty estimation. Atkinson et al. 2011 investigated the effect of seismicity models and new GMPEs on seismic hazard assessment for four Canadian cities and concluded that the selection of correct GMPEs model has an important effect on the resulting hazard assessment. Our motivation in this study is not a re-evaluation of seismic hazard in Canada, but is to expand the boundaries of the GMPEs sensitivity analysis. Here, three sets of representative GMPEs (the medium, low and high) developed by Atkinson, 2013 have been used as an input for ground motion estimation for eastern crustal, western crustal, interface, inslab and offshore events and all for B/C site conditions (Vs30=760 m/s). The sensitivity analysis performed with different sets of assumed weights for the low, medium and high equations of the representative GMPEs. The analysis is complicated by the fact that for high-resolution map calculations must be carried out on a large number of sites, a process requires powerful computational resources. Here, high-resolution hazard maps production in real-time are made possible using corrections in EqHaz1 and EqHaz2 Fortran source programs developed by Assatourians et al., 2012. These are compiled into system object libraries and used as IBM InfoSphere Streams operators to implement the base PSHA procedures and functions in the streaming environment and to overcome EqHaz limitations by pipelining. The number of records in the synthetic catalog are increased up to 10,000,000 records and number of sites for hazard maps are stepped up to 2,500,000 sites.

Title: Modeling of Strong Motion Generation Areas of the 2011 Tohoku, Japan Earthquake using Modified Semi-Empirical Technique Incorporating Frequency Dependent Radiation pattern

Presenter/First Author: Sandeep ., Indian Institute of Technology Roorkee, Roorkee,

Presenter/First Author Email: sandeeparora95@gmail.com

Published Material: Yes this kind of finding has been earlier published in Natural Hazards Journal. Still this is a further extended part of the workA. Joshi, Sandeep, Kamal (2014) Modeling of Strong Motion Generation Area of the 2011 Tohoku, Japan earthquake using Modified Semi-Empirical Technique. Nat Hazards 71:587-609.   Sandeep, A. Joshi, Kamal, Parveen Kumar, Ashvini Kumar (2014) Effect of frequency dependent radiation pattern in simulation of high frequency ground motion of Tohoku earthquake using modified semi empirical method. Nat Hazards 73:1499-1521This kind of work has already been selected for best poster award at Indian Geophysical Union held on 19-21 November 2014 at Kurukshetra University, Kurukshetra

Abstract Body: Abstract In the present work strong ground motion has been simulated using a modified semi-empirical technique, with frequency dependent radiation pattern model. Joshi et al. (2014) have modified the semi-empirical technique to incorporate the modeling of strong motion generation areas (SMGAs). A frequency dependent radiation pattern model is applied to simulate high frequency ground motion more precisely. Identified SMGAs (Kurahashi and Irikura 2012) of the 2011 Tohoku earthquake (M_w 9.0) were modeled using this modified technique. Records are simulated for both frequency dependent and constant radiation pattern function. Simulated records for both cases are compared with observed records in terms of peak ground acceleration and pseudo acceleration response spectra at different stations. Comparison of simulated and observed records in terms of root mean square error suggests that the method is capable of simulating record which matches in a wide frequency range for this earthquake and bears realistic appearance in terms of shape and strong motion parameters. The results confirm the efficacy and suitability of rupture model defined by five SMGAs for the developed modified technique.

Title: Assessing the Hazard of Increasing Earthquake Activity in the U.S. Midcontinent: A Short-Term Hazard Model for Natural and Induced Earthquakes

Presenter/First Author: William L Ellsworth, USGS California Water Science Center Menlo Park, Menlo Park, CA

Presenter/First Author Email: ellsworth@usgs.gov

Co-authors: Charles S Mueller, USGS - Golden, Denver, CO; Mark David Petersen, USGS, Denver, CO; Justin L Rubinstein, USGS California Water Science Center Menlo Park, Menlo Park, CA

Published Material: Some of the introductory material and initial models were presented at the Fall 2014 AGU meeting. This report will build on the previous work with new results and conclusions.

Abstract Body: The dramatic rise in earthquake activity in selected portions of the central U.S. since 2009 is suspected to be a consequence of industrial activities, principally injection of wastewater co-produced with oil and gas from tight formations. In Oklahoma alone, the earthquake rate in 2014 for M ≥ 3 exceeded the rate in 1970-2008 by more than a factor of 100. Oklahoma also experienced 15 earthquakes with MMI ≥ VI, as reported to the USGS DYFI website in 2014, compared with a century-long historical rate of MMI ≥ VI of less than twice per decade. Higher earthquake rates imply higher hazard, but how much higher? And for how long? We are adapting standard Probabilistic Seismic Hazard Analysis methodology to combine the contributions to hazard from natural and suspected induced earthquakes. Because the statistics of the two earthquake populations may be very different, it is necessary to treat them as separate contributions to hazard. Differences may include magnitude-frequency statistics, spatial extent of sources, clustering, focal depth, source parameters, maximum (or corner) magnitude, ground-motion prediction equations, and temporal variations in earthquake rate. Forecasting more than "last year's earthquakes" will require a deeper understanding of the physical processes and conditions that link human perturbations to the Earth system to its response in seismic events. A key challenge is to develop an operational earthquake forecasting capability that not only accounts for temporally varying activity rates, but also anticipates where induced earthquakes may either initiate or shut-off in response to changing industrial activities.

Title: Investigation of Induced Seismicity Related to the Development of Shale Gas in Northeast British Columbia and Northwest Territories, Canada

Presenter/First Author: Honn Kao, Geological Survey Canada, North Saanich, BC

Presenter/First Author Email: hkao@nrcan.gc.ca

Co-authors: Amir M Farahbod, Geological Survey Canada, North Saanich, BC, Canada; Dan Walker, British Columbia Oil and Gas Commission, Victoria, BC, Canada; David B Snyder, Geological Survey Canada, Ottawa, ON, Canada; Scott Cairns, , ,

Abstract Body: The majority of seismicity in British Columbia (BC) and Northwest Territories (NT) are related to tectonic processes along the western and northern margins of the North American continent. Since late 2006 when the shale gas development started in northeast BC, a clear change of pattern in background seismicity was observed, correlating with the practice of hydraulic fracturing (HF). To understand the physical relationship and the significance of seismic risk associated with induced seismicity, the Natural Resources Canada (NRCan) initiated the Induced Seismicity Research (ISR) in 2012. Collaborating with provincial partners and with contributions from both academia and industry, NRCan's ISR focused on enhancing seismic monitoring for major shale gas basins across Canada where the development has started or was imminent. Historical seismograms were re-examined to better calibrate the patterns of regional background seismicity for both pre- and post-HF eras. A detailed database of operation parameters, including both HF and wastewater reinjection, was compiled from reports collected by the BC Oil and Gas Commission. Our results confirm that the increased level of background seismicity in the Horn River Basin, northeast BC, was related to the expansion of local HF operation. Some earthquakes in the Montney Trend of BC were probably associated with wastewater disposal. A dense array was set up in the Norman Wells area to verify any change in local seismic pattern that might be related to a limited HF operation in early 2014. Preliminary analysis reveals that the new array has improved the detection of local earthquakes by a factor of 10 within a radius of 400 km. The higher resolution for small seismic events is critical to establishing a reference baseline should commercial development of shale gas occurs in the future. Collectively, these new observations provide more insight to the understanding of seismogenic processes associated with induced seismicity in a variety of different tectonic and geological settings.

Title: A catalog search for triggered seismicity in Canada and near fluid injection sites in Western Alberta using a match-filter approach with continuous waveform data.

Presenter/First Author: Bei Wang, McGill University, Montréal, QC

Presenter/First Author Email: beiwang88@gmail.com

Co-authors: Rebecca M Harrington, McGill University, Montreal, QC, Canada; Yajing Liu, McGill University, Montreal, QC, Canada; Nicholas van der Elst, Lamont -Doherty Earth Observatory, Palisades, NY; Hongyu Yu, ITAG Institute of Theoretical and Applied Geophysics, Peking University, Beijing, China

Abstract Body: Earthquakes can be triggered by transient stresses generated from passing seismic waves of other distant earthquakes. Here we look for triggered earthquakes in Canada following global mainshocks occurring from 2004 to present with $M_s > 6$, and depths < 100 km. We also require potential triggering mainshocks to have estimated ground motions > 2 cm/s (PGV) in Canada inferred from empirical ground motion regressions. We first search for triggering indicated by increases in cataloged seismicity. We use the NRCAN earthquake catalog data to calculate R-statistical and β-statistical values in 1°1° bins within a 9-day window before and after the mainshocks. While cataloged seismicity is generally low in Canada, the statistical analysis suggests triggering may occur near Vancouver Island, in the Charlevoix seismic zone, and in western Alberta. Based on the results of the catalog approach, we look for triggering near injection sites in Western Alberta (WA) area where seismic station coverage is dense. We search for triggered earthquakes using a match-filter approach on continuous waveform data from the TransAlta Monitoring Network (TD) in time windows surrounding three potential triggering mainshocks during the TD operation period: the 10/14/2014 M_s 7 Nicaragua earthquake, the 07/25/2014 M_s 6.1 southeast Alaska earthquake, and the 08/24/2014 M_s 6 earthquake off the coast of California. After removing the events with approximate M > 0 presumed related to hydrofracturing, preliminary results suggest remote triggering for the California mainshocks, with 119 vs. 336 earthquakes before and after the mainshocks with a 10-day window. We also observe noticeable increases in M > 1 earthquakes following the Nicaragua mainshock in a 24-hour window (0 vs. 5) and increases in M>0 earthquakes following the Alaska earthquake in a same 24-hour window(1 vs. 17), which may suggest triggering. The increased number of naturally triggered local earthquakes suggests that vigorous earthquake activity related to hydrofracturing may result from the local faults being in a critically stressed state.

Title: Hazards from Induced Seismicity: Crooked Lake Case Study

Presenter/First Author: Hadi Ghofrani, University of Western Ontario, London, ON

Presenter/First Author Email: ghofrani_hadi@yahoo.com

Co-authors: Gail Marie Atkinson, University of Western Ontario, London, ON, Canada; Karen Assatourians, University of Western Ontario, London, ON, Canada

Published Material: The study is submitted to the Seismological Research Letter on Oct 16, 2014 and it is under review.

Abstract Body: A case study of seismicity induced by hydraulic fracturing operations near Fox Creek, Alberta, is used to evaluate the extent to which the potential for induced seismicity at a site alters the pre-existing hazard from natural seismicity. We find that in low-to-moderate seismicity environments, the hazard from an induced-seismicity source, if one is activated in close proximity to a site, can greatly exceed the hazard from natural background seismicity at most probabilities of engineering interest, over a wide frequency range. The most important parameters in determining the induced-seismicity hazard are the activation probability, and the b value of the initiated sequence. Uncertainty in the value of the key input parameters to a hazard analysis implies large uncertainty (more than an order of magnitude) in the likelihood of strong shaking.

Title: Hydraulic fracturing of the Alberta Bakken and the Cardston Earthquake Swarm

Presenter/First Author: Ryan Schultz, University of Alberta, Edmonton, AB

Presenter/First Author Email: rjs10@ualberta.ca

Co-authors: Shilong Mei, , , ; Dinu Pana, , , ; Virginia H Stern, Alberta Geological Survey, Edmonton, AB, Canada; Yu Jeffrey Gu, University of Alberta, Edmonton, AB, Canada; David W S Eaton, University of Calgary, Calgary, AB, Canada

Abstract Body: More than 60 small earthquakes (ML 0.7–3.0) were detected from December 2011 to March 2012 north of Cardston, Alberta, an area with little evidence for previous seismic activity. The timing of these events correlate (>99.7% confidence) with hydraulic fracturing completions of the Mississippian aged Alberta Bakken at a nearby horizontal well. Unanimous waveform multiplicity within the swarm suggests that the events share a similar origin and source mechanism. This observation is corroborated by the strong focusing of hypocentres within the crystalline basement from robust, double-difference relocations. Furthermore, the presence of a pre-existing fault is confirmed via formation offset mapping and interpreted to be a Late Cretaceous extensional fault. The confirmation of this fault at depth provides a plausible means of rapid hydraulic communication from the fracturing interval into the crystalline basement. Results of our regional moment tensor inversion provide tectonic constraints which we compare to the regional structural geology and ambient stress regime. We conclude that the genesis of this earthquake swarm was likely due to increased pore pressure within the basement fault during fracturing stimulation.

Title: PASSIVE SEISMIC MONITORING OF CO_2 STORAGE SITES

Presenter/First Author: Anna Stork, University of Bristol, Bristol,

Presenter/First Author Email: anna.stork@bristol.ac.uk

Co-authors: James Verdon, University of Bristol, Bristol, United Kingdom; Michael Kendall, University of Bristol, Bristol, United Kingdom; Don White, , ,

Published Material: Stork, AL, Verdon, JP & Kendall, JM 2015, 'The microseismic response at the In Salah Carbon Capture and Storage (CCS) site'. *International Journal of Greenhouse Gas Control*, vol 32., pp. 159-171Verdon, J, Kendall, J-M, White, DJ & Angus D 2011, 'Linking microseismic event observations with geomechanical models to minimise the risks of storing CO2 in geological formations'. *Earth and Planetary Science Letters*, vol 305., pp. 143 - 152

Abstract Body: Carbon capture and storage (CCS) projects capture carbon dioxide (CO_2) at large point-source producers, e.g. power stations, and subsequently sequester CO_2 in suitable geological formations for permanent storage. Passive seismic monitoring of such sites provides a useful diagnostic tool to understand the geomechanical response to CO_2 injection and to verify CO_2 remains at depth. It is vital that a monitoring programme provides warning of potential leaks at CCS sites. Here, we present and compare passive seismic monitoring results from three large-scale projects, Weyburn, In Salah and Aquistore, to highlight similarities and differences between sites and monitoring methods.

CO_2 injection at the Weyburn site is on-going since 2000 with >30 millions tons (Mt) sequestered; nearly 4 Mt of CO_2 were injected at In Salah between 2004 and 2011; and the Aquistore project is due to begin injection in early 2015. As expected, we have found that rates of microseismicity (small seismic events, generally with magnitudes < 0) increase with injection rate and the distribution of events correlates with the volume occupied by CO_2. However, rates of seismicity differ considerably between the In Salah and Weyburn sites. At In Salah >9000 events were detected 2009 – 2011 with moment magnitudes, M_w, up to 1.6, whereas at Weyburn only ~100 events were detected 2003 – 2007 with $-3.0<M_w<-1.0$. At both sites a small number of microseismic events occur in the overburden above the injection interval but we propose this is not caused by fluid migration or pore pressure changes in the overburden but by stress transfer. Anisotropy studies, using shear-wave splitting analysis, indicate that fractures sampled by the data have strikes consistent with observed pre-existing fracture sets, suggesting seismic activity occurs on pre-existing fractures.

These current and past CCS projects provide important learning opportunities to improve the design and effectiveness of future passive seismic deployments.

Title: Possibilities and Challenges for Mitigating Seismic Hazard from Earthquakes Induced by Disposal of Wastewater by Deep Injection

Presenter/First Author: Arthur McGarr, USGS California Water Science Center Menlo Park, Menlo Park, CA

Presenter/First Author Email: mcgarr@usgs.gov

Abstract Body: Within North America east of the Rocky Mountains, earthquakes induced by fluid-injection activities associated with oil and gas production account for much of the contemporary seismic hazard (e.g., Ellsworth, 2013). This component of hazard is mostly due to disposal by deep injection of co-produced wastewater. Only a small fraction of wastewater disposal operations induce earthquakes large enough to be felt because the injection target is most often a deep aquifer that can readily accept large volumes of injected liquid with little or no seismic response. The exceptions, as reported in various case histories (e.g., Horton, 2012), evidently occur if elevated pore pressure due to injection is transferred into the zone of a fault that is prone to slip seismically in the ambient stress field. This pore pressure transfer may occur where the fault intersects the aquifer or it may involve an intermediate high-permeability channel between the aquifer and the earthquake-prone fault, which is often located in the crystalline basement. Accordingly, one way to reduce the likelihood of inducing earthquakes large enough to be felt or damaging is to avoid fluid injection in the vicinity of faults that are prone to reactivation. Because these faults are rarely mapped beforehand, it is necessary to have seismic networks in place capable of detecting and locating earthquakes at low magnitude thresholds. Timely evidence of fault reactivation could be used to avoid inducing earthquakes of greater consequence. Traffic Light systems, which use seismic data to decide when injection operations need to be adjusted, have proven to be effective for short-term injection activities such as development of Enhanced Geothermal Systems. More research is needed, however, to find out if earthquake control based on early identification of fault reactivation is feasible for longer-term wastewater injection projects.

Title: Induced Aftershock Sequences and Swarms in Geothermal Systems

Presenter/First Author: Robert Shcherbakov, University of Western Ontario, London, ON

Presenter/First Author Email: rshcherb@uwo.ca

Co-authors: M. Burak Yikilmaz, UC Davis, Davis, CA; Donald L Turcotte, University of California Davis, Davis, CA; Louise H Kellogg, University of California - Davis, Davis, CA; John B Rundle, University of California Davis, Davis, CA

Abstract Body: Many natural geothermal systems are associated with high seismic activity. This can be related to large scale injection of fluids to enhance geothermal recovery. Other factors, such as changes in the stress field and pore pressure, can also stimulate the occurrence of earthquakes. These systems are also prone to triggering of seismicity by the passage of seismic waves generated by large distant main shocks. In this particular study, we analyze clustering and triggering of seismicity at the Geysers geothermal field, California, due to the occurrence of relatively large local events as well as due to the occurrence of significant long distant main shocks. For the analysis we use the Northern California Earthquake Data Center Earthquake Catalog. The recent Mw 6.0 South Napa main shock triggered a ml 4.5 event and a subsequent swarm of seismic activity at The Geysers. We compare this sequence of events to several other earthquake sequences generated by local large events with magnitudes greater than 4.5 and sequences generated by several other long distant main shocks. We show that the rate of decay of the aftershock sequences generated by local large events in the first day after the main event follows the modified Omori law reasonably well. On the other hand, the swarms of activity triggered by large distant earthquakes cannot be described by the simple modified Omori law. In almost all cases the frequency-magnitude statistics of triggered sequences follow Gutenberg-Richter scaling to a good approximation with relatively large b-values. The analysis indicates that the seismicity triggered by relatively large local events can initiate sequences similar to regular aftershock sequences. In contrast, the distant main shocks trigger swarm like activity with faster decaying rates.

Title: Are ENA Potentially Induced Earthquakes Different from Natural Earthquakes?

Presenter/First Author: Chris H Cramer, University of Memphis, Memphis, TN

Presenter/First Author Email: ccramer@memphis.edu

Abstract Body: The question of whether induced earthquakes have significantly different source characteristics than naturally occurring earthquakes (NOE) is important if such a difference exists. I review the Brune stress parameter (stress drop) estimates from some recent potentially induced earthquakes (PIE). Transverse velocity Fourier spectra are examined for a corner-frequency peak, taking into account the possible presence of a neighboring spectral peak due to the strong surface waves from shallow events. Brune stress parameters for an assumed geometrical spreading of R^{-1} are estimated from observed magnitude and corner-frequency for each event. (An assumed geometrical spreading of $R^{-1.3}$ would yield a proportionally higher stress parameter as stated by Boore et al., 2010.) Atkinson and Boore (2006) found that the average ENA Brune stress parameter of this type to be 14 MPa. PIEs in Arkansas, Oklahoma, Texas, Kansas, and Ohio have Brune stress parameters ranging from 5 to 10 MPa. Shallow NOEs (depth less than 5 km) appear to have a similar range of Brune stress parameters. Ground motions for a given earthquake can be influenced by stress parameter and by crustal attenuation (Q). PIEs in Arkansas, Oklahoma, Texas, and Kansas are near a Q boundary at about 35N latitude between ENA mid-continental and Gulf Coast Q, which influences ground motions (and intensities) observed to the north differently than to the south. Justin Hollenback for the NGA East project at the PEER Center also shows that event terms from a mixed effects analysis for the NGA East database are similar for PIEs and shallow NOEs and lower than deeper NOEs. Thus both a Brune stress parameter analysis and an event term analysis (allowing for regional Q) show that ENA PIEs are similar to shallow NOEs and lower for deeper NOEs and hence may not be distinct from shallow NOEs.

Title: Ground Motions from Three Recent Earthquakes in Western Alberta and Northeastern British Columbia and their Implications for Induced-Seismicity Hazard in Eastern Regions

Presenter/First Author: Gail Marie Atkinson, University of Western Ontario, London, ON

Presenter/First Author Email: gmatkinson@aol.com

Co-authors: Karen Assatourians, University of Western Ontario, London, ON, Canada; Burns Cheadle, , , ; Daniel Wesley Greig, Nanometrics Inc, Kanata, ON, Canada

Published Material: Findings are review for an article in Seism.Res.L.

Abstract Body: A key issue in the assessment of hazard due to induced seismicity from fluid injection activity is to determine the potential ground motions. Though waste water disposal typically receives the most attention, hydraulic fracturing is increasingly recognized as a significant source of seismic hazard. We present an analysis of the ground motions from the three largest recent events that occurred along the deformation front marking the western boundary of the stable Canadian craton: a **M**4.0 and a **M**4.2 near Fort St. John, British Columbia, and a **M**3.9 near Rocky Mountain House, Alberta. The two Fort St. John events were likely induced by hydraulic fracturing activities in the region. Though the cause of the Rocky Mountain House event remains unclear, it is of interest because it is of similar magnitude to the other events and had significant consequences to the public. The event triggered an automatic shut-down of a nearby gas plant, and a subsequent precautionary flaring of gas; moreover several hundred people were without power for a prolonged period. We examine the ground motions and intensities for these events. We find that ground motions at frequencies up to about 2 Hz are in agreement with corresponding observations for events in California and with the predictions of applicable empirical GMPEs. However, high frequency ground motions appear to be consistently lower than those predicted, suggesting that these events may be associated with a low stress drop; we believe that this is likely a focal depth effect, which may be a mitigating factor that limits high-frequency ground motions from induced events.

Our preliminary findings suggest that moderate induced events (**M**4 to 5) may be damaging to nearby infrastructure, because the shallow focal depth may result in localized strong ground motions to which some infrastructure may be vulnerable; this is a particular concern in low-to-moderate seismicity regions because seismic design measures for structures in these regions may be minimal. Our results highlight the importance of seismic monitoring in the immediate vicinity of fluid injection sites (both waste water disposal and hydraulic fracturing) in order to accurately characterize injection induced seismicity and ultimately mitigate the associated risk.

Title: Source and attenuation parameters for induced seismicity in the Crooked Lake Region of Alberta

Presenter/First Author: Mark Novakovic, University of Western Ontario, Strathmore,

Presenter/First Author Email: mnovako3@uwo.ca

Co-authors: Gail Marie Atkinson, University of Western Ontario, London, ON, Canada

Abstract Body: From December 2013 to present an ongoing sequence of over 70 small earthquakes (M_w 2-3.5) was detected in the Crooked Lake region, near Fox Creek, Alberta. The event hypocenters and timing correspond closely to hydraulic fracture treatments of oil and gas production wells in the immediate vicinity, suggesting a causal relationship. The events thus provide a unique opportunity to study the seismological characteristics of earthquakes triggered by hydraulic fracturing in this region. We obtain all available seismographic data from Alberta and B.C., including data from the TransAlta/Nanometrics, GSC, CRANE and AGS stations, to obtain a rich library of waveforms at distances from a few tens of km to a few hundred km. All waveforms are processed to obtain instrument-corrected Fourier and response spectra. We compare the moment estimates from inversion to those obtained using a new algorithm for moment magnitude estimation from regional seismographic ground-motion. Distance cutoffs are established for magnitude ranges in order to reduce noise effects of distant stations while maintaining accuracy in the magnitude estimation. We present our results on ground motion attenuation and source spectra for this sequence of events relative to natural earthquakes of similar size.

Title: Development of a Ground Motion Prediction Method for Carbon Dioxide Injection Induced Earthquakes

Presenter/First Author: Ian Stone, Los Alamos National Laboratory, Los Alamos, NM

Presenter/First Author Email: istone@lanl.gov

Co-authors: Richard C Lee, Los Alamos National Laboratory, Advanced Engineering and Technology, Los Alamos, NM; Christopher R Bradley, Los Alamos National Laboratory, Los Alamos, NM; Carene S Larmat, Los Alamos National Laboratory, Los Alamos, NM

Abstract Body: The process of injecting carbon dioxide into geologic reservoirs as a means of carbon sequestration is believed to increase the risk of induced seismicity in the region of injection. An important component in characterizing induced seismicity risk is the development of application-specific ground motion prediction (GMP) methods. A method is developed for a proposed injection site utilizing the induced seismicity GMP equations of Douglas et al., 2013, and incorporating site-specific adjustments. Development of the GMP model focuses upon situations in which there is very little in-situ data from the proposed site of injection. The resultant model can estimate ground motion response for induced events between M_w 1.0-4.0 at epicentral distances of 1-50 km, periods of ground motion between 0.01 and 0.5 seconds, and Vs_{30} between 100 and 2000 m/s. A statistical consideration of input uncertainties for an uncharacterized site demonstrates that the total uncertainty of the method is large compared to regional-specific GMP models. However, analysis considering the reduction of input uncertainty through in-situ data collection indicates that the total uncertainty of the method could be reduced to levels appropriate for engineering applications, including probabilistic seismic hazard assessment.

Title: Analysis of Microseismic Events during a Multi-stage Hydraulic Stimulation Experiment at a Shale Gas Reservoir

Presenter/First Author: San Linn Isma'il Kaka, King Fahd University of Petroleum & Minerals, Dhahran,

Presenter/First Author Email: skaka@kfupm.edu.sa

Co-authors: Abdul Latif Ashadi, King Fahd University of Petroleum and Minerals (KFUPM), Dhahran, Saudi Arabia; Abdullah A Alshuhail, , Calgary, AB, Canada; Michael Jervis, , ,

Abstract Body: Microseismic events are a useful indicator of fluid migration associated with hydraulic fracturing and thus monitoring of microseismic events has made significant contributions in understanding the geometry of fractures associated with hydraulic stimulation. The key is to track the creation of fractures during and after the stimulation. One of the most important steps in determining the geometry is to detect and accurately locate microseismic events. In this study, we process and analyze 176 events generated during a multi-stage stimulation experiment at a shale gas reservoir in Saudi Arabia. The monitoring array includes a downhole array of 12- 3C sensors that were deployed in a vertical well with a 100 ft level spacing. There were 12 stages of stimulation and we only focus on the events located during the first 6 stages. Our aim was to analyze microseismic events to better understand fracture growth and fracture directions. This work was conducted as part of a larger study in developing a methodology for generating dynamic, high-resolution seismic and geomechanical models of shale reservoirs before, during, and after stimulation, and interpreting the models in terms of fracture susceptibility and fracture dynamics. Preliminary results show that the data signal to noise ratio is satisfactory for locating local magnitude (M_L) events up to -4.0 during the early stages. We observed events with M_L >+1.0 to a maximum of +1.97 near the injection well in the latter stages. During the initial stages, most events are scattered near the injection well, however, in later stages, they migrated westerly towards the monitoring well and show increased vertical distribution. Additional processing is currently underway to precisely relocate some selected events and estimate the focal mechanism as well as to carry out a magnitude analysis. We believe that this study will provide additional information needed to identify fluid migration associated with the stimulation.

Abstract Body: The compilation of a comprehensive, high-quality and easy-to-use catalog of earthquake events in Alberta and the surrounding region is a fundamental step for the evaluation of the impact of industrial activity on the seismicity in the region. For this purpose, we have developed the Composite Alberta Seismicity Catalog (CASC) by combining the information from several national and international data sources: TransAlta/Nanometrics Network (NMX catalog), the Geological Survey of Canada (GSC catalog), the Alberta Geological Survey (AGS catalog), the Canadian Composite Seismicity Catalog (CCSC), and the Advanced National Seismic System catalog from the US Geological Survey (ANSS catalog). The CASC catalog covers the region of 48°- 59° N latitude, 110°- 121° W longitude, and currently includes events through December 2014. For each event, the CASC lists the occurrence time in Universal Coordinate Time (UTC), hypocentral location, the set of all available magnitude types, and an assigned preferred magnitude. We applied a semi-automatic procedure to identify and remove duplicate information from the alternative source catalogs, while retaining information on alternative estimates of locations and magnitudes from different sources. The magnitudes of all events to the end of 2013 have been converted to moment magnitude where required (i.e. if no estimate of moment magnitude is available in any of the original sources), using the empirical equations in Fereidoni et al (2012). The output files for pre-2014 and post-2014 events are available for download at http://www.inducedseismicity.ca, along with their documentations. Updated files will be available on the website on monthly basis. This compiled catalog provides a useful baseline for studying earthquake hazard due to the induced seismicity in Alberta.

Abstract Body: Simulation of activation of slip on a pre-existing fault due to a perturbation in pore pressure is important for characterizing and understanding potential induced-seismicity hazards. We present a 3D model using a widely used finite-element package, ABAQUS, to simulate activation of slip on a pre-existing fault due to an imposed perturbation in pore pressure on a subregion of the fault. The model inputs are 3 initial principal background stresses, elastic properties of the medium, coefficient of friction and geometry of the fault. Initial stresses are assigned according to Mohr Coulomb theory based on the assumption that the crust is in a critically stressed state. Our proposed method is shown to be stable, consistent with displacement calculations using Okada's analytical formula, and predicts rupture characteristics and stress changes that are generally compatible with observed values. Our results indicate that the fault rupture area is generally larger than the initially perturbed area; moreover, the rupture area, and thus the earthquake magnitude, increases with the size of the perturbed area, irrespective of the overall fault dimensions. For one realization, our model predicts that a 2km by 2km area perturbed by a relatively small pore pressure increase results in a magnitude 4.4 earthquake with 1 MPa (10 bar) of shear stress drop. For a particular fault geometry, stress state and perturbation parameters, we interpret our calculations to constitute an upper limit for earthquake magnitude, as the equivalent stress release could be achieved with a sequence of smaller events.

Title: Identifying quarry blast events in seismicity catalogs based on the ground motion parameters

Presenter/First Author: Azadeh Fereidoni, University of Western Ontario, London, ON

Presenter/First Author Email: azadeh.fereidoni@gmail.com

Co-authors: Gail Marie Atkinson, University of Western Ontario, London, ON, Canada

Abstract Body: Discrimination of quarry and mine blasts from natural seismicity or induced seismicity is a preliminary and fundamental step in compiling a seismicity catalog. It is particularly challenging to discriminate blasts from potentially-induced events, as both induced events and blasts will be characterized by shallow depths. Such discrimination can be done by examining waveforms and seeking information on nearby quarry operations. However, such an approach is tedious and time-consuming, requiring manual review by a seismologist. Using purely statistical approaches is more efficient, but may not be as reliable, as some natural tectonic or induced events may be falsely discriminated as blasts, while some blasts may not be properly identified. In this study, we investigate whether we can identify quarry blasts by an automated analysis of index ground motion parameters. We hypothesize that ground motion parameters from blasts may have definitive characteristics that could be used in automated discrimination procedures. To test the hypothesis, we analyze the data from the TransAlta/Nanometrics seismic network in Alberta, Canada. We focus on the parameters of peak ground acceleration (PGA), peak ground velocity (PGV), pseudo-spectral acceleration (PSA) at different frequencies, and their vertical to horizontal-component ratios. These ground motion parameters are commonly calculated in routine, automated data analysis; therefore, they can be used in a process that automatically identifies quarry blasts. Having a reliable automated process that is based on the spectral characteristics is very useful for the compilation of reliable seismicity catalogs in near-real time.

Title: Statistical Analysis of Seismicity in Alberta

Presenter/First Author: Sidhanth Kothari, University of Western Ontario, Woodstock,

Presenter/First Author Email: skothar3@uwo.ca

Co-authors: Robert Shcherbakov, University of Western Ontario, London, ON, Canada; Gail Marie Atkinson, University of Western Ontario, London, ON, Canada

Abstract Body: In western Canada, hydraulic fracturing treatments as well as extended fluid injection operations have been linked to the generation of seismicity in some areas. An increase in seismographic stations over the last few years enables improved modeling of induced seismicity processes.

Characterization of the statistics of these events is vital to developing a predictive understanding of induced seismicity, which is ultimately required for the mitigation of future induced seismicity.

Using a compiled earthquake catalog (www.inducedseismicity.ca), we perform a statistical analysis to characterize the frequency-magnitude distributions of seismicity across western Alberta, from a regional perspective. We also look more closely at the seismicity distributions within concentrated areas where clusters of activity in time and/or space are evident. The average b-value (the slope of the Gutenberg-Richter relation) is determined for each chosen area, using the Maximum Likelihood Method. We map the b-value variation spatio-temporally. We consider alternative statistical models to describe the observed distributions, including the Poisson process and an ETAS (Epidemic Type Aftershock Sequence) model. We seek preliminary correlations between the properties of the seismicity distributions and industrial activities that may have induced them.

Title: Induced earthquakes associated with the Haynesville shale play identified near Bienville Parish, Louisiana in 2011

Presenter/First Author: Jacob I Walter, University of Texas at Austin, Austin, TX

Presenter/First Author Email: jakeiwalter@gmail.com

Co-authors: Cliff Frohlich, Univ Texas, Austin, TX; Julia Gale, University of Texas at Austin, Austin, TX; Peter Dotray, , ,

Abstract Body: In the last decade, incidences of increased felt seismicity throughout the central United States have been correlated with wastewater disposal to support hydrofracturing operations. However, the relatively few incidences of induced seismicity compared to the number of operating injection wells over different regions is rather surprising. Thus, further investigation and positive identification of incidents of induced seismicity is needed. We focus an investigation of recent seismicity across the broad geographic region of the Haynesville shale play, which encompasses parts of eastern Texas and northwestern Louisiana. We utilize temporary (~2 years) deployments of seismographs during the USArray Transportable Array experiment and analyze seismicity from February 2010 through the end of 2012. In addition to generating a seismicity catalog through standard detection methodologies, we utilize a matched-filter technique whose widespread use in seismology is able to detect potential missing earthquakes within continuous seismograms. We identify many earthquakes in eastern Texas and Louisiana that had not been previously identified. While some earthquakes exist outside two distinct zones, most seismicity is confined to zones near Timpson, in east Texas, and Bienville Parish, in northwestern Louisiana. The Timpson sequence has been studied and discussed extensively by Frohlich et al. (2014). In Bienville Parish, a total of 8 earthquakes between magnitudes 1-2.4 occurred over just a few months (August-October 2011). Further, during this activity a number of the smaller magnitude earthquakes occur without a preceding larger event, which is consistent with classification as a seismic swarm. We are currently investigating the environmental conditions (i.e. injection/production values) associated with the Bienville Parish sequence and will present our findings at the meeting. Regulatory records indicate the existence of 51 active injection wells in Bienville Parish, though the data is inconsistently reported and appears to be missing for all wells prior to 2012. We are currently investigating this issue. This work highlights the continued need for investments in monitoring seismicity in areas of active oil and gas extraction.

Title: *Focal Mechanism Solutions for Earthquakes in Eastern Canada and Alberta Using the Generalized Cut and Paste (gCAP) Method*

Presenter/First Author: Alex Carey, McGill University, Montreal,

Presenter/First Author Email: alexander.carey@mail.mcgill.ca

Co-authors: Hongyu Yu, ITAG Institute of Theoretical and Applied Geophysics, Peking University, Beijing, China; Yajing Liu, McGill University, Montreal, QC, Canada; Rebecca M Harrington, McGill University, Montreal, QC, Canada

Abstract Body: Earthquake focal mechanism solutions (FMSs) provide information on the fracture orientation and the ambient stress field under which seismic ruptures take place. In this study, we first applied the generalized Cut and Paste (gCAP) method (Zhu and Helmberger, 1996) to several recent earthquakes in the Charlevoix Seismic Zone (CSZ) and the Western Quebec Seismic Zone (WQSZ). One attribute of the gCAP method is that it can invert the five phases (two P and three S phases) independently, increasing the weight of P waveforms for the overall inversion and decreasing the influence of earthquake location. Using waveform recordings of high signal-to-noise ratio from a combined 11 CNSN and Earthscope Transportable Array stations in the gCAP, we found the May 17th, 2013, Ladysmith earthquake in the WQSZ was a reverse-faulting event on a high-angle fault, with Mw=4.5 and depth at 12 km (variance reduction of 85.6). Our result is consistent with the FMS determined by another study using the inversion of long-period Rayleigh waves from more distant stations (Ma and Audet, 2014).

Next, we will apply gCAP in the source characterization of induced seismicity from hydraulic fracturing operations in Alberta. We will focus specifically on the Rocky Mountain House (RMH) cluster in August 2014, which includes a magnitude 4.3 event on August 9th that was possibly induced by hydrofracturing. We will also use the USGS Coulomb software to calculate the local stress field perturbations due to injection. By 1) comparing the RMH cluster focal mechanisms to earthquakes duringperiods without injection in the same regionand 2) quantitatively evaluating the spatial correlation in RMH seismicity and Coulomb stress change, we will work toward clarifying the relationship between the RMH seismicity sequence and hydraulic fracturing activity.

Title: Modified Fibre-Bundle Model to Simulate Induced Seismicity

Presenter/First Author: Ryan Kahue, University of Western Ontario, Chatham,

Presenter/First Author Email: rkahue@uwo.ca

Co-authors: Robert Shcherbakov, University of Western Ontario, London, ON, Canada

Abstract Body: An increase in the number of earthquakes in the last ten years or so has been linked to human activity in areas of oil and gas production in the Midwestern United States. This induced seismicity has raised public concerns over the safety of operations of energy-related activities such as wastewater disposal and hydraulic fracturing. Because of the economic effect that the extraction of oil and gas can provide to regions rich in these resources, there has been a significant amount of interest and investment put into these types of operations in Alberta. However, an increased number of earthquakes, including those of larger

magnitude, could be problematic when considering critical infrastructure such as industrial facilities, power plants, dams, etc. located in these regions. Here we apply a modified version of the fibre-bundle model to simulate the process of failure leading to an earthquake due to induced seismicity. This model has been successful in simulating the failure processes in various applications, including earthquakes, damage mechanics models, communication networks, and traffic systems. The fibre-bundle model represents a solid material as a collection of fibres in a bundle, similar to cables composed of intertwined wires. An applied stress is distributed to each fibre within a bundle. The failure of these fibres over time provides valuable insights into the failure of solid materials. In the proposed model the interevent times and frequency-magnitude statistics of the model earthquakes are computed over multiple simulations. The model couples the standard fibre bundle with a fluid that is introduced and diffused into the system and is shown to impact earthquake statistics due to the lowering of the critical thresholds of the fibres exposed to the fluid. The resulting change in statistics observed helps to highlight the effect of decreasing the effective stress within the rock and how this relates to induced seismicity.

Title: Slip Tendency Analysis and Risk of Induced Seismicity

Presenter/First Author: Alan P Morris, Southwest Research Institute, San Antonio, TX

Presenter/First Author Email: amorris@swri.org

Co-authors: David A Ferrill, Southwest Research Institute, San Antonio, TX; Gary R Walter, Southwest Res Inst, San Antonio, TX; Aaron M Price, , ,

Abstract Body: The correlation between unexpected, presumed induced, seismic activity and nearby hydraulic fracturing and its commonly associated water disposal has not gone unnoticed. Elevated pore fluid pressure is usually considered to be the cause of this induced seismicity, triggered by decreased stability (increase in slip tendency) on pre-existing faults and fractures as pore fluid pressure rises. Most active faults experience high slip tendency under present-day stress, and cases of induced seismicity can be explained by increased slip tendency driven by increased pore pressure. Felt earthquakes typically have magnitudes greater than about 2.5, and damaging earthquakes have magnitudes higher than this. Such events can only occur on relatively large slip surfaces, implying that a well-oriented, potentially detectable, fault would need to exist within the rock volume prior to the increase in pore fluid pressure responsible for inducing slip. A well-conducted geological investigation of the proposed site of fluid injection can provide an assessment of existing geologic structures, rock permeability characteristics, and ambient stress states. Combining these into a geologic model and simulating the proposed fluid injection conditions provides a risk evaluation of induced seismicity. Our approach to this simulation uses slip tendency analysis coupled with an anisotropic effective permeability tensor and analytical well hydraulics models provides an alternative to complex numerical models, and provides sufficiently rapid feedback to test a wide range of scenarios. Thus far our results indicate that the most significant variables are the threshold slip tendency at which a fault will slip, and complex permeability anisotropies affecting the pressure distribution within the rock mass.

Title: Reservoir-Triggered Seismicity in the Canadian Shield as an Analogue to the Activity Induced by the Deep Injection of Wastewater

Presenter/First Author: Maurice Lamontagne, Geological Survey of Canada Ottawa, Ottawa, ON

Presenter/First Author Email: malamont@nrcan.gc.ca

Published Material: Because I will present an overview of what we have learned on Reservoir-Triggered Seismicity in Canada, I will refer to some previously published papers on the topic.

Abstract Body: There are numerous examples of seismicity induced by wastewater injection. Although the injection of fluids is made within Palaeozoic sedimentary layers, it appears that most injection-induced earthquakes occur along pre-existing faults of the Precambrian basement. In these areas of deep injection, little is known about the distribution of Precambrian faults and their susceptibility to reactivation when subjected to an increase in pore-fluid pressure. An interesting analogue is the impoundment of large hydro-electric reservoirs that triggers earthquakes in the Canadian Shield.

In the Canadian Shield, the Precambrian basement is found beneath every hydro-electric reservoir and lineaments and faults are clearly visible in remote sensing imagery. The history of reservoir-triggered seismicity (RTS) can help define some characteristics of fault reactivation. Out of the tens of reservoirs with water depth greater than 50 m, only a small proportion caused RTS, similar to the very few deep wells that led to seismicity. Also, RTS does not necessarily occur in the deepest reservoirs. For example, the Manic-5 reservoir (the largest in terms of volume and depth; so large that it is visible from space), has not led to RTS.

Lessons learned from four decades of RTS in the Canadian Shield are: 1) Although 50 m of water depth appears to be the minimum, one cannot predict the likelihood of RTS for greater depth. 2) Although the increase in pore-fluid pressure at the base of the reservoir can exceed 1 Mpa; this does not necessarily translate into RTS. 3) Prominent regional-scale faults are not necessarily those reactivated. 4) The few meters of seasonal water level variations are not sufficient to create RTS. 5) RTS is generally within a few km of the reservoir shoreline. 6) Prior to the 1980’s, it is possible that RTS cases with earthquakes of magnitude less than 3 were not detected due to poor monitoring.

Title: Characteristics of the Earthquake Activity in Southeast New Brunswick, an Area With Shale Gas Potential.

Presenter/First Author: Maurice Lamontagne, Geological Survey of Canada Ottawa, Ottawa, ON

Presenter/First Author Email: malamont@nrcan.gc.ca

Co-authors: Denis Lavoie, , , ; Shutian Ma, Carleton University, Ottawa, Canada; Kenneth B Burke, Retired, Washington, DC; Ian D Bastow, Imperial College London, London, United Kingdom

Published Material: I have presented some preliminary results at the European Seismological Commission Meeting last September. Since then, much progress has been done in the data acquisition and analysis. The results have not been published yet, but they will be submitted to the Seismological Research Letters for a special number on Induced seismicity.

Abstract Body: This project aims at defining the regional natural seismicity of the Moncton and Sussex sub-basins of southern New-Brunswick prior to an eventual full-scale hydraulic fracturing program in this area. This project

gives us the opportunity to define some of the characteristics of the local earthquakes.

New Brunswick is a region of moderate seismicity. From 1764 to 1980, only five events have felt area magnitudes in the 5.4-6.0 range; two in the Central Highlands, two in the Passamaquoddy Bay region and one near Moncton (1855; magnitude 5.4). After 1980, earthquake activity has been monitored by the Canadian National Seismograph Network (CNSN) which provides earthquake location completeness to slightly above magnitude (mN) 2.0. Since 1980, the strongest earthquakes recorded in the sedimentary sub-basins have been two mN 3.6 events, both located just to the southwest of Moncton. A study helped define the depth distribution of earthquakes in SE NB using conversional and regional depth phase modeling (rdpm) methods. A velocity inversion was also performed.

To better monitor the Sussex Basin area, five additional seismographs with broadband sensors were installed (one in 2012 and four in 2013) to complement the permanent CNSN station LMN. Thanks to these additional stations, the area is currently monitored by a dense six-station seismograph network that can improve the monitoring of the background seismicity and allows for the calculation of focal depths within the array. Since 2010, only four seismic events in the Sussex Basin were recorded but the long period between its occurrence and hydraulic fracturing at McCully field (almost two years) makes a connection unlikely. Thanks to the new network, numerous small earthquakes have been detected in the surroundings.

Title: Structural and hydrologic controls on subduction zone slow earthquakes

Presenter/First Author: Pascal Audet, University of Ottawa, Ottawa, ON

Presenter/First Author Email: pascal.audet@uottawa.ca

Published Material: These findings were reported separately in various conferences (e.g., SSA 2014, GSA 2013, AGU 2011). This presentation will be a summary of recent results published in various papers.

Abstract Body: Recent discoveries of slow slip events that recur at intervals of <6 to >24 months (episodic tremor and slip, or ETS) on subduction zone thrust fault have elucidated a down-dip transition in slip behavior from frictionally-controlled slip to continuous plastic creep. In this presentation I review seismic evidence for the role of fluids on the seismogenic behaviour of slow earthquakes. In the slow slip region there is evidence for subducting low-velocity channel with extremely high P-to-S velocity ratio (Vp/Vs) interpreted to manifest elevated pore-fluid pressures generated through the release of water from pro-grade metamorphic dehydration reactions within the subducting oceanic crust. Elevated pore pressures weaken the fault and allow slip to occur at low differential stress. Accordingly, the plate interface likely represents a low-permeability boundary that controls vertical migration of fluids into the overlying crust. Direct evidence of factors controlling the variability in recurrence times is more elusive. We compile seismic data from subduction zone forearcs exhibiting recurring slow earthquakes and show that the average Vp/Vs of the overlying forearc crust ranges between 1.6 to 2.0 and is linearly related with the average recurrence time of slow earthquakes. In northern Cascadia, forearc Vp/Vs values decrease with increasing depth of the plate interface and with decreasing tremor-episode recurrence intervals. Low Vp/Vs values require significant addition of quartz in a dominantly mafic forearc environment. We propose that variable silica enrichment by 5-15% from slab-derived fluids and upward mineralization in quartz veins can explain the range of observed Vp/Vs values as well as the downdip decrease in Vp/Vs. The solubility of silica depends on temperature, and deposition prevails near the base of the forearc crust. We further propose that the strong temperature dependence of healing and permeability reduction in silica-rich fault gouge controls overpressure development and low effective fault-normal stress, and therefore recurrence times of slow slip. Our results imply that temperature-dependent silica deposition, permeability reduction, and overpressure development play an important role in controlling slow earthquake behavior.

Title: Tectonic Tremor observations in Guerrero, Mexico and how SSE strain field modeling including pore fluid evolution explain the observations

Presenter/First Author: Allen L Husker, UNAM National Autonomous University of Mexico, Mexico City,

Presenter/First Author Email: uskerhay@gmail.com

Co-authors: William Frank, Institut de Physique du Globe de Paris, Paris, France; Victor M Cruz-Atienza, Universidad Nacional Autonoma de Mexico, Mexico City, Mexico; Vladimir Kostoglodov, UNAM National Autonomous University of Mexico, Mexico City, Mexico; Nikolai Shapiro, Institut de Physique du Globe de Paris, Paris, France; Carlos David Villafuerte, Universidad Nacional Autonoma de Mexico, Mexico City, Mexico; Emmanuel Caballero, UNAM National Autonomous University of Mexico, Mexico City, Mexico

Published Material: The observations have been partly published in the following publication: Frank, W., N. Shapiro, A. Husker, V. Kostoglodov, A. Romanenko, M. Campillo (2014), Using systematically characterized low-frequency earthquakes as a fault probe in Guerrero, Mexico, *J. Geophys. Res.*, *119*, 7686–7700, doi:10.1029/ 2014JB011457.The modeling will be presented in the SSA meeting in April.This presentation in Montreal will be the first of the two together.

Abstract Body: Tectonic tremor (TT) in Mexico has a complicated behavior. All tremors occur close to the plate interface near 40 km depth. The area of TT activity is divided into 3 zones. The transient zone located ~130 km – 165 km from the trench. The buffer zone, which has very little TT and is located ~165 km – 190 km from the trench. The Sweet Spot (~190 km – 245 km) has the overwhelming majority of TT. Previous studies have shown near continuous TT within the Sweet Spot with large bursts of activity about 3 - 5 times a year. Low frequency earthquake (LFE) studies show that during a burst LFE streaks are seen in the Sweet Spot that travel trench perpendicular (10's km/hr). After several days LFE's are found within the transient zone, however they do not appear to streak or be related to the streaks in the other zones. These bursts correlate with small slip seen on the GPS record and are considered small, short-term slow slip events (small SSE). The Sweet Spot also has a near continuous amount of smaller bursts that do not streak, do not cross into the buffer zone and do not provoke LFE's in the transient zone. The large, long-term slow slip events (SSE) that occur approximately every 4 years in Guerrero provoke a very large number of TT bursts. The LFE's farthest from the trench show no difference in their rate during the majority of the SSE. The closer the LFE's are to the trench the more they are found to occur in separate bursts, which suggests that they are more "stick-slipy". In the last stage of the SSE, the number of LFE's declines dramatically with the greater the decline the further the distance from the trench. Poroelastic modeling of fluid transport during the large SSE shows that fluid migrate toward the Sweet Spot with maximum velocities of ~10^{-3} km/day, which is more than 3 orders of magnitude slower than all of the LFE/TT migration speeds mentioned above suggesting that fluid transport cannot explain these observations. However, Coulomb Failure Stresses due to the SSE strain field including pore pressure evolution (through the effective stresses) are consistent with the time-dependent occurrence frequency of LFEs during the large SSE. A small SSE strain field could potentially produce the smaller

SSE/TT episode observations that fluid migration cannot explain due to the wildly varying TT time scales and velocities.

Title: Constraints on Slab Morphology in Southwest Japan from Low Frequency Earthquakes

Presenter/First Author: Xuejun Han, University of British Columbia, Vancouver,

Presenter/First Author Email: hanxuejun_10@163.com

Co-authors: Michael G Bostock, University of British Columbia, Vancouver, BC, Canada; Shoichi Yoshioka, Kobe University, Kobe, Japan

Abstract Body: Slab morphology below 20 km depth in southwest Japan has been previously mapped using receiver functions and double-difference seismic tomography where a low-Vs, high-Vp/Vs layer is associated with the subducting oceanic crust. Low frequency earthquakes associated with deep tectonic tremor afford an alternative and more direct means of mapping depth to top of plate in the depth range of 35-45 km depth range as these events are usually inferred to represent shear slip on the plate interface. We are compiling catalogues of LFE detections and LFE templates along the Nankai subduction zone from Kyushu east to the Tokai district using waveform data obtained from multiple seismograph networks in southwest Japan. The improved signal to noise ratio of LFE templates over individual LFE detections enables precise measurement of both P and S wave times and estimation of accurate hypocentral depths. We will present a preliminary map of plate depth contours between 35-45 km depth for SW Japan from LFE templates for comparison with estimates based on tomographic and receiver function imaging of the low velocity layer. This comparison should enable insight into the spatio-structural relation between regular seismicity, slow earthquakes and the subducting oceanic plate.

Title: Interfacial controls on glacier stick-slip rupture dynamics and implications for slow earthquakes

Presenter/First Author: Jacob I Walter, University of Texas at Austin, Austin, TX

Presenter/First Author Email: jakeiwalter@gmail.com

Co-authors: Ilya Svetlizky, Hebrew University of Jerusalem, Jerusalem, Israel; Jay Fineberg, Hebrew University of Jerusalem, Jerusalem, Israel; Emily E Brodsky, University of California Santa Cruz, Santa Cruz, CA; Slawek M Tulaczyk, University of California Santa Cruz, Santa Cruz, CA; Zhigang Peng, Georgia Institute of Technology Main Campus, Atlanta, GA; Lucas Beem, California Institute of Technology, Pasadena, CA; Catherine G Barcheck, University of California Santa Cruz, Santa Cruz, CA; Sasha P Carter, University of California - San Diego, San Diego, CA

Published Material: Half of the material was recently published this month as Walter, J. I., I. Svelitsky, J. Fineberg, S. Tulaczyk, E. E. Brodsky, C. G. Barcheck, and S. P. Carter (2015), Rupture speed dependence on initial stress profiles: Insights from glacier and laboratory stick-slip, Earth and Planet. Sci. Lett., 411: 112-120, http://dx.doi.org/10.1016/j.epsl.214.11.025.

Abstract Body: Slow slip events are now well-established in natural faults occurring under a myriad of physical conditions, though the processes controlling slow rupture remain poorly understood. The Whillans Ice Plain provides a window into these processes through bi-daily stick-slip seismic events that displace an ice mass over 100 km long with a variety of rupture speeds observed at a single location (e.g. Bindschadler et al., 2003). During periods between fast slip events, the ice flows downhill at a steady rate of less than 0.001 m/min, then suddenly increases its speed by more than an order of magnitude at tidal periods, slipping up to ~0.5 m in ~30 min. Typically individual rupture fronts initiate at two distinct nucleation regions that vary with the tide (Winberry et al., 2009). Events occurring during high tide have an average rupture speed (when averaged across the Ice Plain) that is faster than low tide events. Though, counter-intuitively, the low tide events tend to have significantly higher initial rupture speeds. We attribute this behavior to local stress configurations that are spatially and temporally heterogeneous and utilize laboratory measurements of stick-slip sliding on plastic blocks to mimic the WIP behavior (Walter et al., 2015). Basal interfacial stresses are known to control rupture speed in numerous laboratory analog experiments. We hypothesize a similar control on the WIP behavior and show that laboratory experiments can explain most of the rupture speed behavior. In addition, we show evidence that nucleation of the events is sensitive to triggering from distant earthquakes. If we simplify our notion of slow slip to events that rupture under the same conditions as earthquakes but at significantly reduced rupture velocities, then the glacier events provide a path forward for understanding slow slip on natural faults. The central conclusion of our studies is that the observed systematic variations in rupture velocities are governed by the applied stresses and may provide insight into some slow slip source processes.

Title: Mechanism of spontaneous and triggered continental shallow creep events

Presenter/First Author: Meng Wei, University of Rhode Island Narragansett Bay, Narragansett, RI

Presenter/First Author Email: matt-wei@mail.uri.edu

Co-authors: Yajing Liu, McGill University, Montreal, QC, Canada; Yoshihiro Kaneko, GNS Science, Lower Hutt, New Zealand; Jeffrey Joseph McGuire, Woods Hole Oceanographic Ins, Woods Hole, MA; Roger G Bilham, University of Colorado, Boulder, CO

Published Material: First half of the presentation has been published.Wei, M., Y. Kaneko, Y. Liu, and J. McGuire (2013), Episodic fault creep events in California controlled by shallow frictional heterogeneity, Nature Geoscience 6, 566–570, doi:10.1038/ngeo1835.

Abstract Body: Slip on tectonic faults take place over a wide range of spatial and temporal scales as earthquakes, continuous aseismic creep, or episodic creep events. Shallow creep events on continental strike-slip faults can occur spontaneously or being triggered by nearby earthquakes. Despite more than five decades of observations, the mechanism of shallow creep events and their implications for seismic hazard are still not fully understood.

To understand the mechanism of spontaneous and triggered creep events, we developed a physics-based numerical model to simulate shallow creep events on a strike-slip fault with rate- and state-dependent frictional properties. We show that a widely used synoptic model cannot explain the wide variability in observed shallow creep characteristics on strike-slip faults in California. Rather, a frictionally unstable layer embedded in the shallow stable zone is required to match the geodetic observations of the creep behavior. We then introduced static and dynamic stress perturbations to this theoretical fault model, to further investigate the observed behavior of triggered creep events. We find that many creep events were likely dynamically triggered because the static stress changes

caused by nearby earthquakes are typically less than 0.1 MPa thus too small to instantaneously trigger creep events. In contrast, we can reproduce the instantaneously triggered creep with dynamic perturbations alone, where the triggering threshold depends on the peak amplitude of and the time-integrated dynamic Coulomb stress change. Based on observations and simulations, the stress change amplitude required to trigger a creep event of 1 and 0.01 mm slip is 0.8 and 0.6 MPa, respectively. This is at least one magnitude larger than the triggering threshold of non-volcanic tremor (2-60 KPa) and earthquakes in geysers (5 KPa), which may due to the difference in the effective normal stress and other friction properties in these systems or different triggering mechanisms. We conclude that shallow frictional heterogeneity on strike-slip faults can explain both the spontaneous and dynamically triggered creep events.

Title: Detecting Very-Low-Frequency Earthquakes in Parkfield, California: Evidence for Slow-Slip Events

Presenter/First Author: Andres Felipe Pena-Castro, McGill University, Montreal, QC

Presenter/First Author Email: andres.penacastro@mail.mcgill.ca

Co-authors: Rebecca M Harrington, McGill University, Montreal, QC, Canada; Elizabeth S Cochran, Organization Not Listed, Washington, DC; Xiangfang Zeng, University of Wisconsin Madison, Madison, WI; Clifford H Thurber, Univ Wisconsin-Madison, Madison, WI; David R Shelly, California Geological Survey Menlo Park, Menlo Park, CA

Abstract Body: Geodetically observed slow-slip events (SSEs) occur in many subduction zones around the world, and are indicative of slip on the plate interface below the brittle-ductile transition, at depths of roughly 30-50 km. SSEs are commonly associated with tremor and low-frequency earthquakes (LFEs) at the up-dip boundary of fault patches hosting SSEs. Another type of seismic signal, termed very-low-frequency earthquakes (VLFs), may potentially represent the seismic signature of SSEs in the region of a fault where tremor and LFEs occur (~20-30 km depth). VLF signals have been observed in association with tectonic tremor and LFEs in the Nankai through subduction zone, and their focal mechanism solutions suggest they result from slip along the plate interface. Here we search for VLF events on the San Andreas Fault near Parkfield, California, where vigorous tremor and LFEs occur in the absence of geodetically observed slip. We test a procedure that analyzes seismograms in the LFE band (2-8 Hz), the VLF band (0.02-0.05 Hz) and the waveform envelope, and stack multiple time windows containing co-located tremor events in the VLF band. We base our stacking time windows on LFE arrival times, and use waveform envelopes to determine peak amplitudes for aligning waveforms in the VLF band. The objective of stacking multiple records is to increase the signal-to-noise ratio of the VLF signal, which is often not visible above the noise level on a single waveform. We use a combination of data from permanent stations and seismic data collected from a temporary deployment of 13 broadband stations installed < 30 km from the San Andreas Fault near Cholame, California in 2010-2011. The postulated VLF origin times result from a LFE catalog calculated using a high resolution 3D velocity model. Our procedure will test wheter VLFs can be detected in the Parkfield region, which will support the existence of slow-slip events that may be below the limits of detection by geodetic methods.

Title: Low-Frequency Earthquakes on the Queen Charlotte Plate Boundary

Presenter/First Author: Tim W Hayward, University of British Columbia, Vancouver,

Presenter/First Author Email: thayward@eos.ubc.ca

Co-authors: Michael G Bostock, University of British Columbia, Vancouver, BC, Canada

Abstract Body: The Queen Charlotte Fault is a major plate boundary located off the northwest coast of North America that has produced large earthquakes in 1949 (M8.1) and more recently in October, 2012 (M7.8). The 2012 event was dominated by thrusting despite the fact that plate motions at the boundary are more nearly transcurrent. We have identified seismic tremor in the region of the Queen Charlotte plate boundary below Haida Gwaii within the frequency band 3 to 12 Hz. The Queen Charlotte Fault region is typified by intermittent tremor activity every few days, which is similar to the San Andreas Fault and in contrast to subduction zones where distinctly episodic tremor and slip is observed. The tremor includes low-frequency earthquakes (LFEs) that are of particular interest due to their relatively high signal-to-noise ratios compared with other areas of investigation such as the northern Cascadia subduction zone, and their distinct phase arrivals. We are currently assembling LFE detection catalogues and templates with two main goals in mind. First, we wish to determine whether LFEs occur predominantly on a shallow crustal transform (*i.e.*, analogous to the San Andreas Fault), a deeper thrust fault (*i.e.,* analogous to the Cascadia subduction zone), or a combination of the two. This information will indicate which portions of the plate boundary system undergo slow slip. Secondly, we will compare LFE activity before and after the 2012 M7.8 earthquake to investigate the influence of the earthquake on fault frictional properties and the stress field.

Title: Slow Slip Processes On Frictional Faults - Simulations in a Laboratory Setting

Presenter/First Author: Paul A Selvadurai, University of California Berkeley, Oakland, CA

Presenter/First Author Email: pa.selvadurai@berkeley.edu

Co-authors: Steve Glaser, University of California Berkeley, Berkeley, CA

Abstract Body: We present laboratory observations derived from a direct shear test subjected to a normal stress and a controlled direct shear, where the effective strength heterogeneity is governed by the non-uniform distribution of asperities throughout the interface. We were able to map out the asperities and normal stress upon them using a pressure sensitive film. Prior to rapid sliding, we observed slow slip, which accumulated non-uniformly along the fault. Large, densely distributed asperities retarded slow slip and produce a 'locked' section with relatively low shear displacement. Slow slip was measured using slip sensors place at seven locations along the fault and a nucleation zone was seen to grow (at rates ~ 3 to 12 mm/s) from the free edge into a 'locked' section of the fault. Slow slip showed intermittent, 'burst-like' increases in spectral power between the frequencies of 60 to 150 Hz. These events lasted between ~ 12 seconds and were accompanied by burst-type acoustic emissions lasting ~ 0.5 to 3 µs. A local increase in slip rate was observed after its cessation. This increase in slip rate is consistent with observations of slow slip made before and after the 2013-2014 Boso slow slip event [Fukuda et al. 2014]. Further examination of these events shows a spatiotemporal dependence described by a time delay between adjacent along-strike slip sensors. Foreshocks were recorded using Glaser-type acoustic emission sensors and they occurred at the latter stages of the slow slip phase and indicated a source radius ranging from 0.21 to 1.09 mm – similar to larger asperity size measured with the film. Duration of these foreshocks were 7 orders of magnitude shorter than the 'burst-like'

signals – similar observations have been made in actual geological settings [Ide, 2007]. These results will aid the development of a mechanistic model of slow slip that will improve the understanding of the interaction of slip and effective fault strength heterogeneity.

Title: Lower Crustal Detachment in the Cordillera and Other Hot Backarcs

Presenter/First Author: Roy D Hyndman, Geological Survey of Canada Sidney, Sidney, BC

Presenter/First Author Email: rhyndman@nrcan.gc.ca

Abstract Body: Lower crust horizontal detachment is widespread in hot backarcs like the Cordillera, based on four lines of evidence. (1) Temperature-depth estimates (~800 C at Moho) and laboratory rheology data indicate the lower crust in backarcs is likely very weak. In contrast, craton crusts are cold and strong, 400-500 C at Moho. Although the crust is more mafic with depth so stronger at the same temperature, the strength generally decreases downward. However, the lowest part of crust may be in dry granulite conditions, >730 C, so stronger than just above in amphibolite conditions (~700C). The uppermost mantle is stronger than the crust because of the rock type. The effective elastic thicknesses, Te, provides a check on the depth to the weak lower crust. (2) Regional lower crust horizontal seismic reflectors are interpreted to indicate current or past horizontal shear detachment; e.g., SW British Columbia, western US, UK, Spain, Germany, Japan. The top of the reflectors is commonly at 15-20 km, ~450-500 C; the base at ~30 km, ~730 C. The base of the reflectors is often ~5 km above Moho, consistent with underlying strong dry granulite rocks. (3) Structural and tectonic evidence for lower crustal detachment include: long distance crustal strain transfer, i.e., Yakatat collision northern BC, southwestern BC overthrusting of craton in Rocky Mtns, Andes thrusting in foreland. Also, many long-distance terrane motions and associated horizontal deformation in oroclines are best explained by motion of only the upper crust. (4) Extensive outcrop sections of former lower crust that exhibit horizontal fabric shearing at 750-800 C and 30 km., e.g., Athabasca granulite terrane. The strong evidence of horizontal detachment in the lower crust means that geological structural and tectonic interpretations need to allow for common 15-20 km thick upper crust transport and deformation, independent of the mantle.

Title: The role of a sharp cratonic keel edge for lithospheric delamination and rapid orogenic plateau uplift, Canadian Cordillera

Presenter/First Author: David W S Eaton, University of Calgary, Calgary, AB

Presenter/First Author Email: eatond@ucalgary.ca

Co-authors: Xuewei Bao, University of Calgary, Calgary, AB, Canada; Bernard Guest, University of Calgary, Calgary, AB, Canada

Published Material: A large fraction of this work was recently published in Nature Geoscience.

Abstract Body: The interior of the Canadian Cordillera is part of an exhumed fossil plateau located in a back-arc tectonic setting. Using data compiled from western Canada and USArray, we integrate new analysis of teleseismic Rayleigh-wave tomography with thermochronology data to investigate lithospheric structure and exhumation history in this region. The edge of the North American craton is marked by a remarkably abrupt change in lithospheric thickness, from > 200 km to < 50 km, coincident with a significant step in surface heat flow. This sharp plate edge delineates the eastern limit of a fossil orogenic plateau that experienced rapid uplift and exhumation (10 to 15 km) during the mid to late Eocene. Our tomographic images show evidence for a high-velocity block in the sub-Cordilleran mantle, at depths greater than 165 km, which we interpret as foundering lithospheric mantle; we propose that delamination of this block was triggered by edge-driven convection and led to rapid uplift, voluminous magmatism and transition from compressional to extensional regime. Similar processes may have resulted in removal of the lithospheric keel beneath the North China craton and regional uplift of the Altiplano.

Published Material: AESRC 2014 Geodiversity, University of Ottawa, March 28-30, 2014.Oral presentationPart of the research presented as oral presentation.

Abstract Body: Let's begin, Anaxagoras' atom's building blocks of the universe; Aristotelian concentric celestial spheres; the middle ages Christian Heaven - a spiritual cosmic shell enclosing a number of concentric shells; Kantian hierarchical, and Cartesian vortex fractal universes. We recognise two states of Universal manifestation: crystalline, structural, or liquid, fluid, vortexial. The vortex dynamics manifestation within a fractal pattern is fundamental to all entities: atoms, star-planetary systems, galaxies, super galaxies. We accept 4D-space vortex treatise: a double helix spiral, two spirals creating a standing wave, stationary oscillation. Now one can stress attention on seismonomy treatise of seismoids' dynamics manifestation in the realm of solid media: stochastic emergence of indestructible quantum oscillating units through their life-span; its five postulates with insight into Universal Coherentism, the Doctrine of Dynamics Monism. Seismoid is a unitary entity which can not contain the same fractal level seismoids as its structural parts. Energy exchange between seismoids can be called Machian-energy quanta radiation. Obviously the basic vortex unit in essence is a seismoid, also possessing electromagnetic attributes. Evidently, the universe is a fractal! Beginning by first stratum with its master unit and subordinate units, which are rotating and revolving around it. This pattern is progressively replicated top-down in varying forms on each hierarchical stratum till Planck's scale. Thus, the whole quantum unit oscillation is the master control over its subordinates and constitutes segregated space-time of the stratum, but in turn it is an element in a greater whole. Contemplating on outermost stratum, its master entity limits further ascension, and can not be a subordinate, one can assume that the entire universe is encapsulated into this superior entity which is devoid of space-time of its own. Obviously cosmogenes in that treatise is plausible from top to down.

Title: Structural and seismic facies analysis of Tytoolz-fiy Field, onshore Niger Delta

Presenter/First Author: Emmanuel A Titus, University of Lagos, Somolu, Lagus,

Presenter/First Author Email: ta_emmy@yahoo.com

Co-authors: Elijah Ayolabi, , , ; Ayodele Ogunniyi, , ,

Abstract Body: Summary:

3D seismic cube from the Tytoolz-Fiy Field, was interpreted based on the reflection continuity, amplitude strength and internal configuration to understand the subsurface geology and depositional environment. This was integrated with the analysis of five well logs, and was carried out to ascertain and control the interpretation of the seismic facies analysis. A sequential workflow involving the identification and analysis of different seismic facies, generation of a synthetic seismogram and seismic attribute analysis was employed. Four seismic facies namely Facies A, B, I and T were identified and classified based on their reflection continuity, internal configuration and amplitude strength. The well log facies results were correlated and tied to the seismic facies analysis results and were used to infer the depositional environment - the delta front, delta plain and pro delta environments. Structural interpretation revealed the different fault systems, simple rollover anticlines and shale diapiric regions. Seismic attribute analysis was also carried out to identify regions of similar lithology and geomorphic features. This supported and aided the interpretation, especially to confirm the shale diapiric region.

FACIES NAME	SEISMIC FACIES	REFLECTION ATTRIBUTE (a) Internal configuration (b) Continuity (c) Amplitude strength
Facies A		(a)Parallel to sub-parallel (b)Semi continuous (c)low to moderate
Facies B		(a)Sub-parallel to Hummocky (b)Disrupted to discontinuous (c)Moderate to High
Facies I		(a)Parallel (b)Semi continuous to Continuous (c)Moderate to High
Facies T		(a)Chaotic (b)Discontinuous (c)Moderate to High

Title: New Methods for Acquiring and Visualizing Surface Wave Data

Presenter/First Author: Brian Miller, Slippery Rock University of Pennsylvania, Slippery Rock, PA

Presenter/First Author Email: brian.miller@sru.edu

Co-authors: Georgios P Tsoflias, University of Kansas, Lawrence, KS; Don W Steeples, , Palco, KS

Abstract Body: The use of surface waves to analyze the upper several tens of meters of the subsurface has become an important technique for near-surface investigations. Typically surface waves are acquired using a single row of geophones which limits visualization to a 2D profile of shear wave velocity versus depth. Acquiring surface wave data along multiple, coincident geophone lines allows a volume of data to be created providing the opportunity to view the data in 2D or 3D. A new method for acquiring surface wave information in 2D or 3D is demonstrated, providing a method of visualization not previously available.

The Autojuggie, developed by The University of Kansas, is a hydraulically driven geophone deployment system capable of deploying a grid of 220 geophones in under two minutes. Employing the Autojuggie an active source surface wave seismic survey was conducted on the campus of The University of Kansas. Rayleigh wave data were simultaneously acquired along eleven coincident receiver lines which was then processed using the Multichannel Analysis of Surface Waves (MASW) method. The current 2D visualization of data processed using the MASW method was expanded by developing a series of computer algorithms allowing seismic shear wave velocity information to be plot within a 3D environment.

Using these new methods seismic shear wave data can be viewed in new and unique ways. The data can be viewed in a traditional 2D profile showing shear wave velocity versus depth along each geophone receiver line. Additionally 2D or 3D profiles can be displayed at selected intervals between, or across, each of the geophone receiver lines. Lastly shear wave velocities throughout the surveyed area can be viewed at selected depths. Using these new methods I was able to identify velocity inversions and lithology changes interpreted to be both a result of natural and construction practices.

Title: Focal depth distribution of the 1982 Miramichi, New Brunswick, earthquake sequence, retrieved by analyzing regional depth phases

Presenter/First Author: Shutian Ma, Carleton University, Ottawa,

Presenter/First Author Email: shutian33@gmail.com

Co-authors: Dariush Motazedian, , ,

Abstract Body: A magnitude mb 5.7 earthquake occurred on 9 January 1982 in the Miramichi region, New Brunswick, Canada. The earthquake was felt throughout much of the Maritime Provinces, Canada and the New England States, United States. The mainshock was followed by an extensive aftershock sequence. The 1982 Miramichi mainshock is the largest earthquake in eastern Canada since the Cornwall-Massena earthquake of 1944. It is the first earthquake in eastern North America recorded on modern seismograph networks world-wide, so its source parameters can be determined by many modern techniques. Focal depth is an important source parameter. As the contribution from forcal depth to travel times are much smaller than that from the distance, the error in focal depth is much larger than that in epicenter obtained by conventional locating method. Regional depth phases are often detectable at regional distances. As the epicentral region of the Miramichi earthquakes lies within the northern Appalachian Mountains, regional depth phases are very well developed and recorded at several seismic digital stations. The waveforms generated by the aftershock sequence are very well saved at GSC database, so these regional depth phase records can be used to retrieve focal depths for the sequence by modeling method which has not been used before. In the epicentral region of the mainshock the documented aftershock number is about 700. To abstract main features we first retrieved waveform records for the aftershocks with magnitude mN >= 2.8 (about 100). These earthquakes are representative and have

clear depth phase records. Then we performed regional depth phase modeling. We found the dominant focal depth range is from 5 km to 7 km. About one third of the analyzed aftershocks occurred at about 6 km. Another small group has focal depths at about 3 km. Some aftershocks have very shallow focal depths, almost near the ground surface, which was confirmed by strong Rg phase records. The deepest is at about 10 km.

Title: The Lamont Cooperative Seismographic Network (LCSN)

Presenter/First Author: Mitchell Evan Gold, Lamont Doherty Earth Observatory, Palisades, NY

Presenter/First Author Email: goldm@ldeo.columbia.edu

Co-authors: Patrick Bastien, Lamont-Doherty Earth Observatory, Palisades, NY; Won-Young Kim, University of Tokyo, Yayoi 1-1, Bunkyo, Tokyo, Japan

Abstract Body: The Lamont Cooperative Seismographic Network (LCSN) consists of 35 broadband seismographic stations and an additional half dozen short-period stations. Stations located in New York, New Jersey, Connecticut, Pennsylvania, Delaware, Maryland, Vermont and New Hampshire, are operated by 40 cooperating partners, with Lamont Doherty Earth Observatory (LDEO) serving as the lead institution. Partners include colleges and universities, community colleges, secondary schools, museums, a state geological survey, conservation organizations, research institutes, and a tourist attraction. The LCSN offers unique educational opportunities for students at a variety of levels, for public officials, and for the general public.

The LCSN serves as one of seven regional seismic monitoring and data center for the Advanced National Seismic System (ANSS) led by US Geological Survey. The backbone of the LCSN real time data acquisition for earthquake monitoring in the northeastern US is the Internet based Earthworm system with the back-end using the ANSS Quake Management System (AQMS) software. All seismogram data acquired by LCSN are archived at the IRIS-DMC in Seattle, Washington in real time, while much of the earthquake data such as catalogs, maps, recent earthquakes, felt reports (Did-You-Feel-It?), and event waveform data are hosted on our website: http://www.ldeo.columbia.edu/LCSN.

The LCSN modernized most of its seismic hardware in 2011 and has continued a strong program of station improvements for greater data availability and quality. We share resources with our partners to minimize costs for telemetry by using their high speed internet, and recently sharing a county's microwave Emergency Management link. Along with these improvements, we continue to test and upgrade with more reliable power and backup systems for our solar-powered stations.

Title: The Central and Eastern United States Network and Repeating Earthquakes in ENA

Presenter/First Author: Won-Young Kim, University of Tokyo, Yayoi 1-1, Bunkyo, Tokyo,

Presenter/First Author Email: wykim@ldeo.columbia.edu

Co-authors: Mitchell Evan Gold, Lamont Doherty Earth Observatory, Palisades, NY; Patrick Bastien, Lamont-Doherty Earth Observatory, Palisades, NY; John G Armbruster, Columbia University of New York, Palisades, NY

Abstract Body: The recent deployment of Transportable Array (TA) seismographic stations of the USArray project by the Incorporated Research Institutions for Seismology (IRIS) in the eastern United States has greatly improved the earthquake monitoring and research in the region. Over 160 TA stations in the eastern United States were selected to be retained beyond their nominal deployment period of about two years. These selected TA stations will be gradually upgraded from 40 to 100 samples/second by the fall of 2015 and will form the Central and Eastern United States Network (CEUSN) with network code "N4". CEUSN will be operated by IRIS until the end of 2017. The CEUSN and existing permanent seismographic stations of the national and regional networks in the region such as, Canadian National Seismic Network (CN), US National Seismic Network (US), Lamont Cooperative Seismographic Network (LD), New England Seismic Network (NE), Cooperative New Madrid Seismic Network (NM) and Penn State Network (PE) provide an unprecedented opportunity to study earthquakes in the stable Eastern North America (ENA).

The initial objective of the USArray component of the EarthScope project was to explore the structure and evolution of North America using continuous recordings from broadband seismometers of TA stations. While research goals of the EarthScope in ENA are still carried out by the EarthScope project, we have begun to look at broad regional scale crust and uppermost mantle structure using receiver function analysis (EARS: EarthScope automated receiver survey) and automated surface wave tomography tools developed during EarthScope project, and report our results on crustal thickness variation and lithosphere-asthenosphere boundary in the eastern US. We report results of our effort to find repeating earthquakes from waveform archives in the Adirondacks, New York and Western Quebec, Canada by employing a waveform cross-correlation technique.

Title: A STUDY ON ACTIVE TECTONICS OF NORTHEASTERN INDIA FROM FOCAL MECHANISM SOLUTIONS

Presenter/First Author: Santanu Baruah, CSIR-North East Institute of Science and Technology, Jorhat,

Presenter/First Author Email: santanub27@gmail.com

Co-authors: Saurabh Baruah, , ,

Abstract Body: Focal mechanism solutions of 132 numbers of local earthquake events ($3.5 \leq M_W \leq 5.9$) in NER, India are determined. Solutions in the Eastern Himalayan zone confirm that the earthquakes in this region are mainly dominated by thrust or thrust with strike-slip component. The P-axis of most of the events is found to be oriented nearly along NNW direction. The focal mechanism solutions in the western and eastern part of Shillong Plateau are found to be mainly pure thrust or pure strike slip in nature. The Mikir Plateau earthquakes are mostly thrust in nature. The earthquakes in the Tripura fold belt may be interpreted as plate-boundary earthquakes and most of them are strike-slip in nature. The P-axis orientation of most of the events associated to Indo-Burma ranges are found to be roughly north-south directed and shows dominance of thrust kind of mechanism. The main objective of the present work is to study the active tectonics of NER, India by characterizing the different active faults and lineaments based on new and reliable fault plane solutions determined through waveform inversion.

Title: Seismic Mapping of the Fenchuganj Structure, Surma Basin, Bangladesh.

Presenter: Al-Tamini Tapu, Jahangirnagar University, Dhaka,

Presenter Email: tamini.tapu@gmail.com

First Author: Mosharof Hossain, Jahangirnagar University, Dhaka,

First Author Email: hossain.pml@gmail.com

First Author Student?: No

Co-authors: Delwar Hossain, Jahangirnagar University, Savar, Dhaka-1342, Bangladesh

Abstract Body: The Surma Basin is a sub-basin of the Bengal Basin occupying the northeastern part of Bangladesh. It is the prime hydrocarbon producing region of Bengal Basin. The Fenchuganj structure is located along the eastern margin of the Surma Basin. This present work comprises the seismic, gravity, magnetic and well data for interpreting the subsurface geology, structural configuration and tectonics of the Fenchuganj structure. The research also involves integrated interpretation of gravity and magnetic data to delineate the subsurface structural condition of the Surma Basin and its surrounding region. In order to interpret the study area, five seismic sections have been considered. Based on the analysis of the sections and correlation with well data, four reflecting horizons are marked, viz., top of Lower gas sand, Bhuban Formation, Bokabil Formation and Tipam Formation. Time and depth contour maps of these four horizons are constructed using the two way travel time of the sections and T-Z curve of the study area. Preparation of subsurface geological maps and interpretation of subsurface features suggest that the Fenchuganj structure is a reversibly faulted, NNE-SSW trending assymmetrical anticline with sharp dip in eastern flank than western. The seismo-stratigraphic study of the area furnish three formations- Bhuban, Bokabil, and Tipam. An attempt has been made to analyze the gravity and magnetic data to configure the subsurface structural features of the Surma Basin and adjoining areas. It is an east-west trending oval shaped basin and is characterized by significant gravity low. The upward continuation and second vertical derivative (VZZZ) methods have been used to enhance residual gravity effects. Regional and residual anomaly maps for gravity field continued to 7.5km, 10km and 15km have been prepared. The three regional anomaly maps show almost similar structural configuration of the basin. Residual anomaly maps are characterized by some positive effects, possibly related with positive density contrast. Considering the findings of this study, the further investigation (3-D seismic survey, advanced software interpretation) can give more valuable information about real subsurface structure and hydrocarbon occurrence in this area.

Title: Body-Wave Scattering from Seismic Interferometry: Preliminary Results from the San Andreas Fault near Parkfield, California

Presenter/First Author: Stephen Glenn Mosher, University of Ottawa, Ottawa, ON

Presenter/First Author Email: stephenmosher@gmail.com

Co-authors: Pascal Audet, University of Ottawa, Ottawa, ON, Canada

Abstract Body: High-resolution direct tomographic imaging of subsurface Earth structures is generally limited by the poor distribution of seismic sources necessary for such studies. However, seismic interferometry has the potential to significantly overcome this issue through the use of ambient seismic noise recordings. Whereas the recovery of virtual surface waves via seismic interferometry techniques are the most abundant results produced by such studies, it has recently been shown that virtual body waves can also be recovered under appropriate conditions. Of particular interest is the scattering of body waves produced by velocity discontinuities in the subsurface, which dramatically improve our ability to characterize the seismic velocity structure. In this work we investigate the possibility of recovering body-wave scattering from interactions with velocity discontinuities associated with the San Andreas Fault using ambient seismic noise recordings across a network of stations near Parkfield, California. In particular we test whether mode-conversions (P to S waves) can be observed using these virtual Green's functions. Additionally, we examine the potential of seismic interferometry to produce time-lapse body-wave characterizations of the San Andreas Fault, in which properties of the fault can be seen to change in time.

Title: Real-time Stress Monitoring Using Ambient-noise Tomography in Deep Mine Environments

Presenter/First Author: Philippe Dales, University of Ottawa, Ottawa, ON

Presenter/First Author Email: pdales@gmail.com

Co-authors: Pascal Audet, University of Ottawa, Ottawa, ON, Canada; Jean-Philippe Mercier, Golder Associates, Montreal, Canada; Andrei Pascu, Golder Associés Ltée, Montreal, QC, Canada; Willem de Beer, Golder Associates NZ Ltd, Montréal, QC, Canada

Abstract Body: Understanding the response of the rock mass to mining is of key importance for the planning of mine operations as well as assessing and mitigating the seismic risk. For decades, studies have shown that passive source tomography, also called local earthquake tomography, can provide information on the rock mass response through the estimation of the temporal variation and 3D distribution (spatio-temporal variations) of stress. The spatio-temporal resolution afforded by passive source tomography depends on the seismicity rate and the location of microseismic events. In a mine, seismicity is not stationary, i.e. the locus and rate of seismicity vary with time, thus limiting the spatio-temporal resolution of this technique. Recent developments in the field of ambient noise seismic interferometry (Green's function retrieval from ambient noise) provide hints that continuous recordings of ambient vibrations collected around mines could be used to obtain information on the evolution and 3D distribution of the stress in the rock mass by providing measures of seismic travel times between pairs of sensors. In contrast to passive source tomography that relies on the distribution of seismic events, the resolution afforded by ambient noise interferometry tomography depends solely on the locations of sensors and the frequency content of the ambient noise. We present preliminary results of temporal variations in body-wave travel times between pairs of sensors obtained through the cross-correlation of continuous recordings collected at an active mine. In addition, we present the adopted processing scheme that exploits Hadoop to parallelize the computation.

Title: Seismic Interferometry for Mineral Exploration: Results from a Test Survey at the Lalor Mine, MB, Canada

Presenter/First Author: James A Craven, Geological Survey of Canada Ottawa, Ottawa, ON

Presenter/First Author Email: craven@nrcan.gc.ca

Co-authors: Saeid Cheraghi, , , ; Eric Roots, , , ; Gilles Bellefleur, Geological Survey of Canada, Ottawa, ON, Canada

Published Material: Preliminary results have been shown at SEG meeting recently in Denver and have been accepted for publication by Geophysical prospecting. We will be showing new beamforming analyses and f-K filerting designed to reduce artefacts in te haimge that have neverbefore been seen.

Abstract Body: Approximately 300 hours of ambient noise data were recorded on a grid of receivers covering an area of 4 km² over the Lalor mine, Canada, to test the capability of seismic interferometry to detect ore deposits in the crystalline rock environment. Underground mining activities create sources of ambient noise in the area which can be used to create virtual sources at the surface. Alongside the ambient noise survey, a larger 3D active-source seismic survey was also acquired and used to evaluate the interferometry results. The calculated virtual shot gathers retrieved by cross-correlating ambient noise at all receivers were processed following both 2D and 3D approaches using a sequence similar to the one applied to the active-source 3D data. The DMO stacked section reveals a number of events similar to those observed on the processed active seismic sections. The passive seismic interferometry results over the Lalor mining area are encouraging but image quality of passive survey is lower than the acquired active 3D survey at the area. A number of techniques such as beamforming and f-k filtering of the virtual data are being explored address this issue. Future ambient noise surveys with longer offset, shorter receiver spacing, and wider azimuth distribution could be acquired in crystalline rock environment to address the pros and cons of the method.

Title: Crustal structure beneath northeastern Tibetan Plateau from teleseismic receiver functions and its relationship with the regional seismicity

Presenter/First Author: Xinfu Li, China University of Geosciences Beijing, Beijing,

Presenter/First Author Email: xinfuli@cugb.edu.cn

Co-authors: Hongyi Li, China Univ. of Geosciences(BJ), Beijing, China

Published Material: No

Abstract Body: More detailed studies of crustal structure in northeastern Tibetan Plateau can be of great benefit to the understanding of crustal deformation and plateau growth mechanisms. We investigate crustal structure beneath 58 seismic stations in northeastern Tibetan Plateau by using the P receiver function method to estimate the crustal thickness, Poisson's ratio and Vp/Vs ratio by analyzing the collected three-component teleseismic data. These data are recorded by 29 stations deployed by China University of Geosciences between June 2008 and July 2010, 19 Ascent stations deployed between May 2007 and August 2008, 2 stations from China National Seismic Network and 8 stations from Central China Network. The images of Moho depth suggests the lateral variations of the crustal thickness decreasing from Qilian Orogen (~63 km) to east Kunlun fault area (~40 km). High Vp/Vs and Poisson's ratio appear along a narrow band from southwest to northeast in the east Kunlun fault area, while lower Vp/Vs and Poisson's ratio appear in the Qilian Orogen.The observations disagree with the crustal composition beneath the northeastern margin of the Tibetan plateau. There is no simple correlation between the regional seismicity and the crustal thickness observed here. Our results of crustal structure and seismicity in this study area not only reveal the lateral inhomogeneity of the crustal structure but also provide some constraints on understanding the mechanism of uplift and crustal thickening of the Tibet.

Title: Coda Q estimates of Bilaspur region of Himachal Lesser Himalaya

Presenter/First Author: Sandeep ., Indian Institute of Technology Roorkee, Roorkee,

Presenter/First Author Email: sandeeparora95@gmail.com

Published Material: THE WORK HAS BEEN ALSO PRESENTED IN INDIAN GEOPHYSICSL UNION HELD ON 19-21 NOVEMBER 2014. THIS WORK IS SOME EXTENDED TO INCLUDE MORE INFORMATION

Abstract Body: In the present work the quality factor (Q) of Coda waves of Bilaspur region of Himachal Lesser Himalaya has been estimated using the single backscattered model proposed by Aki and Chouet (1975). Coda waves of 94 local events located within 100 km of the region having magnitude (0.15<ML<3.03) has been used to study the attenuation of seismic waves in the frequency range of 1.5 to 24 Hz. These events were recorded on digital station in Sikandera (SKND) during the period from May 2008 to April 2011 employing a five station seismological network in the region. The vertical component records were used in the present study. Hypocenter parameters of these events have been estimated with HYPOCENTER computer program. A MATLAB code has been developed for the estimation for Coda Q (Qc). The code follows the guidelines of CODAQ subroutine of SEISAN. The waveforms whose signal to noise ratio (SNR) is greater than 5 are selected for analysis. Only those Coda Q (Qc) values having correlation coefficient 0.7 or more are considered for the region to obtain the reliable values of Qc. By analyzing the Coda waves at different frequencies from 1.5 to 24 Hz the estimated Qc values varies from 155 at 1.5 Hz to 3781 at 24 Hz for lapse time window of 30 sec. This shows that Qc is function of frequency and its value increases as frequency increases. A Q–f relation is obtained for the entire region as Qc=105 f 1.14 the medium covering an area about 21899 sq. km. having lateral extent of 204 km. and vertical extent of 102 km.The observed Qc relation is also compared with those observed in other seismically active regions of the India and found that the estimated Qc value around Bilaspur region of Himachal Himalaya is highly heterogeneous and seismically active as compared to the other seismically active regions of India.

Keywords: Coda waves, Qc, Back-scattering model. Himachal Lesser Himalaya. . Qc estimated in this way represents the average attenuation properties of

Title: Inclined strike-slip fault in a two layered model of the lithosphere-asthenosphere system

Presenter/First Author: Papiya Debnath, Organization Not Listed, Kolkata,

Presenter/First Author Email: debpapiya@gmail.com

Co-authors: Sanjay Sen, , ,

Abstract Body: The lithosphere-asthenosphere system has been represented by layered viscoelastic media consisting of a viscoelastic layer of Maxwell type overlying a viscoelastic half space of liner viscoelastic solid. A long inclined surface breaking strike-slip fault is taken to be situated in the first layer. The medium is taken to be under the action of a tectonic forces arising due to different tectonic phenomena such as mantle convection etc. Expressions for displacement, stresses and strain are obtained during the aseismic period in between two major seismic events. Stresses are found to accumulate near the fault leading to a sudden movement across it resulting in an earthquake. The movement across the fault effect the nature of stress accumulation in the region. In this paper an attempt has been made to obtained and estimate of time to the next major event. Such studies are directly associated with the prediction of an impending earthquake in a medium which has non-homogeneous character.

Title: A generalized quasi-geostrophic model of thermal convection

Presenter/First Author: Mathieu Dumberry, University of Alberta, Edmonton, AB

Presenter/First Author Email: dumberry@ualberta.ca

Co-authors: Daniel Laycock, University of Alberta, Edmonton, AB, Canada; Moritz H Heimpel, University of Alberta, Edmonton, AB, Canada

Published Material: presented (poster) at SEDI 2014, fall AGU 2014

Abstract Body: It is well known that, under the influence of planetary rotation, convective flows tend to have a two dimensional (2D) structure, with small variations along the direction of rotation. Because of the primary force balance between pressure gradients and the Coriolis force, such flows are termed geostrophic. Convective flows are never purely geostrophic because buoyancy (which powers convection) is necessarily present and so is viscous dissipation. Nevertheless, provided rotation is dominant, the first order 2D nature of convective flows is preserved and these flows are often referred to as quasi-geostrophic (QG). QG numerical models of thermal convection, in which only equatorial variations are tracked, have been developed to take advantage of the predominant 2D structure of QG flows. These models can reproduce faithfully some of the features of fully three-dimensional (3D) numerical models. The chief advantage of such QG models is that, because of their 2D nature, a much higher numerical resolution is achievable than for 3D models for the same computing cost and can thus be used to study aspects of convection under a regime not accessible to 3D models. In existing QG models, the buoyancy force is restricted to its component perpendicular to the rotation axis and the modelled region of convection is limited to that outside the tangent cylinder. Here, we present an extension on these models by incorporating the axial component of the buoyancy force and by modelling convection inside the tangent cylinder. Our model can reproduce the salient features of 3D numerical models near onset. Further, our model also captures features of well developed, fully turbulent convection, such as production of zonal jets.

Title: Crustal Heat Flow and a Global Crustal Model to Estimate the Crustal Geoneutrino Flux Near the Sudbury Neutrino Observatory (SNO) .

Presenter/First Author: Lidia Iarotsky, GEOTOP-UQAM, Montreal, QC

Presenter/First Author Email: heylid@hotmail.com

Co-authors: Jean-Claude Mareschal, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Claude P Jaupart, Institut de Physique du Globe de Paris, Paris, France

Abstract Body: The main objective of geoneutrino observations is to determine the concentrations of uranium and thorium in the Earth's mantle. In order to calculate the mantle concentrations, one must precisely account for the crustal component of the geoneutrino flux. This requires knowledge of the crustal radioactivity. Crustal composition and radioactivity can be inferred from global crustal models or obtained directly by measuring the surface heat flow.

We have used heat flow data and the model CRUST1.0 to estimate the geoneutrino flux in eastern Canada where the Sudbury neutrino observatory is installed. The two estimates differ significantly because the global crustal models overestimate the heat production in many parts of the Superior Province. We find that the difference can be reduced by adjusting the heat production used in the global model to fit the heat flux measurements. Heat flux data are available in the Canadian Shield and within the Sudbury structure to constrain crustal radioactivity in the immediate vicinity of SNO and calculate the crustal geoneutrino flux.

Title: Evidence for Instability in Earth's Fluid Core from Paleomagnetic Intensity Records

Presenter/First Author: Keith D Aldridge, York Univ, Toronto, ON

Presenter/First Author Email: keith@yorku.ca

Co-authors: David McMillan, , ,

Abstract Body: A search of composite stacks of relative paleointensity PADM2M, SINT2000 and PISO-1500 has found a signature of luni-solar tidal strain rate (LTSR) over the past 2 Myr. Our search for LTSR in relative paleointensity records is based on a representation of long term fluctuations in geomagnetic intensity as a sequence of growths and decays, which we suggest are due to a tidally-induced parametric instability in Earth's fluid core. Linear stability theory predicts that the external LTSR that could excite an instability can be estimated from the difference between the observed growth rate of the instability minus the decay rate of the previous instability. Under the assumption that the observed paleointensity is a proxy for the perturbation velocity of an instability, we find that estimates of the LTSR directly from the relative paleointensity record are in agreement with calculated LTSR.

An important consequence of this depiction is the precise temporal location of 6 reversal events over the past 2 Myr. Significantly larger fluctuations of LTSR are associated with these reversals. A parametric instability in Earth's core is consistent with both the success in predicting reversals and finding the LTSR in relative paleointensity records. Furthermore, our model predicts that strain rates prior to the onset of a new instability should show only decay of a previous instability and hence be unrelated to the occurrence of a subsequent event. With very few exceptions our results show this and hence are consistent with a parametric instability participating in the geodynamo.

Title: The inertial modes of a uniformly rotating, homogenous, incompressible and inviscid spherical fluid shell: application to the Earth's fluid core

Presenter/First Author: Hossein Naseri, University of Lethbridge, Lethbridge, AB

Presenter/First Author Email: 3naseri@gmail.com

Co-authors: Behnam Seyed-Mahmoud, University of Lethbridge, Lethbridge, AB, Canada

Abstract Body: In this work we investigate the dynamics of a uniformly rotating, homogenous, incompressible and inviscid spherical fluid shell of rigid boundaries. Traditionally, the Poincar equation, a second order partial differential equation describing the perturbed pressure, is solved for the eigenfrequencies and eigenfunctions of the inertial modes of such model. This equation is of hyperbolic type which makes the boundary value problem ill-posed in the sense that the nature of the solutions is sensitive to the geometry of the boundary. General analytical solutions have not been found for thick spherical shell geometry. In recent years approximate solutions have been found using incompressible fluid of small viscosity. Here we use a Galerkin method and directly solve the momentum and the continuity equations subject to appropriate boundary conditions. We show that, as far as we have investigated, there is a one-to-one correspondence between the eigenfrequencies and eigenfunctions of this model and those of a rotating fluid sphere. We will discuss the results in the context of the geophysical literature on the Earth's core.

Title: Structure and Dynamics of the Core from Surface Gravity Measurements - Theory Versus Observations Using the GGP Network

Presenter/First Author: David J Crossley, Saint Louis University Main Campus, Saint Louis, MO

Presenter/First Author Email: crossleydj@gmail.com

Published Material: 25% at Colloque G2, Strasbourg, France, November 2014.

Abstract Body: The Global Geodynamics Project (GGP) was initiated in Canada in 1987 to improve the exchange of data from the increasing number of superconducting gravimeters (SGs) that were being established worldwide. Theoretical speculations in the 1970's concerning the possible existence of a spectrum of modes of oscillation of the liquid outer core (or 'undertones') suggested that SGs would be the best instrument to detect such oscillations. GGP started in earnest in 1997 and now numbers some 30 instruments located in all major continents. Despite numerous papers concerned with the analysis of the large amount of high quality SG data now available, success has been achieved in only a small subset of problems related to the dynamics of the core. This includes well-determined values for the period and Q of the free core nutation (FCN), whereas other rotational modes such as the FICN and ICW are difficult to observe in gravity. Likewise there has been no indication of distinct periods in the SG data that could be unambiguously ascribed to either the Slichter triplet (short-period translation of the inner core) or to fluid core modes of the types known as inertial waves or internal gravity modes. SG data has, however, been effective in improving knowledge of some seismic modes such as ${}_0S_0$, ${}_2S_1$, and ${}_0S_2$ that contribute information about the core. In this paper we review all the above candidate core oscillations against the practical difficulties of their excitation and detection.

Title: Theoretical Description and Excitation of the Translational and Rotational Normal Modes of the Inner Core

Presenter/First Author: Yves J G Rogister, EOST École et Observatoire des Sciences de la Terre, Strasbourg,

Presenter/First Author Email: Yves.Rogister@unistra.fr

Co-authors: Severine Rosat, IPGS-EOST, Strasbourg, France; Bernard Valette, , ,

Published Material: Parts of the results were reported inRogister Y., Valette B. (2009): Influence of liquid core dynamics on rotational modes, Geophysical Journal International, 176, 368-388Rosat S., Boy J.-P., Rogister Y. (2014): Surface atmospheric pressure excitation of the translational mode of the inner core, Physics of the Earth and planetary Interiors, 227, 55-60.

Abstract Body: The Free Inner Core Nutation (FICN), Inner Core Wobble (ICW) and the Slichter modes are the rotational and the translational normal modes of the solid inner core. For realistic Earth models, their periods in a reference frame co-rotating with the Earth range from a few hours for the Slichter modes to a few years for the ICW. We investigate the influence of the structure and dynamics of an inviscid liquid outer core on the rotational modes through the squared Brunt-Va\"\i s\"al\"a frequency N^2, the frequencies of the rotational modes being embedded into the continuous spectrum of inertia-gravity modes, which is governed in the complex domain by N^2 and the Earth's rotation speed. We show interactions between pseudo-modes of the liquid core and the FICN. By considering a very simple Earth model, we show that the dynamics of a neutrally stratified outer core may generate a family of ICWs with periods ranging from a few dozens to thousands of days. As for the Slichter modes, we investigate the efficiency of various excitation sources, such as atmospheric pressure variations, collision of the Earth with a meteoroid, and pressure variations at the outer core boundaries, to generate surface gravity variations above the detection limit by superconducting gravimeters. We show that pressure variations at the core boundaries, with time-scales shorter than the Slichter eigenperiods, provide the most efficient excitation process.

Title: A synthetic model analysis of MT distortion parameters for anisotropic and inhomogeneous media

Presenter/First Author: Pavankumar Gayatri, Institute of Seismological Research, Gandhinagar,

Presenter/First Author Email: gayatri_pavan1982@yahoo.co.in

Co-authors: Yashavant Singh, Institute of Seismological Research, Gandhinagar, India; Mahender E, Institute of Seismological Research, Gandhinagar, India; Damodar K, Institute of Seismological Research, Gandhinagar, India; Ajay Manglik, National Geophysical Research Institute, Hyderabad, India

Abstract Body: Anisotropy in the lower crust and upper mantle has been inferred from various geophysical studies highlighting the significance of anisotropic modelling in geophysical data interpretation. Analysis of MT data for a 2-D medium in the presence of anisotropy is complex as the impedance tensor may not decouple into two polarization modes. Here, we present the results of a study comprising of two synthetic models, one having electrical anisotropy and the other constituted of inhomogeneous block structure. We have computed impedance tensors in the frequency range of 100Hz-10000s for these two models by using an algorithm [*Pek and Verner, GJI, 1997]* for 2-D modelling of anisotropic media. The apparent resistivity and phase curves show splitting for both models. However, the splitting occurs at the interface between the overlying isotropic and the underlying anisotropic block for the anisotropic model whereas the splitting is observed at the top and the bottom of the inhomogeneous block for the inhomogeneous model. The magnitude of splitting depends on the anisotropy ratio and the resistivity contrast of the anisotropic and inhomogeneous blocks from the overlying medium. The phase tensor (PT) analysis of the impedance tensors suggests the non-zero skew angles, representing the asymmetry in the medium along with deviation of the major axis from the regional strike of the body. Study of ellipticities of the telluric vectors (ETV) implies the non-zero ellipticities within the period band of the anisotropic block and splitting in the telluric distortion angle curve, similar to the impedance phase. In case of inhomogeneous medium, the PT-skew angle, ellipticities and distortion angles are zero. Direct proportionality relation between the PT-skew angle and the distortion angle is inferred from the present study.

Title: Tidal Friction: a New Absorption Mechanism at the Sea-Subsea Interface

Presenter/First Author: Pierre Michel Rouleau, Memorial University of Newfoundland Grenfell, Corner Brook, NL

Presenter/First Author Email: prouleau@grenfell.mun.ca

Abstract Body: As the Earth-Ocean system rotates within the lunisolar gravitational field, its figure nominally deforms into prolate ellipsoidal extensions – the tides - over slight but finite time intervals. The delayed response for the principal semidiurnal lunar tide is well-constrained by satellite tracking and altimetry; the associated phase lag is a manifestation of tidal friction which, conventionally, is attributed in a large part to turbulent drag in shallow seas and, in a much lesser yet significant part, to anelasticity of the lithosphere-asthenosphere. Although the combined effect has well-known consequences, e.g. the lengthening of the day and an increasing Earth-Moon distance, the details of the friction mechanisms by which tidal energy dissipates remain uncertain. In particular, little attention has been paid to the energy losses that occur within the synchronously deforming permeable boundary layer that constitutes the interface between sea water and subsea rock formations. Here, I elaborate an absorption mechanism by which tidal-loading mechanical energy is dissipated via viscous flow of periodically squeezed ultra-thin water-films that are confined to rough-wall natural fractures. Based on the theory of linear viscoelasticity, the absorption is quantified by a frequency-dependent dissipation factor, Q^{-1}, along with its corresponding phase lag, δ. Q^{-1} and δ values are first calculated within the framework of micro-mechanics at the nanoscopic scale, then scaled up to the mesoscopic dimensions of subsea rock formations that are fractured. The results show strong absorption within the semi-diurnal tidal band, peaking round the principal lunar constituent M_2. Very high Q^{-1} values and significant phase lags occur in shallow seas, especially in coastal areas where the marine tides undergo resonance. The tidal energy dissipation contributed via this “squeeze-nanoflow” mechanism is compared with the contributions of other mechanisms thought to operate either in the ocean proper or in the solid Earth proper.

Title: River-to-Wetland Surface Water Connectivity in a Cold Region Deltaic Ecosystem

Presenter/First Author: Daniel L Peters, Environment Canada, Victoria, BC

Presenter/First Author Email: daniel.peters@ec.gc.ca

Co-authors: Olaf Niemann, University of Victoria, Victoria, Canada; Donald J Baird, Enivironment Canada @ Canadian Rivers Institute, University of New Brunswick, Fredericton, NB, Canada

Abstract Body: The Peace-Athabasca Delta (PAD) is a deltaic lake/wetland ecosystem of international importance (Ramsar & World Heritage site). This 6000 km^2, low-relief delta, which formed at the confluence of the Peace, Athabasca and Birch rivers, contains more than 1000 lake/wetland basins with varying degrees of connectivity to the main flow system. Wetland hydroperiod is influenced by occasional ice-jam and open-water inundations that recharge the basins. Prior studies have identified pathways of river-to-wetland floodwater connection as a key knowledge gap, limiting our knowledge of deltaic ecosystem status. To address this gap, surface elevation mapping of approximately 1000 km^2 of the PAD was conducted during the summers of 2012 and 2013 using aerial remote sensing LiDAR. The surveyed areas contain 12 critical wetland monitoring sites where ground-based water level/depth, water quality, and aquatic ecology have been monitored for the past three years. The goal of this presentation is to present our assessment of surface water connectivity for select PAD wetland sites and outline an approach to integrate this newly available physical information into a novel aquatic ecosystem observation system for cold regions deltaic wetlands.

Title: Real-time measurements of CO_2 and d^{13}C in volcanic gases on Mt. Etna (Italy)

Presenter/First Author: H.J. Hansjuerg Jost, Thermo Fisher Scientific, Hilterfingen,

Presenter/First Author Email: hj.jost@thermofisher.com

Co-authors: Andrea Luca Rizzo, National Institute of Geophysics and Volcanology, Rome, Italy; Marie-Anne Ancellin, Ecole Nazionale Superieure de Geologie, Vandouvre Les Nancy Cedex, France; Antonio Caracausi, National Institute of Geophysics and Volcanology, Rome, Italy; Peter Stow, Thermo Scientific, , ; Marcello Liotta, Seconda Università degli Studi di Napoli, Caserta, Italy; Marco Liuzzo, Istituto Nazionale di Geofisica e Vulcanologia, Palermo, Italy; Mauro Martelli, National Institute of Geophysics and Volcanology, Rome, Italy; Antonio Paonita, , ,

Published Material: We presented some of this material at the AGU 2014 Fall Meeting

Abstract Body: We present unprecedented data of real-time measurements of concentration and isotope (d^{13}C) composition of CO_2 in fumarolic and plume gases acquired in 2013 and 2014 at Mt. Etna volcano by a laser based Isotope Ratio Infrared Spectrometer (IRIS). We performed about 360 measurements/hour that allowed to extrapolate the d^{13}C of volcanic CO_2. The calculated d^{13}C of Torre del Filosofo (TDF) fumaroles (2,900 m a.s.l.) result between -3.2±0.06‰ and -3.7±0.09‰, comparable to Isotope Ratio Mass Spectrometry (IRMS) measurements of discrete samples collected on the same date. Plume gases collected at more than 1 km from the craters show an extrapolated d^{13}C from -2.2‰ to +1.4‰, partially overlapping crater fumaroles analyzed by IRMS. We also compared Laser with MultiGAS technique in order to evaluate possible relations between d^{13}C and CO_2/SO_2 variations. This approach may represent an important step forward for volcanic monitoring.

Title: Laser-based exploration of underwater hydrothermal vents: a multi-sensor payload proof of concept

Presenter/First Author: Pablo Sobron, SETI Institute Mountain View, Mountain View, CA

Presenter/First Author Email: psobron@seti.org

Co-authors: Laura M Barge, Jet Propulsion Laboratory, Pasadena, CA; Anupam K Misra, Hawai'i Institute of Geophysics and Planetology, Honolulu, HI; Tayro Acosta-Maeda, Hawai'i Institute of Geophysics and Planetology, Honolulu, HI; Michael J Russell, Jet Propulsion Laboratory, Pasadena, CA; Ken Takai, JAMSTEC, Yokosuka, Japan

Published Material: Partial results (<25%) were presented at the GeoRaman conference in 2014.

Abstract Body: Underwater hydrothermal systems (UHS) are produced by volcanic activity (e.g. black smokers) or directly by water-rock reactions (e.g. serpentinization and production of alkaline vents). Either way, commercially valuable seafloor metallic minerals precipitate from hydrothermal fluid as it interacts with the cooler ambient seawater at or beneath the seafloor, and a new industry is emerging: underwater mining. Since the hydrothermal fluids and mineral precipitates that form in a particular vent are highly specific to the geological setting, new instruments and adaptive exploration concepts that are conducive to analyzing a variety of vent conditions are needed in order to characterize seafloor mineral deposits. In response, we have developed an innovative concept for a robotic payload for UHS exploration. It utilizes high resolution 3D mapping and synergistic laser Raman and laser-induced breakdown spectroscopy (LRS+LIBS) to perform integrated, context-preserving, stand-off, in-situ characterizations of vent fluids and mineral precipitates.

In this work we describe an early-stage prototype and discuss a proof-of-concept demonstration of our payload. The samples are mineral precipitates from the chimney wall of a deep-sea black smoker at the mid-Okinawa Trough. We simulate underwater operation by immersing solid samples in a seawater tank and measuring LRS+LIBS from the outside of the tank. The microimages and the LRS and LIBS spectra show features consistent with sulfides, mainly chalcopyrite, a common metal sulfide mineral in acidic hydrothermal systems. The data obtained so far (1) demonstrate the feasibility of using LRS+LIBS for identifying minerals in black smoker precipitates in-situ and in near real time, and (2) help guide the definition of top-level instrument requirements, concepts of operation, and measurement strategies for the in-situ exploration of UHS in the deep-sea using laser-based robotic payloads.

Title: Conditional Random Field for per-line classification of laser point clouds

Presenter/First Author: Gunho Sohn, York University, Toronto, ON

Presenter/First Author Email: gsohn@yorku.ca

Co-authors: Chao Luo, , ,

Published Material: A main findings of this presentation was presented at Photgotammetic Computer Vision Symposium in 2015 and published in ISPRS Annals of the Photogrammetry, Remote Sensing and Spatial Information, II(3):79-86. The presentation will extend it to enabling the proposed Conditional Random Field (CRF) to classify laser point clouds not only in along scannding direction, but also across scanning direction as well. Also, the presentation will demonstrate its application of both static and mobile laser scanning data.

Abstract Body: In recently years, laser scanner rapidly becomes a primary acquisition tool due to its fast acquisition of massive three-dimensional point clouds. For fully utilizing its benefits, developing a robust method to classify many objects of interests from laser point clouds is urgently required. Conditional Random Field (CRF) is a well-known discriminative classifier, which integrates local appearance of the observation with spatial interactions among its neighbouring points in classification process. Typical CRFs employ generic label consistency using short-range dependency only, which often causes locality problem. In this paper, we present a multi-range and asymmetric Conditional Random Field (CRF) (maCRF), which adopts a priori information of scene-layout compatibility addressing long-range dependency. The proposed CRF constructs two graphical models, one for enhancing a local labelling smoothness within short-range (srCRF) and the other for favouring a global and asymmetric regularity of spatial arrangement between different object classes within long-range (lrCRF). This maCRF classifier assumes two graphical models (srCRF and lrCRF) are independent of each other. Final labelling decision was accomplished by probabilistically combining prediction results obtained from two CRF models. We validated maCRF's performance with TLS point clouds acquired from RIEGL LMS-Z390i scanner using cross validation. Experiment results demonstrate that synergetic classification improvement can be achievable by incorporating two CRF models. The presentation will extend it to enabling the proposed Conditional Random Field (CRF) to classify laser point clouds not only in along scannding direction, but also across scanning direction as well. Also, the presentation will demonstrate its application of both static and mobile laser scanning data.

Title: Stand-off detection and mapping of mineral and organic compounds using ultraviolet Raman spectroscopy

Presenter/First Author: Evan Eshelman, York University, Toronto, ON

Presenter/First Author Email: eshelman@yorku.ca

Co-authors: Michael G Daly, York University, Toronto, ON, Canada; Greg Slater, McMaster University, Hamilton, ON, Canada; Peter Dietrich, MacDonald, Dettwiler and Associates Ltd., Richmond, BC, Canada; Jean-Francois Gravel, Institut national d'optique, Quebec, QC, Canada; Edward Cloutis, University of Winnipeg, Winnipeg, MB, Canada

Published Material: A paper discussing the instrumentation used in this work was published in Planetary and Space Science in 2014:Eshelman, E., Daly, M.G., Slater, G., Dietrich, P., Gravel, J.-F. An ultraviolet Raman wavelength for the in-situ analysis of organic compounds relevant to astrobiology(2014) Planetary and Space Science, 93-94, pp. 65-70.Some of the 2D mapping results on unprepared samples were presented at the Fall 2014 AGU conference in San Francisco:P21D-3955 Analysis of In-Situ Organic and Mineral Compounds Relevant to Martian Astrobiology Using 266 nm Raman Spectroscopy. Evan Eshelman, Michael G Daly, Greg Slater, Peter Dietrich, Jean-Francois Gravel and Edward Cloutis

Abstract Body: Developments in ultraviolet lasers and imaging systems have resulted in the potential for a stand-off ultraviolet Raman instrument that is capable of detecting and identifying low concentrations of mineral and organic compounds in-situ in either terrestrial or planetary settings. An ultraviolet wavelength offers several advantages over visual or infrared excitations, including reduced fluorescence in the Raman window, improved sensitivity due to the increased Raman cross section, and resonance with some organics. A sub-nanosecond laser pulse permits gating of the detector to reject fluorescence, and using an intensified CCD can increase the Raman signal to noise ratio. We present a Raman instrument with an excitation wavelength of 266 nm intended for the detection of organic compounds on Mars, and demonstrate the potential of an ultraviolet Raman system for performing spatial mapping of mineral and organic compounds on a millimeter to centimeter scale. We demonstrate the ability to perform this mapping on a suite of unprepared sedimentary samples containing endoliths from the Canadian Arctic and the Atacama Desert, and show that uneven topography and impurity of the sample do not prevent the ability to obtain spatial maps of the primary mineral and organic components. An ultraviolet Raman instrument such as the one presented is a valuable tool for definitive identification of organics and for determining mineralogy rapidly and non-destructively on unprepared samples in the field or on planetary surfaces. This research was carried out at the Planetary Instrumentation Laboratory at York University, and supported in part by both the Canadian Space Agency (CSA) and by the Natural Sciences and Engineering Research Council of Canada (NSERC).

Title: Unfolding 3D Images of Underground Mining Tunnels

Presenter/First Author: PoKong Lai, University of Ottawa, Ottawa,

Presenter/First Author Email: plai036@uottawa.ca

Co-authors: Claire Samson, Carleton University, Ottowa, ON, Canada

Abstract Body: Laser imaging of underground tunnels is increasingly used in mining engineering practice. Using the point cloud output of the laser sensor, a three-dimensional (3D) triangular mesh model can be generated. While laser technology has allowed the topology of rock faces to be captured in unprecedented details, 3D mesh models are typically very large and difficult to manipulate which makes the inspection of the results laborious.

We present two different methodologies which "unfold" a 3D mesh model of undeground mining tunnels so that it can be viewed as one connected two-dimensional (2D) drawing. We first examined traditional surface parameterization algorithms, which are often used by artists in computer graphics, to convert an artibary 3D mesh model into a 2D drawing. We found that while these methods were automatic and could provide 2D drawings which have minimal metric distortion (ie: ensuring that area and angles in 3D are conserved in 2D), they are generally not intuitive to interpret. We then explored mesh deformation methods, often used in computer animation, to reshape the 3D mesh to resemble a 3D plane before applying an orthographic projection to produce a 2D drawing. We found that while these methods required user interaction, and introduced a greater amount of metric distortion, they resulted in more intuitive 2D drawings.

To discuss the relative merit of these two methodologies, a large underground mining tunnel was imaged by a laser camera system and a 8.2m wide by 41m long by 6.7m high subsection was selected for analysis. The metric distortion produced by both methodologies was measured and will be presented along with the output 2D drawings.

Title: Utilization of LIDAR for Geomorphological Analysis of Periglacial Features

Presenter/First Author: Taylor Haid, University of Western Ontario, London,

Presenter/First Author Email: thaid2@uwo.ca

Co-authors: Gordon Richard Osinski, University of Western Ontario, London, ON, Canada

Abstract Body: Periglacial features such as polygonal terrain and gullies are common in polar environments of both Earth and Mars. The ability to accurately analyze and measure these features is crucial to understanding the geomorphological processes that shaped that environment. Historically, often the only way to analyze these landscapes was with traditional ground-based or aerial photography. The emergence of LIDAR scans to analyze terrains has led to multiple advancements over traditional photography, including independence from ambient lighting and the ability to record 3D data of the site at multiple angles and viewpoints. Geomorphological changes and features can then be identified and measured at a later date.

Field tests were carried out at the Haughton impact structure located on Devon Island in the Canadian Arctic in 2008, which included multiple LIDAR panoramic scans of polygonal terrain, gullies, and slump features. These point clouds were reanalyzed and incorporated into ArcGIS for analysis and measurement of these periglacial features. A case study was conducted on the polygonal terrain, with analysis of 30 polygons. Polygon perimeters range from 49 to 180 m, with an average perimeter of 96.7 m. Area of the polygons were also calculated, ranging between 129 and 1937 m^2, having an average area of 601 m^2. It was found that the ability to view these features from multiple viewpoints led to the ability to measure features that could not be measured in traditional photographs. Future scans of the same locations could be undertaken to identify changes over time.

The sensitivity of LIDAR to low angle topography makes it an excellent tool for analysis of periglacial features such as polygonal terrain and slump features. Due to the commonality of these features on Earth with those on Mars, we propose that the superiority of LIDAR over traditional photographs for geomorphological analysis makes a strong case for a LIDAR instrument to be included on a future Mars Polar Mission.

Title: Multisensor Data Fusion to Characterize Evolving Wetland Environments: An example from the Peace Delta

Presenter/First Author: Olaf Niemann, University of Victoria, Victoria,

Presenter/First Author Email: olaf@uvic.ca

Co-authors: Daniel L Peters, Environment Canada, Victoria, BC, Canada; Donald J Baird, Enivironment Canada @ Canadian Rivers Institute, University of New Brunswick, Fredericton, NB, Canada; Roger Stephen, , , ; Fabio Visintini, , , ; Geoff Quinn, , , ; Diana Parton, , , ; Rob Skelly, , ,

Abstract Body: Wetland environments represent an early warning system for changing climates. Changes in flooding regimes of these wetlands, both in terms of timing and duration, can result from both natural and anthropogenic sources, however the results are the same. Wetlands comprise vegetation assemblages that occupy transitional zones between aquatic and upland environments. As such they are particularly sensitive to changes in hydrological regimes and moisture available for evapotranspiration that are reflective of changes to plant functional types and ecosystem services. This translates to changes to both the vegetation type as well as the morphology. The Peace Delta in northern Alberta represents one such wetland environment where, historically, frequent ice-jam induced flooding has resulted in a unique distribution of vegetation stand structures. Changes in the flow regime can result in changes to the frequency of flooding events. These changes in frequency have also resulted in changes to the vegetation structure and ecosystem services provided. Integrated field observations of historic flood levels and a high resolution airborne remote sensing data collection provides us with the opportunity to examine the vegetation structure within the context of historic flood patterns.

This presentation will describe the application of airborne multisensor (LiDAR and hyperspectral) data collected over the Peace Delta, and the application of these data to wetlands characterization. An area west of Fort Chipewyan covering approximately 300 square kilometres was flown in late August 2012. The sensor payload included a discrete multiple return scanning laser, a small imaging spectrometer (VNIR), and an RGB camera. We used the LiDAR digital elevation model (DEM) to derive a suite of terrain metrics. The vegetation point cloud was processed to correspond to the same grid resolution and extent as the upscaled terrain metrics, and a set of structural metrics biometrics were derived. Hyperspecral data were used to determine species.

This presentation will provide an oversight of the results of the analysis of the vegetation structure as represented by the annual flood levels and related it to changes in the flow regimes of the Peace River.

Title: Defining the Iapetan Rifted Margin of Laurentia

Presenter/First Author: William A Thomas, Geological Survey of Alabama, Tuscaloosa, AL

Presenter/First Author Email: geowat@uky.edu

Published Material: Part of this presentation is a historical review of previously published interpretations, in keeping with the title of the session.

Abstract Body: The first interpretations of the Iapetan rifted margin of Laurentia explained curved salients and recesses of the Paleozoic Appalachian-Ouachita thrust belt as inherited from the shapes of embayments and promontories, respectively, of the late Proterozoic–Cambrian rifted margin. Contrasting interpretations attributed the shape of the rifted margin (1) to transform offsets of the rift or (2) to three-armed radial-rift triple junctions. Neither initially considered palinspastic location of the rifted margin, which is complicated because parts of the rifted margin are translated in Appalachian allochthons, whereas other Appalachian-Ouachita allochthons carried off-shelf sedimentary rocks onto the passive-margin shelf, leaving the rift margin in the footwall. Retrodeformed balanced cross sections (from outcrop geology, drill data, and seismic reflection profiles) support quantitative reconstruction of palinspastic locations of external basement massifs, synrift sedimentary and igneous rocks, passive-margin shelf carbonates and shelf-edge facies, and the rifted margin. The palinspastic reconstructions, gravity and velocity models, distribution of synrift sedimentary and igneous rocks, passive-margin thermal subsidence, and load-driven subsidence of synorogenic foreland basins contribute to distinction between upper-plate and lower-plate rift margins and transform margins of continental crust. Ages of synrift igneous rocks indicate two phases of extension (~775–650 and ~615–530 Ma), the significance of which, as well as implications for rifting processes, remains to be resolved. A few segments of the margin (e.g., the New York promontory) require more subsurface data for confident restoration. Documentation of extent and provenance of accreted exotic (generally Gondwanan) continental terranes will constrain the extent of native Laurentian crust. Expression of the rift and transform margins within the mantle lithoshpere may be resolved by EarthScope velocity data.

Title: Shaping of the Appalachian orogen by the breakup of Rodinia and middle-to-late Paleozoic, zippered, transpressional processes: Geologic and geophysical evidence

Presenter/First Author: Robert D Hatcher, University of Tennessee, Knoxville, TN

Presenter/First Author Email: bobmap@utk.edu

Co-authors: J. Wright Horton, , , ; David L. Daniels, , , ; Stephen L. Snyder, , ,

Abstract Body: The Paleozoic Appalachian orogen formed on the Laurentian margin via three orogenies that affected the entire orogen. The Ordovician Taconic orogeny involved arc accretion; the Late Devonian-Early Carboniferous Acadian-Neoacadian orogeny involved accretion of peri-Gondwanan terranes (Gander, Avalon, Meguma); and collison of Gondwana in the Late Carboniferous-Permian Alleghanian orogeny formed supercontinent Pangea. A fourth orogeny, the Late Ordovician to Early Devonian Salinic event, has been documented in the Maritime Appalachians with hints in the central Appalachians. The promontory-embayment shape of the western part of the Appalachian orogen was dictated by the irregular Neoproterozoic margin of Laurentia that formed during supercontinent Rodinia breakup. Much of the Appalachians remain buried beneath sedimentary cover of the Atlantic continental margin, but geologic and geophysical (magnetic and gravity) data locate tectonic boundaries and provide insights into terrane and pluton compositions. These data reveal that the interior (eastern and southern) parts of the orogen were shaped by middle-to-late Paleozoic accretionary-collisional transpressional, rotational processes (zippered), and that peri-Gondwanan terranes make up at least half of the orogen. Middle and late Paleozoic events were dominated by dextral strike-slip as Gondwana collided with Laurentia forming Pangea. Pangea breakup left the Suwanee terrane as a Gondwana remnant. Appalachian structure is truncated to the east by the East Coast magnetic anomaly, which may mark the original suture with Gondwana reactivated as the boundary of Pangea breakup. Despite the dominance of early (north) and late (southern-central) Paleozoic thrusting on the western margin of the Appalachians, strike-slip processes dominate interior parts of the orogen, and non-Laurentian, exotic terranes make up more than half of the orogen.

Title: Evolution of the Tyrone arc system during the Grampian (=Taconic) orogeny: field, geochemical, geochronological and isotope (Nd, Sr) constraints

Presenter/First Author: Steven Philip Hollis, CSIRO Earth Science and Resource Engineering Perth, Perth, WA

Presenter/First Author Email: steven.hollis@csiro.au

Co-authors: Mark Cooper, Geological Survey of Northern Ireland, Belfast, United Kingdom; Stephen Roberts, , Southampton, United Kingdom; Richard Herrington, , , ; Garth Earls, , , ; Daniel James Condon, NERC Isotope Geosciences Laboratory, Keyworth, United Kingdom; J Stephen Daly, University College Dublin, Dublin, Ireland

Published Material: This presentation details our current understanding of the Tyrone Igneous Complex and its role within the Grampian orogen based on recent PhD work by the lead author. The U-Pb zircon age constraints and geochemical data have been published in (Cooper et al. 2008, 2011 - J. Geol Soc, London; Hollis et al. 2012 - GSA Bulletin; Hollis et al. 2013ab - J. Geol Soc, London; Hollis et al. 2014 - Mineralium Deposita). Unpublished data includes new field constraints, whole rock geochemistry, and isotope (Nd, Sr) analyses. Several U-Pb zircon ages are in preparation from key localities across the complex. This work integrates ~350 whole rock geochemical analyses, 19 U-Pb zircon ages (+preliminary, if available), 26 Sr isotope and 55 Nd isotope constraints.

Abstract Body: The Tyrone Igneous Complex of Northern Ireland records the evolution of a relatively short-lived arc system and its accretion to the Laurentian margin during the Grampian orogeny. The ca. 484-479 Ma Tyrone Plutonic Group forms the structurally lowest levels of the complex and preserves a tectonically dissected suprasubduction ophiolite (εNd_t +4.4 to +7.7; $^{87}Sr/^{86}Sr_i$ 0.7039-0.7106), obducted onto an outboard fragment of micro-continental crust (the Tyrone Central Inlier) prior to ca. 470 Ma. The structurally overlying ca. 475-469 Ma arc-related Tyrone Volcanic Group includes mafic to intermediate lavas, tuffs, rhyolite, banded chert, ironstone and argillaceous sedimentary rocks. Geochemical and isotopic signatures are consistent with its formation in an evolving peri-Laurentian island arc/backarc (εNd_t -4.1 to -13.8) that was contaminated by continental crust and underwent several episodes of extension. Rift-related magmatism is characterized by the presence of (i) Fe-Ti rich eMORB (εNd_t +0.6 to +5.9), island-arc tholeiitic basalt (εNd_t +4.8) and FIV-affinity rhyolite breccias in the ca. 474-475 Ma lower Tyrone Volcanic Group; and (ii) OIB (εNd_t +1.3), alkali basalt (εNd_t +2.4) and FIII-affinity rhyolite in the ca. 473-469 Ma upper Tyrone Volcanic Group. Whereas calc-alkaline lavas and tuffs of the Tyrone Volcanic Group have strongly radiogenic $^{87}Sr/^{86}Sr_i$ values (0.7086-0.7212) between Middle Ordovician seawater and Laurentian continental crust, rift-related basalts display lower ratios (0.7055-0.7110) back towards primitive mantle. All units of the Tyrone Igneous Complex are stitched above the Tyrone Central Inlier by a suite of syn- to post-collisional I-type and arc-related intrusive rocks (ca. 470-464 Ma) which contain inherited Proterozoic zircons and have strongly contaminated isotopic signatures (εNd_t -7.1 to -12.2; $^{87}Sr/^{86}Sr_i$ 0.7120-0.7196). Potential correlations across the British and Irish Caledonides will be discussed.

Title: Detrital zircon U-Pb geochronology of the Magog Group, southern Québec Appalachians - tectonic implications.

Presenter/First Author: Morgann Gwenva Perrot, University of Quebec at Montreal, Montreal, QC

Presenter/First Author Email: perrot.morgann@gmail.com

Co-authors: Alain Tremblay, GEOTOP, Montréal, QC, Canada; Jean David, GEOTOP, Montréal, QC, Canada

Abstract Body: In the Southern Quebec Appalachians, the Laurentian continental margin (Humber zone) and adjacent oceanic domain of the Dunnage zone were amalgamated during the Ordovician Taconian orogeny. The Dunnage zone includes ophiolites, overlying synorogenic Ordovician deposits of both the Saint-Daniel Mélange and Magog Group and the remnants of a peri-Laurentian volcanic arc, the Ascot complex.

The Magog Group consists of ~3 km pile of sandstone, felsic volcaniclastic rocks, graphitic slate and sandstone at the base (Frontière, Etchemin and Beauceville formations) overlain by a ~7 km-thick of a turbidites flysch sequence, constituting the St-Victor Formation at the top. The maximum age limit for the Magog Group is currently considered to be Caradocian based on graptolite fauna. This has been proven consistent with a 462 +5/-4 Ma (U-Pb ID-TIMS) from a felsic tuff of the Beauceville Formation, but in obvious contradiction with a detrital zircon U-Pb age of 424 ± 6 Ma recently measured in the St-Victor Formation. A detrital zircon U-Pb geochronology study (LA-HR-ICPMS), focused on the St-Victor Formation, has been therefore initiated in order to better constrain the age and tectonic evolution of the Magog Group. Results were treated according to a Bayesian mixture modeling to highlight different age populations. A feldspar-rich sandstone, directly overlying the Ascot Complex (ca. 460 Ma) and belonging to the base of the St-Victor Formation, yielded ages as young as 431 ± 3 Ma (Wenlockian). Higher in the stratigraphy, a quartz-feldspars sandstone sample contains zircons as young as 419 ±2 Ma (Pridolian). Finally, another sandstone sample from the stratigraphic top of the analyzed sequence yielded a bimodal age distribution, showing prominent populations clustering around ca. 950 Ma and ca. 435 Ma.

These preliminary results suggest a time gap as high as 30 m.y. between the St-Victor Formation and underlying rocks of the lower Magog Group and the Ascot Complex. Combined with current mapping in southern Quebec, this implies the probable occurrence of a major unconformity at the base of the St-Victor, and suggests that a large part of the Magog Group sedimentary sequence has been the result of post-Taconian sedimentation rather than that of a typical forearc sequence as commonly reported in literature.

Title: Recognizing the Cambrian Rheic margin in the Kings Mountain terrane of Carolinia

Presenter/First Author: Allen J Dennis, Univ South Carolina Aiken, Aiken, SC

Presenter/First Author Email: dennis@sc.edu

Published Material: Isotopic data reported at Annual Meeting Geological Society of America, 2012, 2013. Portions of this material presented on Field Trip of Carolina Geological Society, November, 2014. Tectonic model presented at SE Section Geological Society of America, 2015.

Abstract Body: The youngest stratified rocks in Carolinia are within the Blacksburg Formation of the Kings Mountain terrane and the Asbill Pond Formation of the Carolina slate terrane. The 4-5 km thick sedimentary section of the Kings Mountain terrane is interpreted to have been deposited on the lower plate of the rifted Gondwanan Rheic margin, probably adjacent to the Paraguan craton, between 522 – 497 Ma. The Asbill Pond Formation is nominally 1-2 km thick and lies in angular unconformity above the Persimmon Fork and Emory Formations; biostratigraphy of the Asbill Pond Formation indicates it belongs to the *P. atavus* zone (504.5 – 503 Ma) of the Drumian, Series 3, Cambrian. The

Asbill Pond Formation is interpreted to have been deposited on the upper plate rift shoulder of Carolinia. Thus the Kings Mountain terrane and the Asbill Pond Formation are interpreted to been deposited on Carolinian basement on either side of the asymmetric Rheic rift detachment. The present disposition of the Kings Mountain terrane between the Charlotte terrane and the central Piedmont shear zone is an artifact of later terrane dispersal. The Kings Mountain terrane is interpreted to have formed near the North Carolina slate terrane; the epiclastic portion of the Battleground Formation accepted detritus from both the older Hyco-Aaron arc and the younger Uwharrie – Albemarle arc. Additionally the epiclastic section records significant input from Rondonian-San Ignacio (1.55-1.3 Ga) and Sunsas (1.28-0.95 Ga) basement. This interpretation is consistent with 1.551 Ga and 1.229 Ga inheritance reported by Mueller et al (1996) for this part of the North Carolina slate terrane. Above the Jumping Branch Manganiferous Member of the Battleground Formation, the Ediacaran-Cambrian component of the detrital spectrum is lost, and all grains are derived from Amazonian-Paraguan Gondwana. Rheic ridge incision is interpreted to have separated the Kings Mountain terrane from the Gondwanan Paraguan craton.

Title: Provenance of Cape Spear Member conglomerates in the Ediacaran Cuckold Formation, Flatrock area, eastern Newfoundland: Implications for Avalonian paleogeography

Presenter/First Author: Stephen Robert Pearcey, Memorial University of Newfoundland, St. John's,

Presenter/First Author Email: stephen.pearcey@mun.ca

Co-authors: Luke Patrick Beranek, Memorial University of Newfoundland, St. John's, Canada

Abstract Body: Attempts to constrain Avalonia’s position along the Gondwanan margin during the late Neoproterozoic have been a subject of intense debate since it was first recognized that the eastern flank of the Appalachian orogen is composed of exotic terranes. A consensus has been reached that Avalonia was one of several peri-Gondwanan terranes adjacent to the Amazonian or West African cratons, but its precise location is still controversial. To further test the paleoposition of Avalonia, we conducted new field and detrital zircon U-Pb provenance studies of red-bed fluvial strata within the Cape Spear Member of the Ediacaran Cuckold Formation in eastern Newfoundland. The main objective of the study is to identify Amazonian- or West African-derived detrital zircons in the Cape Spear Member in order to advance the long-standing debate about Avalonia’s position along the Gondwanan margin.

Fieldwork and detrital zircon sampling near the community of Flatrock, 20 km north of St. John’s, focused on a 5 m-thick conglomerate section of the Cape Spear Member with “exotic” clasts of pink quartzite, quartz-sericite schist, and other low-grade metamorphic rocks that have no known source. Clast counts were conducted at five separate stratigraphic levels in the conglomerate section (100 counts each). Locally derived volcanic and plutonic rock clasts comprise 95% of the unit, whereas the exotic clasts occur at a 5% level. Four detrital zircon samples were analyzed with laser ablation (LA-ICP-MS) techniques and include cobble-sized clasts of pink quartzite (85 analyses) and feldspathic sandstone (75 analyses) from the exotic section, a whole-rock conglomerate sample from the exotic section containing clasts and sand matrix (76 analyses), and a whole-rock sample of pebbly sandstone collected 10 m below the base of the exotic section (76 analyses). The new U-Pb results will be compared to published detrital zircon reference frames for the peri-Gondwanan terranes and the Amazonian and West African cratons to test sediment source regions and Avalonian paleogeography.

Title: Far-field effects of Silurian-Early Devonian Appalachian/Franklinian orogenesis: a view from the craton

Presenter/First Author: Nicolas Pinet, Geological Survey of Canada Quebec, Quebec,

Presenter/First Author Email: npinet@nrcan.gc.ca

Published Material: An abstract on the same topic has been submitted at the 2015 EGU meeting

Abstract Body: Study of Tethyan orogenic belts indicates that stresses related to plate-interaction affect wide areas, sometimes at considerable distances from mountain fronts. This contrast with eastern and northern North America, where only two regional-scale tectonic features preserved clear evidence of significant Silurian-Early Devonian tectonism: the Hudson Bay Central High (HBCH) and the Boothia uplift/Cornwallis fold belt (BUCF). This contribution makes the hypothesis that intra-plate faulting may contribute to the understanding of Paleozoic plates interaction and geometry by providing a view from the craton on processes that occurred at its margin.

In the Hudson Bay intracratonic basin, the lower part of the sedimentary succession is cut by high-angle faults and overlain by essentially underformed strata. The NNW-trending HBCH is the main structural feature of the basin and extends a minimum length of 500 km. The HBCH includes normal faults characterized by throws up to 500 m that were mainly active during the Silurian - Early Devonian period.

The BUCF is a >700-km long, N-trending feature. In its southern segment (Boothia uplift), it is characterized by an east-dipping reverse fault that puts Precambrian rocks over Paleozoic strata. In its northern segment (Cornwallis fold belt), the Paleozoic succession is involved in open folds and cut by steeply dipping reverse faults. Syn-tectonic sediments constrain the age of structures to the latest Silurian-Early Devonian.

Comparison of the HBCH and BUCF indicates that they are grossly parallel, partly contemporaneous but with different kinematics, suggesting linkages with different segments of the Appalachian/Franklinian orogen. A working hypothesis is proposed in which the HBCH was dynamically linked with the Appalachian orogen located >1400 km to the SE through several grabens. A major change in strike of the developing Franklinian orogen north of the Canadian Arctic islands is proposed and successfully accounts for the orientation and kinematics of the BUCF. In this hypothesis, the nearly perpendicular trends of the BUCF and Franklinian mobile belt were developed in latest Devonian-earliest Carboniferous, well after the formation of the BUCF.

Title: Applications of (U-Th)/He Thermochronology to the St. Lawrence Platform/Humber Zone Sedimentary Basin

Presenter/First Author: Justin Emberley, University of Ottawa, Gatineau,

Presenter/First Author Email: jembe038@uottawa.ca

Co-authors: David A Schneider, University of Ottawa, Ottawa, ON, Canada

Abstract Body: The St. Lawrence Platform and Humber Zone of the W Appalachians has been cited as a potential hydrocarbon reservoir. Previous vitrinite reflectance studies on the basin determined the degree of thermal maturation yet the timing of the thermal events is not well understood. Through the application of apatite and zircon (U-Th)/He thermochronmetry it is possible to resolve the time/temperature events, as a consequence of burial and exhumation, through a 60-180°C window. Late Cambrian to Late Ordovician siliciclastic samples were collected from exposed outcrops along three parallel transects that extend through the St. Lawrence Platform into the Humber zone. From each sample, 5 apatites and 10 zircons were selected for analysis. Samples collected from the autochthonous platform have not been affected by tectonic burial or displacement during the formation of the Appalachians; thermal maturation is directly proportional to depth of burial by sedimentation and thus stratigraphic age. These sub-horizontal sequences typically have a low degree of thermal maturation (1.0< R_o >2.0) with an increase to the SW, along the long axis of the basin, and to the SE. Moderate subsidence in the SW, due to increasing distance from the rigid basement of the Shield, and a new cycle of sedimentation after the Taconic Orogeny is a likely cause for the increase in maturation. Timing of exhumation that occurred after the formation of the fold belt and renewed sedimentation of the Taconic Orogeny, will be resolved by AHe and ZHe cooling ages. Samples collected east of Logan's Line in the allochthonous Humber Zone, deposited during the Early to Middle Paleozoic, have been tectonically displaced during the Taconic Orogeny. Maturation increases from R_o:1.0 in the northwest to R_o > 4.0 in the southeast, primarily due to synorogenic heating as tectonic overburden increases. New AHe and ZHe data will provide constraints on the timing of low temperature tectonism defined by exhumation of the Taconian.

Title: Rift Flank Uplift and Thermal Evolution of an Intracratonic Rift Basin (Eastern Canada) Determined by Combined Apatite and Zircon (U-Th)/He Thermochronology

Presenter/First Author: Rebecca Hardie, University of Ottawa, Ottawa,

Presenter/First Author Email: rhard006@uottawa.ca

Co-authors: David A Schneider, University of Ottawa, Ottawa, ON, Canada; James R Metcalf, University of Colorado - Boulder, Boulder, CO; Rebecca Marie Flowers, Univ of Colorado, Boulder, Boulder, CO

Abstract Body: As a significant portion of the world's oil reserves are retrieved from rift systems, a better understanding of the timing of thermal evolution and burial history of these systems will increase the potential for the discovery of hydrocarbon-bearing rifts. The Ottawa Embayment of the St. Lawrence Platform is a reactivated intracratonic rift basin related to the opening of the Iapetus Ocean at ca. 620-570 Ma, followed by the formation of the well-developed continental passive margin. Siliciclastic sediments derived from the adjacent uplifted Neoproterozoic Grenville basement provide the basin fill material. Apatite and zircon (U-Th)/He thermochronology allows for low-temperature analysis across the exposed crystalline rift flank into the synrift sedimentary sequence to resolve the unroofing, burial and subsidence history of the region. Samples were collected along a ~250 km NE-SW transect, oblique to the axis of the rift, from Mont-Tremblant, Québec (~900 m) to the central axis of the Paleozoic rift in the Southern Ontario Lowlands (~300 m). Targets included Neoproterozoic metamorphic rocks of the Grenville Province along the rift flank and basinal Cambro-Ordovician Potsdam Group. Samples from the rift flank yield zircon ages from ca. 650 Ma to ca. 560 Ma and apatite ages from ca. 290 Ma to ca. 190 Ma, with a weak positive correlation between age and grain size. By incorporating (U-Th)/He ages with regional constraints in the thermal modelling program HeFTy, viable temperature time paths for the region can be determined. Through inverse and forward modeling, preliminary rift flank (U-Th)/He ages correspond to post-Grenville cooling with < 4 km of post-Carboniferous burial. The data define slow and long episodes of syn- to post-rift cooling with rates between 0.4 and 0.1 °C/Ma. (U-Th)/He dating of samples along the full-length of the transect will resolve thermal changes in the basin-orogen system and improve our understanding of the rift related history of the region.

Title: Revised Geological and Tectonic Map of the Quebec Appalachians (Southern Sheet) : Lower St. Lawrence and Estrie-Beauce Areas, Canada.

Presenter/First Author: Alain Tremblay, GEOTOP, Montréal, QC

Presenter/First Author Email: tremblay.a@uqam.ca

Co-authors: Morgann Gwenva Perrot, University of Quebec at Montreal, Montreal, QC, Canada; Stéphane de Souza, , , ; Robert Thériault, , ,

Abstract Body: The Quebec Appalachians comprise three major lithotectonic assemblages : the Cambrian–Ordovician Humber and Dunnage zones, and the Upper Ordovician-Middle Devonian cover sequence of the Gaspé Belt. The Humber and Dunnage zones are remnants of Laurentia and adjacent oceanic domain, respectively, and were amalgamated during the Ordovician Taconic orogeny. Together with the Gaspé Belt, these rocks were variably deformed and metamorphosed during the Devonian Acadian orogeny. Since the last two decades, targeted mapping and structural analysis, combined with U-Pb and $^{40}Ar/^{39}Ar$ analyses of selected magmatic and metamorphic rocks, have been critical to constrain the tectonic evolution of the Quebec Appalachians. Since 2010, an extensive program of geological compilation at the 1 : 50,000 map scale has been inititated in collaboration with the *Ministère de l'Énergie et des Ressources naturelles-Québec*. This contribution presents the 1 : 300,000 scale geological map and cross-sections that resulted from compilation and structural re-interpretation. The map covers a surface area of approximately 36,000 km^2. The Humber zone is represented as a fold-and-thrust belt, subdivided into a very low-grade external zone and an upper greenschist to amphibolite facies internal zone. To the SE, it is bounded by the Baie Verte-Brompton Line (BBL), a «late» and composite fault zone that bears components of normal and strike-slip faulting. The Dunnage zone is exposed to the SE of the BBL. It includes a (1) series of well-preserved to dismembered ophiolite massifs, (2) the Saint-Daniel Mélange, (3) the Magog Group, and (4) the Ascot Complex. The Gaspé Belt occurs in a series of synformal outliers in the Dunnage and Humber zones, and, to the SE of the La Guadeloupe fault, occupies the Connecticut Valley–Gaspé trough where it is represented by siliciclastic and volcanic rocks of the Saint-Francis Group and the Frontenac Formation. The revised structural interpretation shown in the map and sections involves the SE-directed tectonic transport of the Taconian crustal wedge of the Humber and Dunnage zones, followed by normal faulting and juxtaposition of the internal Humber zone and Dunnage zone rocks along the BBL-Saint-Joseph fault zone, and the formation of fault-bounded sedimentary basins, such as the Connecticut Valley–Gaspé trough.

Title: A Viable Thermochronometer for Carbonate-Dominated basins? Results of Conodont (U-Th)/He Thermochronology of Anticosti Basin, Eastern Canada

Presenter/First Author: Jeremy Powell, University of Ottawa, Ottawa, ON

Presenter/First Author Email: jpowe068@uottawa.ca

Co-authors: David A Schneider, University of Ottawa, Ottawa, ON, Canada; Rebecca Marie Flowers, Univ of Colorado, Boulder, Boulder, CO; James R Metcalf, University of Colorado - Boulder, Boulder, CO; Daniel F Stockli, University of Texas, Austin, TX

Published Material: We presented preliminary data at Thermo2014, the international thermochronology conference, and GSA2014. We've added conodont data to that dataset and have new apatite fission track data from the basement that also pertain to the geologic history of Anticosti Island and the St Lawrence Platform throughout.While some of the data is similar to the previous presentations, the work has matured significantly.None of these data have been published in a journal or are yet under review for a publication.

Abstract Body: Apatite and zircon (U-Th)/He thermochronometry (AHe, ZHe) have become increasingly popular in sedimentary basin analysis due to advances in our understanding of thermally controlled diffusion of radiogenic helium. In particular, the AHe system is sensitive to temperatures that correspond to the onset of oil generation, and can provide accurate estimates to the thickness of eroded sedimentary columns. Unfortunately, these methods are of limited use in regions dominated by carbonate sedimentary rocks, as the accessory minerals required for the analyses are not common in the strata. An initial investigation suggested that the chemistry of, and He diffusion in, conodonts is kinetically similar to igneous apatite. Our study resolves to do a first-of-its-kind empirical investigation into the effects of temperature on conodont (U-Th)/He age, sampling a vertical profile in the subsurface of the Lower Paleozoic Anticosti Basin, Eastern Canada. In this study, ten samples were collected from two different boreholes. While sampling primarily targeted conodont-rich lithologies, material for AHe and ZHe thermochronology was also collected where available. Analyses of the crystalline basement (1700 m depth) yield a mean AHe age of 29 ± 2 Ma whereas the Ordovician Mingan sandstone (1520 m depth) record AHe ages between 64-40 Ma. These data, along with apatite fission track analysis and organic thermal maturity parameters are integrated to constrain potential thermal histories for each well. Preliminary conodont (U-Th)/He ages exhibit significant scatter: a few ages (78-26 Ma) are in accord with our existing borehole AHe data. Other age populations (113-97 Ma; 291-195 Ma) are likely associated with partial resetting during the model-derived heating events in the basin. Interestingly, several conodonts yielded ages between 464-425 Ma and have not experienced significant post-depositional He loss. Experiments to assess relationships between the observed age scatter and conodont morphology, structure and chemistry are ongoing. While conodont thermochronometry has great potential, more work is required to understand the complexities of this system.

Abstract Body: Metamorphic soles found at the base of obducted ophiolites provide valuable information on the early history of subduction / obduction systems. Metamorphic soles are characterised by rocks originating from the ocean floor (basalts and sediments in variable proportions) metamorphosed up to granulite facies, where the intensity of metamorphism increases to the top of the unit, towards the contact with peridotite. Their mafic and less frequently pelitic lithologies make them sensitive recorders of their pressure-temperature conditions of crystallization and allow radiometric dating. In addition, metamorphic soles have directly witnessed slab dehydration as they underwent similar fluid-producing metamorphic reactions before being accreted to the mantle wedge peridotites (i.e. before “underplating”). The mechanisms of underplating remain uncertain, because of the somewhat obscure link between weakening through fluid production and hardening via garnet crystallization, with direct consequences on the rheology of the plate interface.

In this study, we document metamorphic reactions occurring during the prograde history of the metamorphic sole of the Taconian (ca. 460 Ma) ophiolite from Mont Albert (Quebec, Canada). This metamorphic sole shows variably metamorphosed mafic and pelitic rocks with metamorphic gradients over the scale of 10 metres, with clinopyroxene-garnet-amphibole granulite facies mafic rocks at the contact with the overlying peridotites. Evidences of melting of pelitic lithologies increase towards the contact, and no remains of metapelites have been found within about 20 m from the contact. Fluid channelization and melt migration is evidenced by decimetric dykes and veins. Away from the contact, metamorphism intensity gradually decreases to greenschist facies with abundant hydrated silicates. The aim of the study is to provide constraints (i) on the pressure-temperature conditions of crystallization of observed mineral assemblages, (ii) on the nature of the fluids produced during prograde metamorphism (aqueous versus melt), and (iii) on the composition of these fluids. This will allow a better understanding of the rheological behaviour of subducting slabs in subduction zones and of amphibolites in the lower continental crust.

Title: New Constraints on Cambrian Stratigraphy and Correlations in Avalonia Based on Acritarchs in Atlantic Canada

Presenter: Soren Jensen, Universidad de Extremadura, Badajoz,

Presenter Email: broom62@gmail.com

First Author: Sandra M Barr, Acadia University, Wolfville, NS

First Author Email: sandra.barr@acadiau.ca

First Author Student?: No

Co-authors: Teodoro Palacios, , , ; Chris White, Department of Natural Resources, Halifax, Canada

Abstract Body: Cambrian sedimentary rocks of Avalonian Nova Scotia (NS), New Brunswick (NB), and Newfoundland (NL) contain generally well preserved acritarchs recovered from the majority of sampled levels. The data provide considerable additional age constraints for the largely siliciclastic successions. The recovery of characteristic acritarchs that are also found in Baltica and other regions offers new possibilities for correlation, especially important for the scarcely fossiliferous Lower Cambrian. Acritarchs of the *Asteridium-Comasphaeridium* Zone, which on Baltica has been suggested to have a first appearance that approximates the base of the Cambrian, have been recovered from the lower part of the Ratcliffe Brook Formation (NB), the MacCodrum Formation (NS), and the Random Formation (NL). The Chapel Island Formation (NL) is dominated by leiosphaerids and *Granomarginata*, also possibly best assigned to the *Asteridium-Comasphaeridum* Zone. Acritarchs of the *Skiagia-Fimbriaglomerella* Zone, which on Baltica has been taken to approximate, or somewhat precede, the first global appearance of trilobites, has been recovered from the upper part of the Ratcliffe Brook Formation, close to the top of the Random Formation (NL), and from the Canoe Brook Formation (NS). In NB the late Early Cambrian *Heliosphaeridium-Skiagia* Zone has been identified from the top part of the Ratcliffe Brook Formation and the lower part of the overlying Hanford Brook Formation; in NS it is found in the upper part of the Canoe Brook Formation. The stratigraphic distribution of acritarch zones suggests alternative correlations among these areas of Atlantic Canada than those traditionally employed. Rich acritarch assemblages also have been recovered from Middle and Upper (Furongian) Cambrian units of NS and southern NB. Of particular note is the recovery of diverse acritarchs from the *Protolenus* Zone of the Hanford Brook Formation, which provides important new means of correlation of this unit, and which places dated ash beds from this unit in a more robust biostratigraphic context.

Title: RECONCILING MUTUALLY INCOMPATIBLE MODELS FOR THE TECTONO-STRATIGRAPHIC ZONATION OF THE VARISCAN OROGEN IN WESTERN EUROPE

Presenter/First Author: J Brendan Murphy, St. Francis Xavier University, Antigonish, NS

Presenter/First Author Email: bmurphy@stfx.ca

Co-authors: Cecilio Quesada, Universidad Complutense, Madrid, Spain; Gabriel Gutierrez Alonso, , Salamanca, Spain

Abstract Body: The Late Paleozoic Variscan orogen in Europe is widely acknowledged to be the result of convergence and collision between Laurussia and Gondwana during closure of the Rheic Ocean. The orogen is classically divided into a number of tectonostratigraphic zones that have a distinctive curvature (Ibero-Armorican Arc, IAA) and record different aspects of the Late Cambrian-Early Ordovician opening of the Rheic Ocean and the migration of terranes from the Gondwanan margin towards Laurussia, as well as the tectonothermal events that accompanied the closure of that ocean and the development of the IAA. Although there is a general consensus that the curvature originated at some stage during the development of the Variscan orogen two models have emerged to explain the distribution of tectonostratigraphic zones:

(1) a consequence of indentation tectonics due to collision with Laurussia by a (Ibero-Aquitanian) promontory of Gondwana during the Devonian;

(2) development of the Cantabrian orocline at ca. 295 Ma at the inner core of the IAA, an interpretation supported by a wealth of paleomagnetic, structural and geochronological data.

These models have been viewed to be mutually incompatible because the former requires curvature along the Gondwanan margin prior to its ca. 400 Ma collision with Laurussia, whereas the latter requires that the tectonostratigraphic zones were linear prior to bending at ca. 295 Ma.

Recent sedimentological and structural data have rekindled the hypothesis that the Cantabrian Orocline is connected to a second orocline to the south (Central Iberian Orocline), highlighting the possibility that inner (Gondwanan) and outer (Laurussian) zones of the Ibero-Armorican arc may be structurally discordant with respect to each other, implying that the geographic limits of orocline formation are presently unclear.

The two models can be simply reconciled if the geography of Gondwana's leading edge was irregular, but the tectono-stratigraphic zones remained approximately linear within the inner zones of the putative Ibero-Aquitanian indenter and (ii) deformation associated with initial collision was largely accommodated by sinistral (SW Iberia) and dextral (Armorican Massif) motion along shear zones on either side of the promontory).

Title: Kinematics of Orocline Related Shortening in the Ponga Unit: Structural Analysis of the Tama Synform and the Rio Monasterio Antiform, Northern Spain

Presenter/First Author: Kassandra Del Greco, University of Victoria, Victoria,

Presenter/First Author Email: k.delgreco@gmail.com

Co-authors: Gabriel Gutierrez-Alonso, University of Salamanca, Salamanca, Spain; Javier Fernandez Lozano, VU University Amsterdam, Amsterdam, Netherlands; Theron Finley, , , ; Stephen T Johnston, University of Victoria, Victoria, BC, Canada

Abstract Body: The Cantabrian orocline of NW Iberia is interpreted to be a secondary orocline that was formed by the vertical axis rotation caused by N-S shortening of an originally linear, N-S trending Western European Variscan Belt (WEVB). Here we report on a structural study of the WEVB foreland fold and thrust belt from the core region of the Cantabrian orocline. Our goal was to determine what, if any, structures within the fold and thrust belt are attributable to deformation during orocline formation.

The Ponga Unit, a tectonostratigraphic package in the hinge zone of the Cantabrian orocline, is characterized by a sinuous fold interference pattern. We restricted our study to the Rioseco, Laviana and Campo de Caso thrust sheets within the Ponga unit. The thrust sheets are folded forming the Tama synform and Rio Monasterio antiform. We collected over 800 structural data points across these two folds. This data, along with existing geological maps have allowed us to construct detailed quantitative cross-sections both parallel to the axial planes of the folds and perpendicular to the axes of these steeply-plunging folds (down plunge projections). Palinspastic restorations of these cross-sections suggest that 1) the Tama and Rio Monasterio folds post-date and deform the WEVB fold and thrust belt, 2) the folds accommodate north-south shortening that we relate to orocline formation, and 3) that shortening within the orocline hinge region exceeded 60%. WEVB thrust faults are continuous around the younger orocline-related folds, exhibit a stair-step geometry with thrusts climbing up-section to the east, and have related east-verging fault bend folds. Along the axial planes of the orocline-related folds, WEVB fault bend fold axes are perpendicular to the axes of the younger folds, and suggest that the principal compressive stress responsible for orocline formation was perpendicular to the principal compressive stress during WEVB fold and thrust belt formation.

Title:

Flexural accommodation of oroclinal buckling: A structural study of the Cantabrian orocline, NW Iberian Massif

Presenter/First Author: Jessica Shaw, University of Victoria, Victoria, BC

Presenter/First Author Email: jesshaw@uvic.ca

Co-authors: Stephen T Johnston, University of Victoria, Victoria, BC, Canada; Gabriel Gutierrez-Alonso, University of Salamanca, Salamanca, Spain

Published Material: These findings were presented in part at GSA 2014 in Vancouver.

Abstract Body: An 'orocline' is an orogen that expresses plan view curvature either developed over the course of orogen formation (progressive orocline) or subsequent to orogen formation (secondary orocline) by vertical axis buckling in response to a reorientation of regional compressive stress from orogen perpendicular to orogen parallel. An s-shaped pair of coupled oroclines characterizes the Iberian segment of the Western European Variscan belt. The more southerly Central Iberian orocline was only recently documented; the more northerly and well-exposed Cantabrian orocline is one of the best-studied structures of its kind. Structural continuity between the coupled Iberian oroclines suggests that they formed contemporaneously and in the same fashion, however, the nature of the development of the Cantabrian orocline remains a topic of significant debate. Interpretation of the Iberian coupled oroclines as secondary predicts buckling of an originally linear Variscan belt to have been accommodated, at least in part, by flexural shear. Exposures of the Ediacaran Narcea Slates within the so-called Narcea Antiform trace a 150 km long arcuate belt around the 180-degree Cantabrian orocline. In the Western flank of the Narcea Antiform, the Narcea Slates are characterized by a penetrative steep to vertical slaty cleavage (S1) and subparallel 2-km wide reverse shear zones with a penetrative fabric (S2) that are affected by asymmetric meso- to outcrop-scale vertical-axis folds with a dominant vergence toward the oroclinal hinge; i.e. fold sense is dominantly dextral in the southern limb of the Cantabrian orocline and dominantly sinistral in its northern limb. Vertical-axis folds affecting the Narcea Slates are of the appropriate scale and geometry to be parasitic structures developed in response to flexural shear within the limbs of the Cantabrian orocline. A model of formation of the Iberian coupled oroclines by buckling in response to a principle compressive stress oriented at a high angle to orogenic trend is therefore supported.

Title: Developing a High Sensitivity Magnetic Gradiometer for Unmanned Aerial Vehicles

Presenter/First Author: Blair Walker, GEM Advanced Magnetometers, Markham, ON

Presenter/First Author Email: BLAIR.WALKER@GEMSYSTEMS.CA

Co-authors: Ivan Hrvoic, GEM Advanced Magnetometers, Markham, ON, Canada; Michael Wilson, , ,

Abstract Body: It is anticipated that UAV-borne magnetometer systems will replace most ground portable and high resolution airborne magnetometer and magnetic gradiometer surveys. The predicted adoption of UAV-borne magnetic and magnetic gradient systems will only be possible if the data quality is comparable to what is collected with manned systems today.

After assessing a number of UAV vehicles, UASUSA's (Boulder Colorado) Tempest was selected as the platform to carry the ultra-light magnetic gradiometer; the selection was based on the minimal amount of magnetic interference generated by the vehicle, its available payload for a magnetic gradiometer system, its comparable range to a manned helicopter and its affordability.

The customizations to the Tempest included fitting the aircraft with wing tip pods for the GEM Systems' optically pumped potassium vapour magnetometer sensors and relocating servos in the wings that move the aircraft's control surfaces, closer to the fuselage to further improve the noise of the system.

For mineral exploration applications requiring high resolution magnetic measurements, some ancillary software and hardware is required to account for any magnetic interference from the UAV. Those subsystems, which are compact and light weight equivalents of the systems on a manned aircraft, are all components of the GEM Systems UAV gradiometer.

An area near the boundary of the Paleozic Salina and Guelph formations, near Caistorville, Ontario, Canada, was surveyed with the customized unmanned aircraft system at a terrain clearance of 30 m. The survey site was chosen on the basis of its low magnetic gradients. The total magnetic intensity (TMI) and horizontal magnetic gradient data recorded were compared to that obtained during a conventional ground survey.

The study demonstrates that affordable, autonomous vehicles for collecting high resolution magnetic gradient data, are viable replacements for manned vehicle, and can be used in environments that may be too dangerous for a manned vehicle, or too costly / remote for manned vehicles.

Co-authors: Brad Nelson, , , ; Zahir Daya, , ,

Abstract Body: There are currently a number of various magnetometers that are being developed for use with small (under 25kg total payload) Unmanned Aircraft Systems (UAS), or Remotely Piloted Aircraft Systems (RPAS). While it is clear that these systems will eventually become common in the geophysical survey industry, very little work exist that shows the comparison between potential UAS/RPAS compliant systems and the accepted manned aircraft versions that are currently the accepted standard for aeromagnetic surveying.

In this work we show the results of simultaneously flying various new UAS/RPAS compliant and standard manned magnetometers. The UAS/RPAS flights are performed on various fixed- and rotary-wing commercial UAV platforms, while the standard-manned comparison flights are performed on the National Research Council of Canada's (NRC) Convair 580 aeromagnetic research aircraft - the NRC's Convair 580 is the Government of Canada's national aeromagnetic testing aircraft. The measured values from all flights are comparatively analysed with each other and with the specifications of Federally-regulated aeromagnetic surveys.

The present investigation suggests that the quality of the data of potential systems is highly variable with some systems effectively matching the manned versions and others that perform poorly. This association currently, and not surprisingly, is proportional to expense, power requirement and weight of the UAS/RPAS compliant system.

Title: Assessing the Capabilities of Unmanned Fixed and Rotary Wing Systems for Geomagnetic Surveying

Presenter/First Author: Michael Cunningham, Carleton University, Ottawa,

Presenter/First Author Email: michael.cunningham@carleton.ca

Co-authors: Claire Samson, Carleton University, Ottowa, ON, Canada; Alan Wood, , , ; Ian Cook, , , ; Buddy Doyle, , ,

Abstract Body: There is increasing interest in unmanned aircraft systems (UASs) for mineral exploration. UASs have the potential of providing higher resolution data and lower operation cost compared to traditional airborne platforms. However, there have been few studies assessing quantitatively the capabilities of UASs. This contribution presents a theoretical analysis of the UAS capabilities for geomagnetic surveying. The analysis uses: (1) mathematical models describing the magnetic response of geological targets, (2) design parameters from unmanned aircraft systems, such as the precision and accuracy of on-board magnetometers, and (3) realistic noise levels during surveys. Design parameters come from two separate systems currently under development. The first system is a 55kg (with fuel) fixed-wing UAS with a wingspan of 4.95m and a length (tail-to-tip) of 2.74m which is instrumented with two cesium vapour magnetometers in pods on each of the wing tips allowing it to record magnetic gradiometry. The second system is a rotary wing (i.e. helicopter) UAS that can fly as low as 2m above ground level. It is intended to become a cost-effective alternative to magnetic ground survey crew. The performance of these two systems for target identification is assessed for various geological target shapes (i.e. spherical body, vertical dykes, etc.) with a range of target size, depth, and magnetic susceptibilities. Further analysis on the longitudinal gradiometry capabilities of the fixed-wing UAS is performed to determine the minimum separation required between magnetometers to provide reliable data above a specified signal-to-noise ratio. Finally, an analysis focused on the expected data improvements from the enhanced ability of a UAS to closely follow topography (i.e. improved draping) is performed.

Title: Development of Purpose-Built Remotely Piloted Aircraft Systems for Airborne Geophysics and Remote Sensing

Presenter/First Author: Jeremy Laliberte, Carleton University, Ottawa,

Presenter/First Author Email: jeremy.laliberte@carleton.ca

Abstract Body: Since 2000, teams of Carleton University undergraduate and graduate students, under the guidance of faculty members and external advisors, have been developing a series of purpose-built remotely piloted aircraft systems (RPAS) for remote sensing and geophysical applications. This development program began with the *Hammerhead* RPAS (2000-2002) developed in collaboration with Transport Canada to support the detection of illegal bilge oil dumping by ships in Canadian waters. Over the two years, a detailed conceptual design and 1/3 scale flying prototype was built and taxi tested.

Next, in 2002, the Carleton team began collaborating with Sander Geophysics Ltd (SGL) to develop a purpose-built geophysics unmanned aircraft. This aircraft, *GeoSurv I* (1000 kg take-off weight), was designed to replace Cessna Caravan-class manned aircraft while carrying a full suite of geophysics instruments including a gravimeter, alpha ray spectrometer and cesium magnetometers. A 1/20 subscale demonstrator for wind tunnel and remote control flight testing was constructed. Next, from 2004-present, *GeoSurv II* (90 kg take-off weight) was designed and tested. A full-scale flight-ready prototype was built and subjected to several rounds of low and high speed taxi testing including a failed attempt at first flight. The *GeoSurv II* is presently undergoing a significant re-design and is being readied for a future flight attempt. From 2009-present the team designed the *Corvus*, a multi-mission small (25 kg take-off weight) remotely piloted aircraft. The *Corvus* aircraft was flown in October 2013 and is now being readied to carry magnetometers for geophysics flight testing starting in Summer 2015.

In this paper, the evolution of the design requirements and lessons learned from lab and field testing will be presented. Additionally, the authors will discuss the challenges of remotely piloted aircraft system design, certification and flight testing based on 15 years of accumulated experience.

Title: Terrain Modelling - When to Use LiDAR and When Imagery Will Do

Presenter: Chris Polowick, , ,

Presenter Email: chris@ngfgeomatics.com

First Author: Curtis Parks, Organization Not Listed, Ottawa,

First Author Email: curtis@ngfgeomatics.com

First Author Student?: No

Abstract Body: Organizations waste valuable time, spend unnecessary money and risk lives in performing survey operations that are required to fulfil their corporate purpose, be it mining exploration, oil and gas surveying, forestry management or agriculture operations. For this reason, unmanned aircraft systems have experienced a dramatic increase in popularity. This technology, outfitted with the latest in remote sensing technology can provide an array of data collection capabilities up to survey-grade accuracy. Photogrammetric methods are a proven method of generating a variety of orthorectified imagery, in addition to digital elevation models, but can be limited in accuracy and point density depending on the specific application. These capability gaps have been filled by aerial LiDAR technology, which when coupled with aerial imagery, has excelled to form the basis of remote sensing data for a variety of industries. Although, the large difference in sensor cost has limited the majority of unmanned aircraft to photogrammetric technology. NGF's experience with UAV LiDAR has demonstrated the advanced capabilities for applications where imagery won't do. An analysis is presented of the capabilities and limitations of photogrammetry compared to LiDAR as they apply to real-world applications. This considers several variables such as: terrain profile, point density, vegetation cover, accuracy, time-to-data, budget, in addition to primary feature extraction. Summarized by application and industry, the capabilities for cheaper photogrammetric surveys will be presented while detailing when the advanced capabilities of UAV LiDAR should be employed to not compromise on data quality.

Title: UAV-based topographic and vegetation mapping in a northern peatland complex using Structure from Motion (SfM)

Presenter/First Author: Murray Richardson, Carleton University, Ottawa, ON

Presenter/First Author Email: murray_richardson@carleton.ca

Co-authors: Koreen Millard, Carleton University, Ottawa, ON, Canada; Doug Stiff, , , ; Lindsay Armstrong, , ,

Abstract Body: Vegetation and geomorphology are defining surface characteristics of northern peatland ecosystems that can be used to infer underlying hydrological and ecological processes. In recent years, airborne LiDAR-surveys have greatly enhanced our ability to quantify these surface characteristics with unprecedented precision and accuracy, but costs associated with LiDAR acquisitions are often prohibitive, especially in remote areas. This presentation will report on our ongoing efforts to map surface topography and vegetation in northern peatlands using small, multi-rotor UAV platforms, low cost digital camera equipment and 3D surface generation with Structure from Motion (SfM). Results will be presented from two peatland complexes near Ottawa, ON: Mer Bleu Bog and Alfred Bog. Resolution, precision and accuracy of ground surface elevations and vegetation heights derived from UAV-based SfM will be compared against discrete-return, airborne LiDAR surveys and derivatives at both locations over length-scales ranging from 10 – 100 m, demonstrating remarkable mapping capabilities over these relatively short distances. Limitations are encountered in low dense shrub conditions, along with practical challenges associated with surveying larger areas using small UAV platforms.

Title: Unmanned Aerial Vehicle based Remote Sensing for crop disease monitoring and surveillance in Bomet county, Kenya

Presenter/First Author: Osunga MICHAEL Otieno, Regional Centre For Mapping Resource For Development, Kasarani,

Presenter/First Author Email: mosunga@rcmrd.org

Co-authors: Eunice WANJIRU Kibung`a, Regional Centre for Mapping of Resources for Development, Nairobi, Kenya

Abstract Body: This project intends to develop remote sensing (RS) methods using unmanned aerial vehicle (UAV) for crop disease monitoring and surveillance in Bomet county, Kenya. The crop disease to be monitored is maize lethal necrosis disease (MLND). It has no cure and spreads rapidly through disease vectors .MLND was reported in Kenya in September 2011 in Bomet county. To date it has spread to other counties with negative implications. Maize crops are susceptible to MLND at all growth stages. Once infected the only option left for the farmers is to burn their maize plantations. According to agricultural ministry of Kenya, 2 percent of the national maize harvest was affected in year 2012.

UAV surveys are to be conducted over affected farmlands in Bomet county with intentions to detect early signs of MLND, to detect MLND infestation extent and damage degree and to detect pest and weed infestation level. The overall objective is to prevent MLND from spreading to unaffected maize fields.

Radiometric calibrations and geometric corrections would be applied on the acquired images. Extraction of information will be through band rationing and classification. Multi-spectral image processing would produce indices to be used to study maize crop health whilst classified images would identify crop cover clusters by differentiating the variations in spectral signatures in the image hence distinguish weeds and infected crops. The data contained in indices will be used to create crop health maps to highlight areas that require closer examinations. From classification, spatial distributions of classes in the crop field will be ascertained and be used in generating prescriptions for site-specific pest management. Classification and indices correlation would provide input data to generate prescription data to prevent the spread of MLND. From the findings, farmers in the area will be advised on the best practices to prevent the spread of MLND hence having a positive impact on their livelihoods.

Title: Deployment of an unmanned aerial system to assist in mapping an intermittent stream network

Presenter/First Author: Christopher Spence, Environment Canada Saskatoon, Saskatoon, SK

Presenter/First Author Email: chris.spence@ec.gc.ca

Co-authors: Samson Girma Mengistu, Environment Canada Saskatoon, Saskatoon, SK, Canada

Abstract Body: The recent growth in the capability of unmanned aerial vehicles (UAVs) and systems (UASs) as airborne platforms for collecting environmental data has been very rapid. There are now ample examples in the literature of UASs being deployed to map fine scale vegetation patterns, glacier dynamics, soil moisture, canopy temperatures, turbulent heat fluxes, and river bathymetry. The purported advantages of UASs are their ability to collect spatial data over extensive areas at lower cost, lower risk, higher resolution, and higher frequency than ground surveys or satellite platforms. In this study, whether or not obtaining high resolution UAS imagery was advantageous for identifying an intermittent stream network was determined by comparing it to coarse scale satellite imagery collected for the same purpose. Because UASs that are typically deployed for these purposes have flight distance limitations, and there remains interest in obtaining widespread measurements of intermittent stream network dynamics, it was also determined if the higher resolution UAS imagery was an improvement to GPS acquired ground truth points for classifying an intermittent stream network with the same large scale satellite imagery. The UAS and satellite acquired imagery was derived from a visible spectrum camera capable of 5 cm resolution, and multispectral SPOT-5 with 10 m resolution, respectively. The SPOT-5 imagery with its relatively coarse resolution could not always detect the narrow intermittent stream, which was well resolved in the UAS imagery. When a classified UAS image was applied as a training area for the SPOT-5 image, the identification of the stream network improved. UASs have the potential to revolutionize hydrological research the same way that geographic information systems (GIS) did three decades ago. A final point of the paper will be to provide insight into the advantages and disadvantages of deploying a UAS to evaluate if this technology will live up to its potential.

Title: Borehole Gravity Mining Applications Case Studies

Presenter/First Author: Roman Wasylechko, Abitibi Geophysics, Ottawa,

Presenter/First Author Email: rwasylechko@ageophysics.com

Abstract Body: This presentation reviews the Borehole Gravity technology and shows results from exploration surveys conducted by Abitibi Geophysics. GRAVILOG is a slim-hole gravimeter developed by Scintrex (Nind et al, 2007, First Break v 25). Based on miniaturized CG-5 surface meter technology, it resolves the gravitational field to 1 microgal with a repeatable accuracy of <10 microgals. The primary uses of borehole gravity in mining are detection and estimate of tonnage of mineralization and determination of in-situ apparent density.

Now explorationists can test an electromagnetic anomaly for a coincidental excess mass prior to determining the volume of mineralization. Borehole gravity readings and density determinations are not affected by poor core recovery, washouts, or cementing because measurements have a large radius of exploration and are not affected by the casing. In-situ apparent density is useful for deposit evaluation, grade control, structure, and rock property analysis. In-situ bulk density determinations helped James Mine in Labrador to complete the orebody tonnage estimate in spite of poor core recovery due to strong alteration.

The residual borehole gravity response over a nickel deposit near Sudbury showcases a typical cross-over anomaly. From this one-hole gravity survey a tonnage estimate was made that was close to the geologically derived estimate based on many holes.

A multi-hole gravity survey on Coulon Mines Lens 44 demonstrates excellent correlation of the 3D mass model from an unconstrained Stochastic 3D Inversion (Pejman Shamsipour et al, 2010, Geophysics v 75) compared to a geological model based on drilling. The borehole gravity detects the in-hole and the off-hole excess mass and the 3D unconstrained inversion accurately positions it straddling the geological model.

Borehole gravity data collected in five holes surrounding Hudbay's Lalor Mine show how density variations correlate with lithology and identify a potential new target.

Prudent use of borehole gravity to detect and estimate excess mass of target mineralization early in the exploration cycle can save money and time. Similarly, in-situ density measurements improve information on lithology and grade control. Multi-hole gravity data can be inverted to accurately position the excess mass model in a 3D subsurface space.

Title: The Walferdange Underground Laboratory for Geodynamics in Luxembourg

Presenter/First Author: Olivier Francis, University of Luxembourg, Luxembourg,

Presenter/First Author Email: olivier.francis@uni.lu

Abstract Body: The underground laboratory for geodynamics in Walferdange has been established more than 40 years ago. At the origin, it was dedicated to the development and test of instruments mainly used in tidal research and volcanology (gravimeters, titltmeters, strainmeters, water tubes, etc. ...). Since 2000, the activities have been concentrated on gravity. The laboratory was equipped with a superconducting gravimeter, an absolute gravimeter FG5X, two spring relative gravimeters Scintrex and two portable tidal spring gravimeters gPhone. The laboratory already hosted 3 international comparisons of absolute gravimeters. In 2013, for the first time, the international comparison of absolute gravimeters, traditionally organized by the BIPM in Sèvres, took place in Walferdange. Results from the recent developments will be presented: comparisons, calibrations as well as noise characterization of gravimeters. Finally, applications and new instrumental developments will be presented.

Title: Using Airborne Gravimetry to Develop a Geoid-based Vertical Datum for the U.S. with the Redefinition of the American Vertical Datum (GRAV-D) Project

Presenter/First Author: Monica Youngman, National Geodetic Survey, Germantown, MD

Presenter/First Author Email: monica.youngman@noaa.gov

Co-authors: Vicki A Childers, NOAA, National Geodetic Survey, Silver Spring, MD; Theresa Damiani, National Geodetic Survey, Silver Spring, MD; Sandra A Preaux, NOAA, Boulder, CO; Simon A Holmes, SGT inc., Greenbelt, MD; Carly Weil, DST, Silver Spring, MD

Abstract Body: The U.S. National Geodetic Survey is nearing 50% completion of airborne gravity data collection through the Gravity for the Redefinition of the American Vertical Datum (GRAV-D) Project, which was started in 2008 to modernize the vertical datum using a gravimetric geoid accurate to 1 centimeter where possible. With data collected over multiple decades and covering approximately 15.5 million square kilometers when complete, the GRAV-D project continues to face unique challenges to incorporate changing technology and research developments as well as demonstrate the improvements to the geoid. In this presentation we outline the evolution of collection and processing methods as well as results of ground validation and geoid improvement. We also discuss current and future research work, including the effects of kinematic GPS processing, platform motion and off-level corrections, and the potential to use unmanned aerial vehicles.

Cumming et al., Design and development of the advanced LIGO monolithic fused silica suspension, Classical and Quantum Gravity, Vol. 29, 035003, 2012.

Abstract Body: Gravitational wave detectors are the most sensitive length measuring devices in the world. They are broadband long baseline interferometers capable of achieving 10^{-19}m/√Hz at a frequency of 10Hz, and operating up to a few kHz. A worldwide network of 2nd generation detectors is currently under construction/commissioning. This includes the US LIGO detectors with 4km long arms, the 3km VIRGO detector in Italy, GEO-HF in Germany and the KAGRA 3km detector in the Kamioke mine. The goal of these detectors is to measure gravitational waves, tiny ripples in spacetime which are produced by the most extreme environments in

the universe; including supernova, coalescing neutron stars and black holes. This will open a new window on the universe which is complimentary to our current electromagnetic view.

The detectors are limited by a variety of fundamental noise sources including gravity gradient noise, seismic noise, thermal noise and quantum noise. The latter is the effect of the Heisenberg uncertainly principle as applied to the free test masses of the interferometer. In this talk I will provide an overview of the science & sources which are being pursued and some of the technical challenges & hardware development necessary to push the limits of detection sensitivity; this will include the technology to hang 40kg mirrors on fused silica fibres for ultra low thermal noise systems and low scatter optical coatings. Many of these technologies have spin-offs in the field of precision measurement and gravity sensing, including fused silica borehole meters and low frequency MEMS gravimeters. I will further describe the future opportunities in the field, plans for future ground-based and space-based detectors, and the remarkable potential of gravitational wave astronomy.

Title: Recent Advances in the FG5 Absolute Gravity Meter, Dynamic Gravity Meters, the Gphone, and Borehole Gravity

Presenter/First Author: Timothy M Niebauer, Micro-g Scintrex, Lafayette, CO

Presenter/First Author Email: tmn@microglacoste.com

Co-authors: Andrew Hugill, , , ; Ryan Billson, , , ; Fred Klopping, , , ; Patricia MacQueen, Colorado School of Mines, Golden, CO

Abstract Body: There have been large advances in the gravity meters that are being developed at Micro-g LaCoste, Inc. and Scintrex Ltd. These instruments span applications of absolute gravity, static spring gravity instruments that are useful for looking at low frequency gravity signals, dynamic gravity meters that can be used to measure gravity on an airplane or ship and even drone aircraft. Very small gravity meters are being developed to deploy in very deep vertical or horizontal boreholes for reservoir characterization.

The FG5 absolute gravity meter has recently been upgraded to have a longer dropping length. The additional length of freefall allows the extraction of the gravity and gravity gradient during a single drop. A counterweight has been added to the dropping chambers to greatly reduce the recoil of the dropping chambers. A novel method has been developed to balance the free-fall mass to reduce rotational errors.

Two other instruments derived from the FG5 are being developed that have multiple simultaneous freefall masses in the same vacuum system. These instruments directly measure vertical gravity gradients and higher order gradients can be measure simultaneously.

The gPhone noise has recently been reduced to very low noise level (~0.2microGal/sqrt(Hz)) consistent noise measurements measured by superconducting gravity meters. An interesting new method has been developed that is useful for characterizing instrument noise levels even in the presence of ambient seismic noise without the need to difference gravity meters.

An important advance in dynamic gravity meters that allow the much heavier damped beams to be used with a true force feedback loop to greatly reduce the crosscouplings that limited the performance of these gravity meters in high turbulence. The sensors are also being reduced in size so that they can be used in drone aircraft.

Finally, a new line of ultra-small gravity meter sensors have been developed to deploy in boreholes many miles deep in the earth. The sensors can be leveled in vertical or horizontal boreholes. These instruments will have great utility in reservoir monitoring applications in oil, gas, or water.

Title: Gravity and Gravity Gradient Monitoring of Fluid Migration in SAGD Reservoirs: A modeling study

Presenter/First Author: Alexander Braun, Queens University, Kingston, ON

Presenter/First Author Email: braun@queensu.ca

Co-authors: E Judith Elliott, Queen's University, Kingston, ON, Canada

Abstract Body: Steam assisted Gravity Drainage (SAGD) is a process to mobilize heavy oil or bitumen through steam injection into a reservoir for increased production. Consequences of the injection of steam include a change in the subsurface density distribution, which outlines the fluid migration processes in the reservoir. Monitoring the status and changes of reservoirs is critical for optimizing production as well as mitigating socio-environmental risks associated with developing a reservoir. Time-lapse gravity is a recent approach to measure gravity or gravity gradient over time to infer subsurface mass redistribution. For SAGD reservoir monitoring, major obstacles include the required sub-microGal sensitivity to sense the small density changes as well as the significant noise level originating from other processes in the proximate environment. We develop forward models of two operational SAGD reservoirs and calculate the gravity and gravity gradient signals considering confirmed density effects of 0.05 to 0.25 g/cm^3 in the growing steam chamber. Results outline the importance of measuring gravity gradients for varying baselines in order to exploit its higher spatial focusing ability compared to gravity observations alone. At present, field-deployable superconducting gravimeters are the only relative gravimeters capable of performing such observations at the required sub-microGal level. The forward modeling results enable the development of optimized survey geometry and observation schedule. The models include realistic density distributions as well as randomly distributed variations of reservoir thickness and morphology of geological interfaces. Inversion of simulated gravity gradient data constrained by sedimentology and SAGD operational parameters will be presented.

Title: Using Airborne Gravity Data to De-Risk Petroleum Exploration in Frontier Areas: An Example from the Cauca-Patia Basin of Colombia

Presenter/First Author: Malcolm Argyle, Sander Geophysics Ltd., Ottawa, ON

Presenter/First Author Email: argyle@sgl.com

Co-authors: David Westlund, Gran Tierra Energy Inc., Bogota, Colombia

Published Material: A more seismically oriented presentation related to the same project was presented at the CSEG-EAGE Land Seismic Workshop in Banff, Sep. 23-25, 2014.

Abstract Body: The search for petroleum is increasingly focussed on frontier areas, where there is little available subsurface information and exploration risk is high. In addition, these regions have often undergone tectonic activity, leading to complex structures. Acquiring seismic is time consuming and expensive, especially in remote areas, so having reliable information to target seismic line locations becomes critical. Airborne gravity data (usually acquired in conjunction with magnetics) is often useful in this situation, and can be used to target locations for acquiring seismic data, as well as to assist in the processing and interpretation of seismic data.

Gran Tierra Energy (GTE) has been actively exploring in several frontier areas, including the Cauca Patia Basin in Colombia (Figure 1). In 2012, GTE conducted an 8,757 line kilometre helicopter-borne aeromagnetic and gravimetric survey over the Patia sub-basin. The survey was flown and processed by Sander Geophysics Ltd. (SGL), and gravity data were acquired using SGL's airborne gravity system, AIRGrav (Airborne Inertially Referenced Gravimeter).

Results of the airborne survey are excellent, and the potential field data correlates closely with the basin boundaries and other mapped structural features (Figure 1). The potential field data were used along with surface geology to delimit the edges of the sedimentary basin and identify areas likely to result in inherently chaotic seismic data. The potential field data were also used to map areas where higher velocity material has been thrust over the lower velocity sediments, resulting in low velocity seismic zones. Conversely, the data were also used to indicate where lower velocity material is at the surface, in which case seismic imaging issues in these areas are likely the result of structural complexity rather than velocity inversions. Through an iterative analysis, the structural model was re-evaluated, resulting in the generation of a suite of exploration prospects.

Title: Kauring Test Range Airborne Gravity Comparisons using AIRGrav Data Incorporating Measured Horizontal Components

Presenter/First Author: Stefan Elieff, Sander Geophysics Ltd, Ottawa,

Presenter/First Author Email: selieff@sgl.com

Co-authors: Stephen Ferguson, Sander Geophysics Ltd, Ottawa, ON, Canada

Abstract Body: A Sander Geophysics AIRGrav airborne gravity system was flown over Geoscience Australia's Kauring airborne gravity test site in Western Australia. The test site has been very carefully surveyed with land gravimeters for the purpose of making comparisons between airborne gravimetry and gradiometry results and the ground data. The survey area is divided into a 5 km by 5 km inner “AGG” area and a surrounding 20 km by 20 km “AG” area (see figure). Comparisons with both Geoscience Australia ground data over the “AG” area and airborne gravity gradiometer data acquired by CGG using the Falcon system over the “AGG” area are presented. A series of band pass filters of the vertical gravity and vertical gravity gradient are employed to highlight performance at different wavelengths. While the Falcon system is best suited to the shortest wavelengths present at the Kauring test site, the AIRGrav system is also able to resolve relatively short wavelength features. This is due to noise reduction through the oversampling present with tight line spacing combined with the unique characteristics of the AIRGrav system. Horizontal gravity components (or deflections of the vertical) have been obtained from the AIRGrav system using methods that incorporate the latest Australian geoid model. Improved techniques to combine the horizontal components with the vertical to increase vertical gravity accuracy are implemented in the AIRGrav data presented here.

Title: Evolution and structure of Mercury's interior from MESSENGER observations

Presenter/First Author: Nicola Tosi, Technical University Berlin, Berlin,

Presenter/First Author Email: nic.tosi@gmail.com

Published Material: 75% of the talk will be based on two published papers and 25% on new materials that was only presented as a poster at the AGU Fall meeting 2014

Abstract Body: During the past four years, the MESSENGER mission (MErcury Surface, Space Environment, GEochemistry and Ranging) has delivered a wealth of information that has been dramatically advancing the understanding of the geological, chemical, and physical state of Mercury. Taking into account the latest constraints on the interior structure, surface composition, volcanic and tectonic history, we employed numerical models to simulate the thermo-chemical evolution of the planet's interior [1]. Typical evolution scenarios that allow the observational constraints to be satisfied consist of an initial phase of mantle heating accompanied by planetary expansion and the production of a substantial amount of partial melt. The evolution subsequent to 2 Ga is characterised by secular cooling that proceeds approximately at a constant rate and implies that contraction should be still ongoing. Most of the models also predict mantle convection to cease after 3-4 Ga, indicating that Mercury may be no longer dynamically active. In addition, the topography, measured by laser altimetry and the gravity field, obtained from radio-tracking, represent fundamental observations that can be interpreted in terms of the chemical and mechanical structure of the interior. The observed geoid-to-topography ratios at intermediate wavelengths are well explained by the isostatic compensation of the topography associated with lateral variations of the crustal thickness, whose mean value can be estimated to be ~35 km, broadly confirming the predictions of the evolution simulations [2]. Finally, we will show that the degree-2 and 4 of the topography and geoid spectra can be explained in terms of the long-wavelength deformation of the lithosphere resulting from deep thermal anomalies caused by the large latitudinal and longitudinal variations in temperature experienced by Mercury's surface.

Title: Early geodynamic evolution of Mars-type planets with core-mantle coupling

Presenter/First Author: Siqi Zhang, Macquarie University, Sydney, NSW

Presenter/First Author Email: siqi.zhang@mq.edu.au

Co-authors: Craig O'Neill, Macquarie University, Sydney, Australia

Abstract Body: The coupling between the mantle and core is important in understanding the long-term evolution of the Earth and other terrestrial planets. However, most previous models use very simplified treatments for this coupling – eg. a predefined core cooling is often used in mantle dynamic studies. In our mantle dynamics models using the open-source code ASPECT, we developed a parameterized core evolution model which dynamically evolves with core-mantle boundary heat flux. It allows us to model the dynamic evolution of the core and the mantle together.

The question of whether Mars possessed mobile-lid or not still under debate, and the mechanism that generated Mars' early magnetic field is not well determined. We apply ASPECT to the study of the evolution of early Mars. To study the different possible evolutionary paths of early Mars-like planets, we explore a range of parameters such as initial conditions, the existence of surface water, and mantle rheology. We observed different behavior with different model settings; from either stagnant-lid or mobile-lid/episodic mantle convection regimes, and the planetary tectonics can shift from one state to another at certain critical points. In our models, we found that the dynamo activity is strongly related to the convection regime. Models with an early mobile-lid, or which demonstrated a mantle overturn, and which later shifted to a stagnant-lid, are more likely to generate dynamo activity that fits our current understanding of the magnetic history of Mars. And the cessation of mobile-lid tectonics is also likely the cause of the cessation of the dynamo. In the contrary, models that possessed only stagnant-lids throughout their entire evolution seldom produce similar dynamo behavior. From our models, we suggest that early mobile-lid tectonics, or an episodic overturn, is the preferred scenario for producing the early Martian magnetic field.

Title: Mantle Viscosity

Presenter/First Author: Scott D King, Virginia Tech, Blacksburg, VA

Presenter/First Author Email: sdk@vt.edu

Abstract Body: One of the least-well constrained properties of the mantle is the viscosity. There are three approaches to constraining mantle viscosity: experimental studies of creep parameters; comparison of viscous flow models with geophysical observations, and guessing. There is actually a long and rich history of the latter approach. Due to the uncertainties of extrapolating from laboratory to geologic conditions, largely the large extrapolation in stress, experimental studies provide constraints on changes in viscosity as a function of temperature and grain-size. Geophysical constraints provide constraints on viscosity integrated over a finite depth interval and are thus non-unique. In this work I will test experimentally derived creep parameters by calculating geoid, dynamic topography, and plate velocities from 3D viscous flow models. The experimental constraints on the effect of pressure have large uncertainties and allow for either an increasing or decreasing in viscosity with depth. The uncertainties in the distribution of water and grain-sizes through out the mantle allow for a wide range of viscosity models.

Title: Long Mantle Mixing Times for the early Earth Inferred from Convection Models with Grain-Damage

Presenter/First Author: Bradford J Foley, Carnegie Institution for Science, Washington, DC

Presenter/First Author Email: bfoley@dtm.ciw.edu

Co-authors: Hanika Rizo, Carnegie Institution for Science, Washington, DC

Abstract Body: The style of tectonics on the Hadean and Archean Earth, particularly whether plate tectonics was in operation or not, is hotly debated, with conflicting lines of evidence coming from geochemistry, petrology, and geodynamics. For example, Hadean zircons show evidence for low temperature, hydrous melting by ~ 4.0 Ga, indicating that some form of crustal recycling, and possibly even subduction, was active on the very early Earth. On the other hand, ^{142}Nd anomalies recorded in 3.8 to 3.4 Ga rocks from southwest Greenland and 2.7 Ga rocks from the Superior Province (Canada) indicate that chemically heterogeneous reservoirs, formed during the first ~ 100 million years of Earths' history, survived their remixing into the mantle for over 1 Gyr. Such a long mantle mixing time is difficult to explain with a traditional model of plate tectonics, where plate speeds increase significantly in the past due to a hotter mantle. However, a new model for generating plate tectonics from mantle convection based on grainsize reduction (called grain-damage) proposes that plate speeds may have decreased with increasing mantle temperature. Higher mantle temperatures lead to higher grain-growth rates that inhibit the formation of weak lithospheric shear zones. As a result, plate boundaries are more viscous and provide a stronger resistance to plate motions, and thus mantle mixing times may still be long even for Hadean or Archean mantle temperatures. We use new numerical models of convection with grain-damage to constrain mantle mixing times for the early Earth with the effects of grainsize variation included. We find that mantle mixing times remain long as mantle temperature increases because of faster grain-growth rates in the mantle and lithosphere. Therefore the preservation of chemical heterogeneities for over 1 Gyr in the Hadean-Archean mantle is not inconsistent with the operation of plate tectonics at this time, and geodynamic models of early Earth plate tectonics can be reconciled with geochemical observations.

Title: The Influence of Subduction and Mantle Rheology on the Position of Large Igneous Provinces Following Supercontinent Formation

Presenter: Philip J Heron, University of Toronto, Toronto, ON

Presenter Email: pjheron@physics.utoronto.ca

First Author: Julian Philip Lowman, University of Toronto, Toronto, ON

First Author Email: lowman@utsc.utoronto.ca

First Author Student?: No

Co-authors: Claudia Stein, University of Munster, Munster, Germany

Published Material: The majority of this work was presented at the 2014 Fall AGU and much of this work is currently included in a paper under review for JGR.

Abstract Body: Several mantle convection studies analyzing the effects of supercontinent formation and dispersal show that the genesis of subcontinental plumes results from the formation of subduction zones at the edges of the supercontinent, rather than from the effect of continental thermal insulation or thermo-chemical piles. However, the influence of subduction zone location on the position of subcontinental plumes has received little attention. This study analyzes 2D and 3D numerical models of supercontinent formation (in an isochemical mantle) to assess the role of subduction and mantle viscosity contrast in the generation of sub-continental mantle plumes. We find that once a critical supercontinent width is reached, plumes do not form under the center of a supercontinent. In studies featuring a relatively low viscosity lower mantle, the surface plume positions become locked at a distance 2000-3000km from the continental margins. The broad downwellings of simulations that feature a lower mantle viscosity 100 times greater than the upper mantle viscosity generate longer wavelength perturbations in the basal thermal boundary layer, forming plumes at a greater distance from the continental margin subduction. For all mantle viscosity profiles, sub-continental plumes show dependence on the location of supercontinent margin subduction. Furthermore, we analyze how subduction due to a dispersing supercontinent changes mantle dynamics and offer some discussion on the pattern of large igneous provinces post-Pangea breakup. As theories differ on the role of chemical piles in plume formation, it is significant that our isochemical models show that the formation of subduction zones at the margins of a supercontinent has a profound effect on subcontinental mantle dynamics. Our results may help to explain what determined the eruption sites of past (and future) large igneous provinces.

Title: Seismic and Geodynamic Constraints on Lower-Mantle LSVP: Implications for Mantle Upwellings

Presenter/First Author: Alessandro M Forte, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: forte.alessandro@uqam.ca

Co-authors: Petar Glisovic, Université du Québec à Montréal, Montreal, QC, Canada; David B Rowley, University of Chicago, Chicago, IL; Nathan A Simmons, Lawrence Livermore National Laboratory, Livermore, CA; Stephen P Grand, University of Texas, Austin, TX; Chang Lu, University of Texas at Austin, Austin, TX

Published Material: Some preliminary results were presented in an oral presentation at the 2014 Fall Meeting of the AGU in San Francisco.

Abstract Body: Past efforts to obtain direct constraints on the composition and dynamics of so-called Large Shear Velocity Provinces (LSVP) in the lower mantle have used tomography-based mantle flow models. Such modelling requires additional assumptions on the relationship between seismic anomalies and density and on mantle viscosity, thus compounding the uncertainties already present in the global tomography models. Here we explore the range of these uncertainties and we evaluate the combined tomographic and geodynamic evidence for compositionally distinct material in the lower-mantle LSVP. We consider a suite of published tomography models, differing mantle viscosity inferences and a range of thermally-derived conversions of seismic velocity to density perturbations, yielding nearly 100 distinct models of mantle flow. We evaluate the geodynamic plausibility of each model by directly comparing their predictions of convection-related observables against the data. We find it is difficult to obtain a satisfactory fit to the combined set of surface geodynamic data (especially the global, long-wavelength gravity anomalies) and space-geodetic inferences of excess CMB flattening, with a purely thermal interpretation of lower-mantle heterogeneity. In contrast, the introduction of compositionally-distinct material in the central portions of the LSVP yields a notably improved fit to the gravity anomaly and CMB ellipticity data. We evaluate the dynamical implications of this deeply-rooted compositional heterogeneity by calculating the 3-D convective flow in the lower mantle, using a subset of the models that yield the best fits to the geodynamic data. The flow predictions reveal two dominant upwellings in the Pacific lower-mantle: below the East Pacific Rise (EPR) and under the Caroline Islands in the Western Pacific. The EPR "plume" has a special significance because of its obvious connection with the fastest spreading ridge on Earth today. Under the African plate the two dominant lower-mantle upwellings are below the East-African Ridge and the Cape Verde Islands. A separate large-scale upwelling is also found at high latitude under the North Atlantic. In summary, this analysis of the most robustly constrained lower-mantle upwellings reveals a constellation of five active large-scale plumes.

Title: Constraining the Lithosphere-Asthenosphere Coupling from Geodynamical Modeling Based on Tomography Models over the North American continent

Presenter/First Author: Claudia Maria Adam, Virginia Polytechnic Institute and State University, Blacksburg, VA

Presenter/First Author Email: claudia.m.adam@gmail.com

Co-authors: Scott D King, Virginia Polytech State University, Blacksburg, VA; Mark J Caddick, Virginia Tech, Blacksburg, VA

Abstract Body: Understanding the interaction between the lithosphere and asthenosphere is one of the most fundamental problems in geodynamics, and coupling is especially complex in the continental context. We take advantage of major imaging improvements brought through the set up of the mobile EarthScope/USArray, to quantify this interaction. We couple the DNA13 tomography model with thermodynamic calculations to derive realistic density and temperature anomalies. We then compute instantaneous mantle flow in a 3D spherical geometry with realistic temperature and pressure dependent rheology, and derive the lithospheric stresses and the induced tectonic regimes. Our model can account for several complex seismicity patterns.

For example, the San Andreas Fault systems divide into three segments, each with different characteristics. Along the southernmost segment the deformation is transtensional, while the central and northern parts are in transpression. Our model reproduces this transition. We find radial extension between latitudes 30 and 35^{o}S, and compression between latitudes 35 and 39^{o}N, which may be related to a downwelling flow created by lithospheric drip. Our modeled stresses also reproduce the main characteristics of the surface deformation observed along the Yellowstone–Snake River Plain volcanic region. We predict extension over the tectonic parabola of deformation, as observed in focal mechanism and strain-rate tensors derived from GPS measurements. We also predict an extensional regime parallel to the volcanic track. Such a regime will develop faults perpendicular to the track direction, i.e. along the NW-SE direction, consistent with the direction of the Pleistocene-Quaternary major faults. In the New Madrid seismic zone, we retrieve the thrust regimes with a P-axis orientation along the NE-SW direction. This suggests that at least a part of the active seismicity is generated by the present-day state of the mantle, not to older re-adjustment processes.

Title: The Effects of Internal Heating Rate, Rayleigh Number and Plate Representation on the Preponderance of Couette and Poisseuille Flows in the Asthenosphere

Presenter: Christine Shiels, University of Saskatchewan, Saskatoon, SK

Presenter Email: christine.shiels@usask.ca

First Author: Samuel L Butler, University of Saskatchewan, Saskatoon, SK

First Author Email: sam.butler@usask.ca

First Author Student?: No

Published Material: These findings were submitted for publication in Physics of the Earth and Planetary Interiors in November, 2014.

Abstract Body: It has recently been shown that mantle convection models with high viscosity surface plates and a low viscosity asthenosphere display two distinct flow types in the asthenosphere depending on the mobility of the surface plates. When plates are highly mobile, the flow in the asthenosphere is similar to a Couette flow and it is driven by the surface plate. When surface plates are sluggish, the asthenospheric flow is similar to a Poisseuille flow and is driven by lateral pressure gradients. When a low viscosity asthenosphere is present, large aspect ratio convection cells are found to arise and, contrary to the case with no asthenosphere, the surface heat flux is found to increase with increasing aspect ratio when the plates are sluggish. The difference in the flow type in the asthenosphere may thus be important for understanding Earth's thermal state and for understanding the pattern of seismic anisotropy in the upper mantle. In this study, we examine the effects of internal heating rate, mantle Rayleigh number and the representation of surface plates on the nature of the flow in the asthenosphere and on the dependence of surface heat flow with aspect ratio. We find that the flow type in the asthenosphere is fairly insensitive to the internal heating rate and Rayleigh number, however, in models with lower internal heating rates, the surface heat flow does not increase substantially with aspect ratio. However, when a force balance representation of surface plates is used, the flow regime in the asthenosphere is found to be insensitive to the plate aspect ratio and the surface heat flux decreases with convection cell aspect ratio.

Title: Study of the Earth's Interior using Measurements of Sound Velocities in Minerals by Ultrasonic Interferometry Robert C. Liebermann*[1,2,], Xuebing Wang[1], Ting Chen[1], Yongtao Zou[2], Baosheng Li[1,2] [1]*Department of Geosciences, Stony Brook University, Stony Brook, NY USA* [2]*Mineral Physics Institute, Stony Brook University, Stony Brook, NY USA*

Presenter/First Author: Robert C Liebermann, Stony Brook University, Stony Brook, NY

Presenter/First Author Email: Robert.Liebermann@stonybrook.edu

Published Material: 3% published in PEPI in 2014

Abstract Body: This paper reviews the progress of the technology of ultrasonic interferometry from the early 1950s to the present day. During this period of more than 60 years, sound wave velocity measurements have been increased from pressures less than 1 GPa and temperatures less than 800K to conditions above 25 GPa and temperatures of 1800K. This technique is complimentary to other direct methods to measure sound velocities (such as Brillouin and impulsive stimulated scattering) as well as indirect methods (e.g., resonance ultrasound spectroscopy, static or shock compression, inelastic X-ray scattering). Newly developed pressure calibration methods and data analysis procedures using a finite strain approach are described and applied to major mantle minerals for the implication for the composition of the Earth's mantle. The state-of-the-art ultrasonic experiments performed in conjunction with synchrotron X-radiation can achieve simultaneous measurements of the elastic bulk and shear moduli and their pressure and temperature derivatives with direct determination of pressure. Recent examples of such studies are presented for a synthetic KLB-1 peridotite and polycrystalline SiO_2-coesite and the current status and outlook/challenges for future experiments are summarized.

This research is supported by the U. S. National Science Foundation and Department of Energy.

Title: Large-Volume, High-Pressure Research at GSECARS Beamlines, Advanced Photon Source

Presenter/First Author: Tony Yu, University of Chicago, Chicago, IL

Presenter/First Author Email: tyu@cars.uchicago.edu

Co-authors: Yanbin Wang, The University of Chicago, Argonne, IL; Julien Gasc, University of Chicago, Argonne, IL

Abstract Body: The development of synchrotron-based large-volume high pressure (LVP) techniques for studying earth-related materials under extreme pressure and temperature (PT) conditions has been an ongoing effort at the GeoSoilEnviroCARS (GSECARS) of the Advanced Photon Source (APS). Over the years, these developmental efforts have enabled us to conduct coordinated studies on earth materials in both the solid and liquid states under high PT conditions. In this presentation we will show, with the following examples, how state-of-the-art techniques were used in our recent scientific studies: (1) high PT ultrasonic velocity measurements, (2) rheological properties of earth materials at high pressure and temperature, using the deformation DIA (D-DIA), (3) acoustic emission recording coupled with D-DIA for monitoring ductile vs. brittle behavior and reaction progress in rock deformation studies, (4) high pressure 3D imaging of composite materials using the high-pressure x-ray tomographic microscope (HPXTM), and (5) structure studies of non-crystalline materials using a Paris-Edinburgh Press (PEP) combined with a multi-channel collimator (MCC). These techniques have the potential to provide the community with a complete suite of tools for structure, density, elasticity and viscosity measurements of earth materials.

Title: Elastic and Inelastic Properties under Simulated Earth's Mantle Conditions in LVPs in Conjunction with Synchrotron Radiation

Presenter/First Author: Hans J Mueller, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam,

Presenter/First Author Email: hjmuel@gfz-potsdam.de

Co-authors: Joern Lauterjung, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam, Germany; Christian Lathe, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam, Germany

Abstract Body: The interpretation of highly resolved seismic data from Earth=s deep interior require measurements of the physical properties of Earth's materials under experimental simulated Earth's mantle conditions. More than a decade ago seismic tomography clearly showed subduction of crustal material can reach the core mantle boundary under specific circumstances. That means there is no longer space for the assumption deep mantle rocks might be much less complex than deep crustal rocks known from exhumation processes. Viscosity data of melts measured under in situ high pressure conditions are crucial for the understanding of Earth's lower mantle and the interior of terrestrial and extrasolar Super-Earth planets. Consequently in situ data of the elastic and inelastic properties of complex Earth's materials are of extraordinary importance for the interpreation of geophysical data from great depths of planets. Recent large volume presses provide sample volumes 3 to 7 orders of magnitude bigger than in diamond anvil cells far beyond Earth's transition zone conditions. The sample size of several cubic millimeters allows elastic wave frequencies in the low to medium MHz range. Ultrasonic interferometry necessarily requires in situ sample deformation measurement by X-radiography. Time-resolved X-radiography makes in situ falling sphere viscosimetry and even the measurement of elastic and inelastic properties in the seismic frequency range by using the recent deformation technique achievable. This way current geophysical high pressure research is more and more bridging the gap between indoor and outdoor seismology. The paper presents recent techniques of geophysical high pressure LVP research and their results.

Title: Investigating the Possibility of Invariance in Electrical Resistivity in Transition Metals along their Pressure Dependent Melting Boundary

Presenter/First Author: Innocent Chinwe Ezenwa, University of Western Ontario, London,

Presenter/First Author Email: iezenwa5@gmail.com

Co-authors: Richard Secco, University of Western Ontario, London, ON, Canada

Abstract Body: Understanding core cooling through heat conduction and modelling the geodynamo requires knowledge of the thermal and electrical conductivities of relevant liquid Fe alloys at high pressures. Fortunately, the electronic component of the thermal conductivity of metals, which dominates their conductive heat transport, can be calculated from the electrical conductivity using the Wiedemann-Franz law. Measurement of physical properties at core pressures and temperatures (P-T) are challenging which motivates an alternative approach. We take advantage of the fact that the interface between the solid inner core and the liquid outer core is on the high pressure melting boundary of the core constituents. Attempts to evaluate a theory that predicts the electrical resistivity of a metal is constant on its P-dependent melting boundary is on-going using a large volume press up to 5 GPa. The evaluation is being made on transition metals Cu, Zn and Ni which offer comparison of the roles played by filled and partially-filled 3d bands in the electrical resistivity. Using a four-wire resistivity method, experiments are being conducted to provide a possible way to access core conductivity values at low, relative to core, P and T. The aim is to apply electrical conductivity measurements on Fe at low P and T to the inner core boundary in order to study the thermal regime of the core.

Title: Detection of a Pressure-Induced Liquid ⇌ Solid Phase Transformation by Measuring Sound Velocity in a Multi-Anvil Apparatus

Presenter/First Author: Timothy Officer, University of Western Ontario, London, ON

Presenter/First Author Email: tofficer@uwo.ca

Co-authors: Richard Secco, University of Western Ontario, London, ON, Canada

Published Material: A samll portion (~20%) of this presentation was presented at the 2013 AGU fall meeting. These findings are currently under review.

Abstract Body: A technique for detecting and measuring phase transitions in a multi-anvil apparatus by measuring the change in longitudinal sound velocity as a function of pressure is reported. The system measures the time for pulsed ultrasonic signals to travel through a high pressure assembly with a sample in the center. Upon phase change from liquid to solid, the sound velocity shows an abrupt increase due to the intrinsic increase of velocity in the sample and a reduced delay between the triggering of an amplitude threshold and the arrival of the waveform. As a proof of concept, results are shown for Hg as it undergoes pressure-induced liquid ⇌ solid transitions at room temperature.

Title: Botswana's Nationwide Tie Line Survey and New Magnetic Compilation

Presenter/First Author: Stephen Reford, Paterson, Grant & Watson Limited, Toronto, ON

Presenter/First Author Email: stephen.reford@pgw.on.ca

Co-authors: Mogomotsi Nyepetsi, Department of Geological Survey, Gaborone, Botswana; Gomotsang Tshoso, , , ; Mojaboswa Koketso, , , ; Billy Steenkamp, , , ; Abri Crous, , ,

Published Material: 13th SAGA Biennial Conference and Exhibition - 2013

Abstract Body: The Department of Geological Survey (DGS) of Botswana, over a period spanning the late eighties through to early 2000s, acquired high-resolution aeromagnetic surveys over most of the country except for the southwest (Nossop - Ncojane Basin) area. These surveys were mostly conducted at survey specifications of 250 m line spacing and 80 m mean terrain clearance. The line direction for each survey block depended on the dominant strike of the geology. Additional coverage of aeromagnetic survey data was provided by private exploration companies, in places, at higher resolution.

The compilation of the above individual, separate aeromagnetic surveys into one seamless magnetic grid and the long-term endeavour to produce a country-wide high resolution magnetic map prompted DGS to conduct a fixed-wing tie line magnetic survey over the entire country and then merge all existing high resolution aeromagnetic data. The country wide Tie Line Survey serves as a reference datum for past and for future surveys and preserves a full magnetic spectrum magnetic anomaly map of Botswana. Most institutions have opted for the use of satellite magnetic data and/or occasional/sparse low altitude magnetic traverses in an attempt to define a datum for merging multiple surveys to generate a single seamless compilation. However, near-earth satellite magnetic data regrettably do not have the spatial resolution and consequently, the long wavelength components of the magnetic anomaly map still suffer from artefacts.

DGS has realized its first objective of constructing a nationwide magnetic datum through the acquisition of a state-of-the-art tie line survey, incorporating careful compilation of the data to account for variations in the geomagnetic field over the course of the survey. After compilation of the Tie Line Survey, some 70 higher resolution magnetic surveys were recompiled, most acquired by DGS supplemented by some from industry. They were then levelled to the magnetic datum provided by the Tie Line Survey, from which a new nationwide grid of total magnetic intensity at 50 m resolution was prepared. These data and enhanced nationwide magnetic grids were released by DGS in 2012. The Tie Line Survey, separate aeromagnetic surveys and resultant magnetic compilation are shown in Figures 1 through 5.

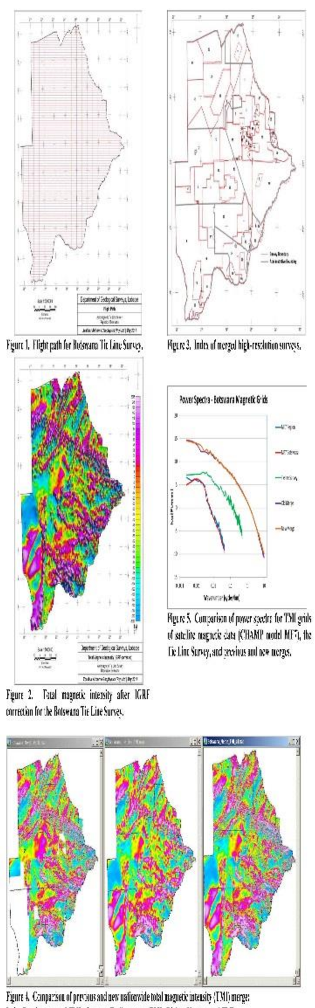

Figure 1. Flight path for Botswana Tie Line Survey. Figure 3. Index of merged high-resolution surveys.

Figure 2. Total magnetic intensity after IGRF correction for the Botswana Tie Line Survey. Figure 5. Comparison of power spectra for TMI grids of satellite magnetic data (CHAMP model MF7), the Tie Line Survey, and previous and new merges.

Title: Removing barriers to accessing Geological Survey of Queensland (GSQ) survey data - a case study

Presenter/First Author: Kenneth John Howieson, Geosoft Inc., Toronto,

Presenter/First Author Email: ken.howieson@geosoft.com

Co-authors: Henry Wang, Geosoft Inc., Toronto, ON, Canada; Mark Thornton, Geological Survey of Queensland, Brisbane, Australia

Abstract Body: The Geological Survey of Queensland (GSQ) provides geoscience and resource information to improve the understanding of the geology and mineral and energy resource potential of Queensland, and promotes the geoscientific data and exploration potential to attract investment. GSQ has under its management a wide range of data types including geophysical data (including airborne magnetic, radiometric, electromagnetic and gravity, deep seismic, 2D and 3D seismic survey data, magnetotellurics), exploration geochemistry data, digital geological mapping data, mineral occurrence and geological observation data, wireline log data, hyperspectral imagery and 3D models. A big challenge facing GSQ was how to get this data into the hands of exploration companies in a cost effective manner. Explorers had limited ability to search and find what data was available from GSQ. Requests for data were then handled manually within the GSQ, which took time and resources to find, clean and deliver datasets. This paper will examine how the GSQ implemented the new Queensland Digital Exploration (QDEX) Data system, enabling customers to search for and download large spatial datasets via a simple web interface. It also provides a data management solution for the GSQ data managers to index and catalog the many different forms of exploration data held within the GSQ.

The case study will review the drivers for the new system, the challenges faced and lessons learned, during the implementation.

Title: A Country-wide Airborne Geophysical Survey of Malawi

Presenter/First Author: Martin Bates, , Ottawa,

Presenter/First Author Email: mbates@sgl.com

Co-authors: Luise Sander, , ,

Abstract Body: In 2013, the Government of Malawi organized a country-wide airborne geophysical survey to unveil “the true mineral potential of Malawi”. The World Bank and European Union funded the survey with the goal of attracting more foreign mining sector investors to the country. The project was preceded by a large socialization campaign conducted by the staff of the Malawi Mining Governance and Growth Support Project.

Sander Geophysics Limited (SGL) was contracted to conduct a fixed-wing high resolution aeromagnetic, gamma-ray spectrometric, and gravimetric survey. Three SGL owned Cessna Grand Caravans were outfitted with magnetic and radiometric survey systems and one of them was also equipped with SGL's Airborne Inertially Referenced Gravimeter (AIRGrav) system. The survey included the acquisition of magnetic and radiometric data throughout the entire country. Gravity data were acquired over three separate blocks of particular interest to the Government of Malawi. A total of 442,933 line kilometres of magnetic and radiometric data and a total of 14,546 line kilometres of gravity data were acquired. Three infill blocks were flown to provide better radiometric data resolution. Survey operations were conducted from Lilongwe, Blantyre and Karonga from

September 23rd, 2013 to July 28th, 2014, and involved 51 members of SGL's staff.

Final products include digital data and a total of 1,100 maps at scales 1:100,000 to 1:250,000, consisting of 22 different map types. Training for geoscientists from the Malawi Ministry of Mines was conducted in-country and at SGL's head office in Ottawa.

The presentation will include a description of the project and preliminary results, logistical hurdles encountered in performing such a large project, the training component of the project and SGL's involvement in the socialization campaign.

Title: ONTARIO AIRBORNE GEOPHYSICS – MAKING THE MOST OF RESOURCES

Presenter/First Author: Desmond Rainsford, Ontario Geological Survey, Sudbury, ON

Presenter/First Author Email: des.rainsford@ontario.ca

Co-authors: Saurav Biswas, Ontario Geological Survey, Sudbury, Canada

Published Material: The Ontario Geological Survey (OGS) publishes all airborne geophysical data that it acquires. Some aspects of this talk have been previously presented to KEGS, Laurentian University, Northwest Ontario Mines and Minerals Symposia, Northeast Ontario Mines and Minerals Symposia, Ontario Exploration Geoscience Symposia and Summaries of Fieldwork and Other Activities published annually by the OGS. These findings are not under review and are not published in a scientific journal.

Abstract Body: Federal aeromagnetic surveying of the province began in 1947 and coverage of Ontario, at 800m line spacing, was completed in the 1987. Beginning in 1975 the Ontario Geological Survey (OGS) has been acquiring high resolution airborne geophysical data throughout the province. The objectives of this work are to improve the understanding of Ontario geology by assisting OGS mapping efforts, to promote mineral exploration and to provide geoscience data to aid in land use planning. Owing to the large landmass to be covered and limited financial resources, several program models have been used to acquire data. These include internal funding, federal – provincial collaborations, regional initiatives, government – industry partnerships and purchase of existing proprietary data. Through these processes, the OGS has been able to acquire high quality airborne geophysical data over large parts of the province. This paper discusses the benefits and limitations of each of these methods. The acquisition of new data is on-going and consultations with stakeholders have shown that there is continued high demand for the results of these surveys. To manage this, the OGS has developed processes to select and prioritize new areas to be surveyed. Finally we will discuss quality control, how the data are distributed, how the data are used and the work that remains to be done.

Title: The Effect of Lower Mantle Viscosity on Surface Mobility in 3D Spherical Shell Convection Models

Presenter/First Author: Sean Michael Langemeyer, University of Toronto, Toronto, ON

Presenter/First Author Email: sean.langemeyer@mail.utoronto.ca

Co-authors: Julian Philip Lowman, University of Toronto, Toronto, ON, Canada; Paul J Tackley, ETH Zurich, Zurich, Switzerland

Abstract Body: Identification of the conditions that allow for ongoing surface mobility in a mantle convection model featuring a temperature and stress-dependent rheology has received considerable attention for over a decade. The importance of discovered trends that appear to increase the likelihood of obtaining a stagnant-lid mode of convection, such as increasing internal heating rates, higher yield stresses, and large planetary cores, is still not fully understood due to the various degrees of feedback that exist with complex rheologies and mixed mode heating. Specifically, allowing for new variables in increasingly complex models can reset previously identified thresholds for transitions between mobile and stagnant-lid regimes. Here we investigate, through the use of 3D spherical shell models, the effect of temperature dependent viscosity and heating mode on surface mobility in cases varying the radial viscosity profile of the mantle. The influence of lower mantle viscosity on surface mobility is explored by considering the viscosity contrast occurring across the 670km depth phase boundary. Additionally, we look at the effects of plastic yielding on the mobility of the surface with the use of both constant and depth dependent yield stresses in cases with different radial viscosity profiles. The planetary bodies to be modelled feature Earth-like core size relative to radius and feature a variety of heating modes including, purely basally heated models, internally heated models and mixed heating models.

Title: The Feedback Between Continents and Compositional Anomalies in the Deep Mantle

Presenter: Julian Philip Lowman, University of Toronto, Toronto, ON

Presenter Email: lowman@utsc.utoronto.ca

First Author: Sean James Trim, University of Toronto, Toronto, ON

First Author Email: strim@physics.utoronto.ca

First Author Student?: No

Published Material: Part of this presentation was shown at the AGU Fall Meeting 2014.

Abstract Body: Findings from global seismic tomography studies suggest that the deep mantle may harbor a pair of broad, steep-sided, relatively dense compositionally anomalous provinces. The longevity and stability of these Large Low Shear-Wave Velocity Provinces (LLSVPs) has received considerable interest but their possible influence on surface motion has drawn lesser attention. Recent work using numerical mantle convection models investigated the feedback between oceanic plate motion and high density compositional anomalies. It was found that surface mobility is affected by the presence of compositional anomalies such that critical density contrasts and volumes of the enriched material produce a transition to stagnant-lid convection. For lesser volumes and density contrast (for example, volumes that are representative of the concentrations in the Earth's mantle) the presence of the compositional anomalies affects mean plate velocity and size when compared to the characteristics of systems in which the enriched material is absent. In addition, numerous studies and lines of evidence in the geologic record suggest that the presence of the density anomalies plays a role in determining the location of mantle upwellings, which in turn influence surface dynamics. We present the results from a study implementing a two-dimensional mantle convection model featuring an anomalously

dense component and distinct continental and oceanic lithosphere. The mass, momentum, and energy equations are solved using a hybrid spectral-finite difference code. Lagrangian tracers are used to track composition. Tectonic plates are modeled using a force-balance method and plate boundary locations evolve in response to interior stresses, plate velocity, age and lithospheric chemistry (i.e., oceanic versus continental). We examine the influence of continents on compositional anomaly morphology and longevity and the influence of compositional anomalies on continental size, mobility and aggregation.

Title: Modeling the Formation of Porosity Bands in a Mid-Ocean Ridge Corner Flow

Presenter: David Gebhardt, University of Saskatchewan, Saskatoon, SK

Presenter Email: djg142@mail.usask.ca

First Author: Samuel L Butler, University of Saskatchewan, Saskatoon, SK

First Author Email: sam.butler@usask.ca

First Author Student?: No

Published Material: Some of the material was presented at the Geological Society of America, 2014 conference.

Abstract Body: Porosity bands are the regions of contrasting high and low porosity that form when an external shear is imposed on a system of partial melt that has a matrix viscosity that decreases with increasing porosity. Previous laboratory experiments have been conducted using simple and torsional shear geometries while previous numerical and theoretical studies have employed simple shear, pure shear and torsional shear geometries. Additionally, mid-ocean ridges present a mass discrepancy between the mass of the new oceanic crust at the top of the ridge axis and the mass of the melt material rising vertically along the ridge axis. This implies the need for lateral melt channelling in order to achieve mass balance. In this contribution we make use of the velocity field derived for a mid-ocean ridge to impose a shear on a partial melt system in a numerical model so as to evaluate the suitability of porosity band formation as a mechanism for channelling melt beneath mid-ocean ridges; this is done for both slow and fast spreading ridges with a variety of strain-rate dependencies for the melt matrix viscosity.

Title: Organomineralizing cryptic communities as an element of carbonate mound formation

Presenter/First Author: Stephanie Nathalie Larmagnat, Laval University, Quebec,

Presenter/First Author Email: stephanie.larmagnat.1@ulaval.ca

Co-authors: Fritz Neuweiler, Laval University, Quebec City, QC, Canada

Published Material: Parts of the content of this presentation will appear in the 2015 February issue of the journal PALAIOS.

Abstract Body: Late Ordovician bryozoan carbonate mounds exposed in the upper part of the Deschambault Formation (Trenton Group, Montmorency Falls, Quebec) are local features within a well bedded sequence of bryozoan-rich carbonate sedimentary rocks. An array of taphonomic filter mechanisms was at work to produce subtle changes in rock texture and microfacies hence controlling early diagenesis and buildup formation. These mechanisms encompass bioerosion, mechanical fragmentation, transport, automicrite formation and marine cementation. Growth cavities between bryozoan colonies were filled with up to four generations of muds, one authigenic and locally up to three infiltrated muds. Stable isotope signature of all microcrystalline indicates that precipitation occurred in equilibrium with marine water. The distribution pattern of rare earth elements is consistent with an oxic marine environment. Intriguingly, the variation of bryozoan zooecium size between mound core, mound flank and off-mound sediments does not support the assumption that bryozoan growth rate was higher in the core of the mound. Instead centimeter-size patches of automicrite with scalloped outer margins are present in mound core facies and are thought to have reinforce the bryozoan colonies. The automicrite together with the first stage of infiltrated mud contains clusters of microsparitic microtubules. The interpretation of these microtubules remains a subject of discussion; they might represent the remnants of non-spicular, keratosan sponges or Wedl-type tunnels associated with the assimilatory action of marine fungi. Irrespective of their specific biological origin, organomineralizing cryptobionts and the subsequent formation of ephemeral substrates might have induced stabilization and fixation of the bryozoan skeletons, and favour local mound formation.

Title: Cnidarian Medusae (Jellyfish): the Ultimate Taphonomic Proxies

Presenter/First Author: Graham Young, Organization Not Listed, Winnipeg, MB

Presenter/First Author Email: gyoung@cc.umanitoba.ca

Co-authors: James Hagadorn, Denver Museum of Nature and Science, Denver, CO

Published Material: My colleague made a presentation of this work in progress at the international Taphos meeting last year.

Abstract Body: Cnidarian medusae have very low preservation potential. They have almost no hard tissues and usually decay or are scavenged after death. They have been around for at least ~550 Ma, yet even in the hundreds of known *Konservat-Lagerstätten*, Cnidaria and their medusae are the least common major metazoan phylum. Despite frequent taphonomic opportunities for preservation, they are known from just a dozen fossil deposits. Thus, their presence in ancient deposits signals anomalous conditions.

Medusae thrive in many environments, yet are only preserved in three types of depositional settings. They are most abundant in strata from tidal sand- and mud-flats, where their deposition at the strandline provides a precise shoreline indicator. Medusae are also preserved in lagoonal mudstones, where they indicate fluctuating salinity or salinity stratification, rapid burial in fine mud, and/or the presence of anaerobic bottom waters. Fossil medusae are rare in shales representing deeper water settings, where they signal rapid burial often associated with bacterial fermentation and mineralization.

Over Phanerozoic time, taphonomic windows that permitted preservation of medusae have shrunk or shut entirely. Strandline deposits are restricted to the early Paleozoic, before metazoans began eating buried carcasses or disrupting microbial mats that bioimmured soft tissue. Preservation of medusae in deeper marine settings disappears by the end-Paleozoic, possibly owing to colonization of basin bottoms by bioturbating organisms. All Mesozoic and Cenozoic fossil medusae are in lagoonal settings, where metazoan activity and microbial degradation were retarded by fluctuating salinity or oxygen, where fine sediment facilitated burial of carcasses, and where microbially-mediated mineralization was fostered.

The present is often a key to the past, but are medusae being preserved anywhere on earth today?

Title: *Halysis* Høeg, 1932 (Early Ordovician-Middle Devonian): calcification history and role in mound formation.

Presenter/First Author: Yuefeng Shen, Laval University, Quebec, QC

Presenter/First Author Email: yuefeng.shen.1@ulaval.ca

Co-authors: Fritz Neuweiler, Laval University, Quebec City, QC, Canada

Published Material: A part of the results was under review as a manuscript by the journal of PALAIOS, Dec, 2014.

Abstract Body: *Halysis* Høeg, 1932 is a calcareous microproblematicum which occurs in abundance in Ordovician fine-grained, reddish carbonate mounds rich in spar-cemented cavities (Tarim Basin, NW China). *Halysis* consists of laterally branching tubes arranged to form a U-shaped skeleton punctually attached to a soft substrate. The skeleton consists of an inner and an outer layer of microcrystalline calcite, and a central layer of imbricated, radially arranged calcite tablets. An affinity of *Halysis* with extant calcareous green algae (Bryopsidales, Udoteaceae) is likely. A literature review of the skeletal robustness of *Halysis* (quantified by size, tube number, wall thickness) concludes for a sudden appearance of most robust growth forms in the Early Ordovician. *Halysis* might have acquired its skeleton *de novo* from a soft-bodied ancestor and by consequence might represent an example of a green alga which obtained its mineralogy (low magnesian calcite) in accord with the ambient sea-water chemistry (calcite sea). In the aftermath, there is a continuous decline of skeletal robustness spanning the Ordovician and Silurian. During the Devonian, the trend is reversed before extinction occurred in the Givetian. Strongly calcified *Halysis* contributes to Ordovician mound formation by creating a significant volume of shelter cavities. The mound sediments consist of algal pellet packstones and grainstones which contain unsupported voids. These voids are similar to those produced from experimental sediment-laden flows operating at the limit of their capacity thereby implying vast areas of highly mobile algal pellet sediments (carbonate silt) in inner carbonate ramp settings (highly productive, high energy). Shelter cavities and unsupported voids together make up about 10% of the total rock volume thereby reducing accommodation space in enough quantity to explain hydrodynamic mound formation.

Title: Factors leading to the development of a Precambrian quartz arenite: the Paleoproterozoic Bar River Formation, Huronian Supergroup

Presenter/First Author: Rohan David John Aranha, University of Western Ontario, London,

Presenter/First Author Email: raranha2@uwo.ca

Co-authors: Patricia L Corcoran, , , ; Fred J Longstaffe, University of Western Ontario, London, ON, Canada

Abstract Body: The Bar River Formation is the youngest unit of the 2.45-2.2 Ga Huronian Supergroup and represents the final pulse of sediment deposition before the Great Stratigraphic Gap. The formation is quartz arenite-dominated and contains abundant planar and trough crossbeds, ripple marks, herringbone crossbeds, and dessication features, which are consistent with deposition on a tidal flat. Recently recognized microbial mat destruction features in the Flack Lake area also support a tide-influenced environment. These mat features include filled sand cracks, petee ridges and patchy ripples. Combined with the quartz-rich nature of the formation, the tide-influenced depositional environment is consistent with development along a passive margin. Paleocurrent analysis of the Bar River Formation at Flack Lake reveals a polymodal trend. The two strongest trends point ESE and SSE, indicating the main flow directions, and point to a sediment source NW of the present-day Flack Lake region. Increasing complexity of paleocurrents up-section reveals a possible aeolian influence, which is supported by the presence of large-scale cross-beds (1.5 m sets). Samples of fine-grained sandstone plot within the passive continental margin field on the Th-Sc-Zr/10 ternary plot, which further supports deposition along a continental shelf. The quartz-rich nature of the formation can therefore be attributed to wave and tide reworking in the depositional environment. A previous investigation of the Bar River Formation east of Manitoulin Island produced ZTR (zircon-tourmaline-rutile index) values between 70-100, which indicates a substantial recycling component. This is further supported by the logZr/Sc vs logTh/Sc diagram where the samples plot in the sediment recycling field. Chemical weathering of the source rock is indicated by CIA values of 74-83. The combined results suggest that the composition of the Bar River Formation detritus was controlled by transport and climatic effects.

Title: Source rock analysis of the Agbada shales of Niger Delta basin, Nigeria, using well log data and Attribute analysis

Presenter/First Author: Ahmad Adeola Adeniji, , Lagos,

Presenter/First Author Email: j_adeniji@yahoo.com

Co-authors: John Ramon Onayemi, University of Lagos, Oshodi, Nigeria

Published Material: Society of Exploration Geophysicists 83rd Annual Meeting

Abstract Body: The Agbada Formation is a parallic sequence of the Niger delta basin, composed of sand-shale intercalation. Sands in the Agbada formation are known to be the major reservoir rocks in the area. The research work aimed at employing geophysical approach to carry out a study on the shale lithologies of the Agbada Formation in the Niger Delta basin to prove whether they have mature
source rock potential or their major responsibility is to seal the reservoirs, which has been the major argument among researchers.
Two separate fields; 'LAG' and 'JAY' located in the basin were studied. Seismic and Well log data of 10 wells from the studied areas were used and the interpretation was carried out with Schlumberger's Petrel 2012 software package, using gamma ray log to differentiate between the sand and shale lithologies. Overlay of sonic log and resistivity log was used to identify kerogen rich zones, and overlay of sonic log and derived pseudo-sonic log (derived from the cross-plot LogR and sonic log) was used to test for maturity of the potential source rock zones, Seismic attribute (RMS Amplitude) was used to check for generated hydrocarbon in the shales as part of the property of mature source rock is to contain hydrocarbon about to be migrated.

Four major shales were studied and their petrophysical analysis revealed that two of the shales were kerogen-rich source rocks, while the others were kerogen-defficient, Attribute analysis showed the absence of generated hydrocarbon. The sonic-pseudosonic overlay and attribute analysis revealed that none of the studied shales is a matured source rock. This work has been able to prove that Agbada shales are not matured source rocks, but rather sealing the reservoir.

Title: Upscaling permeability in bioturbated, heterogeneous tight reservoir rock using the K_{eq} approach

Presenter/First Author: Amy Hsieh, Simon Fraser University, Burnaby,

Presenter/First Author Email: aih2@sfu.ca

Co-authors: Diana M Allen, Simon Fraser University, Burnaby, BC, Canada; James A MacEachern, , ,

Abstract Body: There is considerable interest in recovering hydrocarbons from marginal reservoirs using horizontal drilling techniques and hydraulic fracturing. In such reservoirs, subtle changes in the distribution of sedimentary media such as generated by bioturbation can greatly affect the porosity and permeability distribution of the facies. While burrow-affected permeability trends in reservoirs must be considered in order to properly define reservoir flow characteristics, the marked variability generated at the bed/bedset scale makes such bioturbated media difficult to model. This paper attempts to simplify the variability in K at the bed/bedset scale by estimating an upscaled composite K_{eq} that represents the thickness-weighted sum of K at the bed/bedset scale. Using plug permeability data measured at the bed/bedset scale, K_{eq} is calculated using expressions for layered media in both the vertical (K_z) and horizontal (K_{xy}) directions for hydrofacies (HF) at the composite scale. Numerical block models are then generated using MODFLOW for both the bed/bedset HFs and the composite HFs. Vertical and horizontal flows are simulated by assigning prescribed hydraulic gradients in the vertical and horizontal directions, respectively, in each representation of K. The volumetric flows (Q in m^3/s) in each direction are compared to verify the representativeness of using K_{eq}. The results show that the horizontal and vertical Q for the bed/bedset simulations and the upscaled composite simulations differ by less than ±5%. This technique can potentially be used as a conceptual framework for upscaling K, where there is high variability in K at the bed/bedset scale.

Title: Integrated Geomechanical, Geological, and Geophysical Investigations of the Cretaceous Pierre Shale

Presenter/First Author: Bill Roggenthen, South Dakota School of Mines and Technology, Rapid City, SD

Presenter/First Author Email: wroggen@silver.sdsmt.edu

Co-authors: Jay R. Nopola, , , ; Larry D. Stetler, , , ; Lance A. Roberts, , ,

Abstract Body: The Pierre Shale, a thick Late Cretaceous shale sequence, has one of the largest outcrop areas in the world. The geomechanical and geochemical characteristics of the outcrops have been studied extensively due to the large outcrop area and its importance for civil construction. However, the properties of the Pierre Shale in outcrop and in the subsurface differ greatly due to chemical and mechanical weathering processes of these poorly indurated and often smectitic shales. An ongoing, integrated study is being conducted to investigate geomechanical, chemical, paleontological, and petrophysical properties of the shale in the deep subsurface. Two continuous core drilling sites, located 75 km apart on the eastern side of the Cretaceous Seaway in central South Dakota, have recovered 150 m and 170 m of core from the lower Cretaceous (Campanian). The primary purpose of the coring was to recover unaltered sample to perform long-term creep testing (approximately 1 month) which will assist in the development of a constitutive model for time-dependent deformation of shale. In addition to the geomechanical study of the shale, the ongoing investigations associated with the coring activity include studies of shale microscopic textures (micro-CT and SEM), oxygen isotope stratigraphy, correlation between petrophysics and cores, and micropaleontology. Of stratigraphic interest, both of these drill holes have captured notably dissimilar samples from the Crow Creek Member, which has been ascribed to being derived from tsunamite deposits associated with the Manson Meteorite Impact in Iowa at ~74 Ma. Potential applications for the geologic unit that are being investigated include its use as a storage medium and evaluation of its potential as a source rock for hydrocarbon generation. Numerical modeling has been performed that provide a basis for a preliminary design for a shale-hosted underground research laboratory.

Title: Correlation Between Zooclast Reflectance and Rock-Eval T_{max} in the Upper Ordovician Cape Phillips Formation, Nunavut

Presenter: Jennifer Cuthbertson, University of Calgary, Calgary,

Presenter Email: cuthberj@ucalgary.ca

First Author: Dane Patrick Synnott, University of Calgary, Calgary,

First Author Email: Synnott.dane@gmail.com

First Author Student?: No

Co-authors: Keith Dewing, , ,

Abstract Body: Determination of thermal maturity is an important step in the establishment of a basin model and in the reconstruction of the basins thermal history. The reflectance of certain zooclasts has been demonstrated to correlate with the maximum thermal maturity (T_{max}) of the organic material in the rock (kerogen). Quantification of this relationship has however remained difficult. This study examines the correlation between the reflectance of Graptolites and Chitinozoans and the T_{max} parameter obtained using Rock-Eval Pyrolysis in order to evaluate the suitability of zooclast reflectance as a tool in thermal maturity studies and quantify the correlations between these datasets. Forty-nine samples from the Upper Ordovician Cape Phillips Formation of Nunavut, Canada were powdered for Rock-Eval testing, and prepared into slides for measurement of reflectance. Rock-Eval is an established, reliable method of obtaining thermal maturity data (converted to VR_{eqv} using VR_{eqv}=0.018*T_{max}-7.16) and will be used as a baseline to examine the suitability of zooclast reflectance. Reflectance was measured approximately 100 times per sample across as many individual specimens as possible. Eighteen samples were eliminated due to unreliable results caused by low total organic carbon or lack of zooclasts. Preliminary statistical evaluation shows a reasonable correlation within a prediction interval and an R^2 value of 0.49 for Chitinozoans and 0.57 for Graptolites compared to T_{max} values. Results suggest that zooclast reflectance could be reliably used as a tool in thermal maturity studies. Study is currently ongoing, and future work will focus on developing a conversion factor for the zooclast reflectance to VR_{eqv} (industry standard), and comparing previously published conversions of Graptolite and Chitinozoan reflectance.

Title: Seismic Stratigraphic Analysis of the Messinian Evaporite Deposits and Their Temporal and Spatial Distribution in the Western Cyprus Arc, Northeastern Mediterranean

Presenter/First Author: Pinar Gunes, Memorial University of Newfoundland, St John's, NL

Presenter/First Author Email: pnrgunes@gmail.com

Co-authors: Ali Aksu, Memorial University of Newfoundland, St John's, Canada; Jeremy Hall, Memorial University of Newfoundland, St John's, NL, Canada

Abstract Body: At the end of the Miocene (~ 6 Ma), progressive closure of the straits connecting the Mediterranean Sea with the Atlantic Ocean triggered the desiccation of the Mediterranean Sea. This caused significant amounts of evaporation in a relatively brief period of ~0.63 My, and is known as the Messinian Salinity Crisis (MSC). The sea level drop during the MSC represents the most striking environmental change in the Cenozoic history of the Mediterranean Sea. During this event, rapid sea level drop resulted in an increased salinity and in the deposition of evaporites within shallow water marginal basins (today located onshore and isolated from the offshore deep basin), followed by massive erosion at the continental margins and deposition of thick Messinian Evaporite succession in the deep Mediterranean basins. This paper describes temporal and spatial seismic facies variations across the southern Antalya Basin, Anaxagoras Mountains and the Florence Rise in the eastern Mediterranean Sea. Interpretation of new high resolution seismic reflection data collected from the western Cyprus Arc (Eastern Mediterranean) has revealed the complex depositional and structural setting of the basinwide late Miocene (Messinian) evaporites. Isochron maps and seismic cross-sections are correlated with borehole information from DSDP Leg XLII Sites 375 and 376 and the onland Aksu-1, Manavgat-1 and Manavgat-2 wells, as well as successions in the eastern Mediterranean, and these data are used to describe the spatial variations of the evaporite architecture in the study area. The late Miocene (Messinian) and early Pliocene evaporite successions are divided into four seismic stratigraphic subunits, and a thorough acoustic and thus proxy sedimentary description of these subunits is used to place these subunits into a chronostratigraphic framework.

Title: Mid-Miocene Vegetation and Climate Development on the Atlantic Coastal Plain (IODP Expedition 313)

Presenter/First Author: Sabine Prader, Organization Not Listed, Hamburg,

Presenter/First Author Email: sabine.prader@uni-hamburg.de

Co-authors: Ulrich Kotthoff, Hamburg University, Hamburg, Germany; Francine M G McCarthy, Brock Univ, St Catharines, ON, Canada; David R Greenwood, Brandon University, Brandon, MB, Canada

Abstract Body: Among other goals, IODP Expedition 313 aims at assessing sea-level changes and ecosystem and climate dynamics during the Oligocene and Miocene. We have investigated the palynology of sediment cores from IODP Site M0027, 45 km off the present-day coast of New Jersey. We have focused on pollen studies for the second half of the Mid-Miocene Climatic Optimum (MMCO) and the subsequent transition to globally cooler conditions (ca. 15 to 13 million years before present) in order to examine if the global climatic trends are reflected in ecosystems in the hinterland of the New Jersey shelf. Transport-caused bias of the pollen assemblages was identified via analysis of the terrestrial/marine palynomorph ratio. Palynomorphs were analyzed via both light and scanning electron microscopy and showed good preservation.

Generally, pollen assemblages were not very diverse in the time interval analyzed. Most abundant taxa through all samples were *Quercus* (oak) and *Carya* (hickory). Pollen grains of *Fagus* (beech) were also frequent in most samples, while pollen grains of typical wetland elements like Cyperaceae, *Taxodium* (cypress), *Nyssa* (tupelo tree) were rarer. Taxa like Sapotaceae, Symplocaceae, Arecaceae (palm trees), Buxaceae, and *Alangium*, which today grow in the tropics and subtropics and thus indicate particularly warm climate conditions, were only sporadically found. However, these taxa indicate warmer phases during the second half of the MMCO. Herbal pollen was generally infrequent, but members of the Asteraceae, Apiaceae, and Ericaceae families, together with infrequent occurences of Poaceae pollen indicate the presence of areas with open vegetation.

The Mid-Miocene pollen assemblages reflect ecosystem conditions in the hinterland of the New Jersey shelf which were reminiscent of Oligocene and early Miocene conditions analyzed in previous studies. Frequent occurrences of conifer pollen (*Pinus*, *Picea*, *Abies*, *Sciadopitys*, and *Tsuga canadensis*) indicate that conifer forests prevailed in higher altitudes during the MMCO, while the lowlands were probably dominated by deciduous woodland. We assume that a Miocene uplift of the Appalachian Mountains as postulated by other authors led to a spread of mountainous taxa in the middle Miocene and thus to an increase of related pollen taxa in the palynological record.

Title: Paleoenvironmental records from alaskan Late Pleistocene yedoma permafrost : A case study from the Itkillik river

Presenter/First Author: Lyna Lapointe Elmrabti, University of Montreal, Pointe-aux-Trembles, QC

Presenter/First Author Email: lyna.lapointe.elmrabti@gmail.com

Co-authors: Julie Talbot, University of Montreal, Montreal, QC, Canada; Jens Strauss, Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research Potsdam, Potsdam, Germany; Mikhail Z Kanevskiy, University of Alaska Fairbanks, Fairbanks, AK; Yuri Shur, University of Alaska Fairbanks, Fairbanks, AK; Bianca Fréchette, GEOTOP-UQAM, Montréal, QC, Canada; Daniel Fortier, University of Montreal, Quebec City, QC,

Published Material: Same pollen diagram and sedimentologic raw data presented at Arctic Change because the paleoclimatic recontruction (Modern Analog Technique) that I want to introduce at the Joint Assembly conference 2015 are based on these.

Abstract Body: The cold-arid climate associated with the late Pleistocene environment of unglaciated Beringia was favorable to active sedimentation processes and accumulation of ground ice leading to the formation of a relic form of ice-rich syngenetic permafrost, termed yedoma. These periglacial features provide interesting snapshots of well-preserved old terrestrial paleoenvironmental data (80-12kyr BP). The Itkillik river yedoma exposure (400m x 30-35m) is located in northern Alaska at the border of the Arctic Coastal Plain and the Arctic Foothills. This yedoma provides new information about the extent and temporal dynamics of the former tundra-steppe biome which acted as refugium for plant species and the megafauna during the Pleistocene. Paleoecological records from the site is mainly associated to late and middle Wisconsinan (~10-+43,5kyr BP). Pollen analysis and reconstruction of paleoclimatic parameters (modern

analogue technique) reveal a tundra-steppe environment dominated by herbaceous community. We observed that vegetation was dominated by *Cyperaceae* during warmer periods (middle Wisconsinan (~27-+43,5kyr BP) and Holocene (-15kyr BP)). Summer temperature reconstructed were warmer, near the modern value (8.6 °C), and correlated to δ18O deviations. The total carbon (TC) was slightly higher (+3%) compare to colder episodes and more represented by organic carbon. The volumetric ice content was also higher (average 75%), potentially linked to climatic conditions promoting peat layers formation and segregation of ice during synegenetic development of the permafrost. In contrast, during cold and dry periods (late (~10-27kyr BP) and early (+45kyr BP) Wisconsinan)), the vegetation was mainly represented by *Poaceae* and a higher diversity of minor herbs and forbs. TC was low and mostly represented by inorganic carbon (average 84%). Volumetric ice content values were lower likely due to an increase of eolian sedimentation accelerating more than than twice syngenetic surface elevation during this period.

Title: What was happening when earthquake suddenly deformed the sediments earth in Liwa region, Sumatera, Indonesia?

Presenter/First Author: Yudhi Cara, Geological Agency of Indonesia, Cimahi,

Presenter/First Author Email: yudhicara.geo@gmail.com

Abstract Body: Liwa is a place where the Sumatra Fault crosses this area and produced some devastating earthquakes occurred in 1933, 1984 and 2005. Geological evidences produced by the earthquake could be easily observed immediately after the event, but will quickly disappear after a few days. Therefore the investigation of the earthquake should not wait until a few days, but it should be done immediately after the incident. Very few traces of the earthquake stored properly in the affected areas. The geological evidences were found and show the events that occur suddenly due to an earthquake in Liwa region in a channel of a stream offset, the material which is deposited in a channel. The position of this evidence is on one of the offset of the river in the southwest of the fault. The appearance of the outcrop, shows a discontinuity located at the lower part of the outcrop, while filler material which has relatively young sedimentary structures, seen filling the channel. We suspect that when the earthquake occured, there was an abrupt mass movement and bring materials slide into the channel. To prove these evidences, the grain size analysis and sediments age determination using carbon dating are performed in this research.

Keywords: Liwa, paleo channel, filling material, grain size analysis, carbon dating.

Title: Late Holocene Wood and Vertebrates from Gravels Near Fort Saskatchewan, Alberta

Presenter/First Author: Alwynne B. Beaudoin, Royal Alberta Museum, Edmonton,

Presenter/First Author Email: Alwynne.Beaudoin@gov.ab.ca

Co-authors: Christopher N. Jass, , ,

Published Material: Initial version of this research presented (poster) at Alberta Palaeontological Society 17th Annual Symposium in Calgary in 2013

Abstract Body: Gravels in central Alberta are a major source of late Quaternary fossils, which are often found during active gravel mining operations. Most are of pre-last glacial age (20,000 – 40,000 YBP). Plant macroremains are found less frequently than vertebrate remains but are known from several localities. Here we describe plant and vertebrate remains from a new locality along the North Saskatchewan River valley between Edmonton and Fort Saskatchewan. The remains were recovered from an active gravel operation situated on a low terrace about 10 m above present river level. We were alerted to the fossils by the operator and, thanks to an excellent working relationship, were enabled to visit the pit and examine the context. We collected in-situ wood exposed in a thin layer about 4 m below the present surface. Wood fragments were well-worn, rounded, and aligned roughly west-east, consistent with fluvial transport. The layer was underlain by cross-bedded sands and matrix-supported gravel, containing Shield clasts indicative of a postglacial maximum age. The upper part of the deposit was mostly fine sands, with some cross-bedding. Seven wood specimens were analyzed and were identified as conifer. Skeletal remains of elk (*Cervus elaphus*) and bison (*Bison bison*) were also recovered from the site, though none were clearly from primary context. Elk remains consist of a partial cranium whereas bison remains include both cranial and post-cranial elements. Two AMS dates on samples from cranial remains of elk and bison and three from samples of wood show a tight grouping of 500 – 900 ^{14}C YBP (about 570 – 800 cal YBP). The thick sedimentary deposits and radiocarbon data indicate considerable late Holocene fluvial deposition by the North Saskatchewan River.

Title: Preliminary assessment of Nevado del Ruiz geothermal potential from laboratory measurements of thermal properties

Presenter/First Author: Maria Isabel Velez Marquez, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Medellin,

Presenter/First Author Email: maria_isabel9207@hotmail.com

Co-authors: Daniela Blessent, Universidad de Medellín, Medellín, Colombia; Idalia Jacqueline López Sánchez, Universidad de Medellín, Medellín, Colombia; Jasmin Raymond, Institut national de la recherche scientifique (INRS), Québec, QC, Canada

Abstract Body: This study aims to evaluate the geothermal potential of Nevado del Ruiz volcano, in Colombia, through determination of thermal properties of rock samples collected in the field. The Nevado del Ruiz is a stratovolcano located in Los Nevados Colombian Natural National Park between the limits of Caldas and Tolima departments. Exploitation of geothermal resources could help to supply the local energy needs, particularly for agriculture based mainly on coffee crops.

Geothermal research in this region began in 1968 with a geothermal regional reconnaissance study. In 1983, a prefeasibility study located a promising area on the South Western side of Nevado del Ruiz, due to the presence of various active volcanoes (Santa Isabel, El Cisne and Ruiz) and the existence of fumaroles having a temperature up to 83 °C. At the end of 1990s, the geothermal potential of the Ruiz complex was estimated to 50 MWe.

Recent researches concerned hydrothermal alteration, kinematic characteristics of westward faults, geochemical and thermal evolution, and rock resistivity profiles. Other studies shown that faults may act as preferential flow paths for geothermal fluids. Nevertheless, there are no

published studies about rock thermal properties, which can improve resource assessment.

Therefore, this work focuses on the evaluation of thermal properties of 62 rocks samples collected in surface outcrops. Thermal conductivity and specific heat will be measured using a needle probe and a calorimeter, allowing the calculation of thermal diffusivity. These thermal properties coupled to geothermal gradient values will lead to estimation of heat flow, extrapolation of temperature at depth and improvement of the geothermal resources assessment.

This work represents a first step towards the construction of a simple conceptual model for the geothermal reservoir of Nevado del Ruiz volcano.

Title: Mapping the geoexchange potential of the St. Lawrence Lowlands from thermal conductivity measurements of rock samples

Presenter/First Author: Cédric Sirois, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Québec,

Presenter/First Author Email: ced_90@hotmail.com

Co-authors: Jasmin Raymond, Institut national de la recherche scientifique (INRS), Québec, QC, Canada; Michel Malo, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, Canada; Maher Nasr, Institut national de la recherche scientifique (INRS), Québec, QC, Canada

Abstract Body: The objective of this project was to determine the geothermal heating and cooling potential of the St. Lawrence Lowlands sedimentary basin. This region encloses major cities such as Montreal and Quebec City and is the most important market for ground source heat pumps in the province of Quebec because of the population density. Tables and maps were developed from a thermostratigraphic assessment of rock samples to illustrate the geothermal potential associated to vertical closed-loop systems.

Sizing calculations were first performed for 45 locations to evaluate the drilling length needed for the installation of a ground heat exchanger at a typical home. The building design parameters were kept constant for each location and the subsurface properties were varied according to laboratory measurements of samples collected in surface outcrops. The subsurface thermal conductivity was measured with a needle probe and the subsurface heat capacity was calculated according to the mineralogy estimated with thin section descriptions. Thus, for all rock samples, sizing calculations revealed that bore length should vary between 101 and 213 m.

Thermostratigraphic classifications of the geological units were subsequently created according to their geothermal potential (high, medium or low) based on drilling depth. Results highlight high potential for units such as Theresa, Covey Hill and Cairnside formations having depth of drilling varying from 101 to 129 m and thermal conductivity ranging from 4 to 6,9 W/mK.

Thermal conductivity measurements and sizing calculations were finally mapped using ArcGIS software. Two separate maps showing results with points over the surface distribution of the geological units were designed to simplify visualization. The maps shows that thermostratigraphic units with high geothermal potential are mostly found in the western part of the sedimentary basin.

Title: Measuring terrestrial Precambrian atmospheric oxygen levels: An isotopic approach

Presenter/First Author: David J Auerbach, Yale University, New Haven, CT

Presenter/First Author Email: david.auerbach@yale.edu

Co-authors: Noah Planavsky, Yale University, New Haven; Christopher T Reinhard, California Institute of Technology, Pasadena, CA; J Barry Maynard, , , ; Axel Hofmann, University of Johannesburg, Auckland Park, South Africa; Nadezhda Alfimova, , , ; Xiangli Wang, Yale University, New Haven, CT; Bleuenn Gueguen, Yale University, New Haven, CT; Dan Asael, , ,

Published Material: Part (<50%) of the Cr isotope data have been presented at the 2014 AGU Fall Meeting.

Abstract Body: The history of atmospheric oxygen levels through Earth history has been the topic of intense interest since at least the 1960s (Cloud, 1968). By 2000, a two-step model had become strongly established in Precambrian research in which oxygen is hypothesized to have remained relatively constant except for large, geologically rapid, unidirectional increases in O_2 in the early Paleoproterozoic (the “Great Oxidation Event”) and the Neoproterozoic. Work in the last decade has begun to add detail to this simple view, discriminating between different O_2 levels rather than simply assessing its presence or absence (e.g., Lyons et al., 2014). While typically less common or complete than marine records, terrestrial records such as paleosols form in direct contact with the atmosphere and thus provide direct records of atmospheric composition (e.g., Rye and Holland, 1998).

Uranium and chromium are redox-sensitive isotope systems that are thought to behave relatively simply in terrestrial soils. Uranium fractionation occurs at O_2 levels above ~10^{-5} times present atmospheric levels (PAL) (Partin et al., 2013), while chromium responds above ~10^{-3} PAL (Crowe et al., 2013). Here we present paired U and Cr isotope measurements on a set of globally distributed paleosols that span the time interval from Mesoarchean (≥3.0 Ga) to Mesoproterozoic (1.1 Ga). These paleosols are considered to have excellent preservation based on textural, mineralogical, and chemical examination. By pairing these two isotope systems, we construct a quantitatively constrained history of oxygen levels, rather than simply assessing “almost none” versus “more than almost none.” The record shows, perhaps surprisingly, that O_2 levels remained below ~10^{-5} PAL until at least 2.45 Ga, just before the GOE. However, other records (e.g., Anbar et al., 2007; Crowe et al., 2013) suggest that higher levels of O_2 were present at least locally prior to the GOE for perhaps several hundred million years. Reconciling these results with the rapid mixing time of the atmosphere will be a future challenge, and will inform our understanding of the critical transitions in Earth history occurring during the late Archean and Proterozoic, including the Huronian glaciation, the expansion of oxidative photosynthesis, and the appearance of eukaryotes.

Title: Hyperventilation During the Paleoproterozoic – Evidence for Extensive Oxidation of Terrestrial Surfaces in Fennoscandia

Presenter/First Author: Kyle Rybacki, Pennsylvania State University Main Campus, University Park, PA

Presenter/First Author Email: ksr5112@psu.edu

Co-authors: Lee Robert Kump, Pennsylvania State Univ, University Park, PA; Weiqiang Li, Univ. of Wisconsin - Madison, Madison, WI; Clark Johnson, University of Wisconsin Madison, Madison, WI; Ronny Schoenberg, University of Tübingen, Tübingen, Germany; Victor Melezhik, , , ; Eero Hanski, , ,

Published Material: The major element chemistry used to identify the altered volcanic rocks as a weathering profile was presented at the 2014 Goldschmidt conference.

Abstract Body: The *ca.* 2.06 Ga Kuetsjärvi Volcanic Formation (KVF) is a subaerially erupted volcanic sequence in Fennoscandia that displays an anomalously elevated ratio of oxidized to total iron ($Fe^{3+}/\sum Fe$) compared to those of typical volcanic rocks. To date, two hypotheses have been put forth to explain the oxidized nature of KVF: 1) eruption from a highly oxidized magma source region, or 2) oxidation during terrestrial exposure by oxygen-charged groundwaters in the wake of the proposed atmospheric oxygen 'overshoot' 2.2 Ga ago.

Petrographic observations from Fennoscandia Arctic Russia – Drilling Early Earth Project (FAR–DEEP) Cores 7A and 8B suggest that the KVF's elevated $Fe^{3+}/\sum Fe$ ratios result from post-crystallization hematization of the rocks. We propose that oxidation of the KVF was initiated at the erosional contact marking the top of the KVF, and progressed downward through interactions between the bedrock and oxidizing groundwaters exploiting the oldest fracture sets prior to regional metamorphism. This interpretation is supported by the strong correlation between the measured $Fe^{3+}/\sum Fe$ ratios and the calculated chemical index of alteration of the altered rocks, and the presence of anomalously oxidized KVF clasts within the overlying conglomerate whose matrix does not exhibit any signs of pervasive oxidation. Detailed U–Th–Pb isotope work indicates that the precipitation of the secondary Fe–oxides occurred after the initial crystallization, but prior to regional metamorphism. Iron appears to have undergone limited mobility as indicated by our detailed Fe–isotope work. Conversely, our preliminary Cr–isotope data indicate that Cr may have been transported laterally during weathering. Altogether, these observations and data support that the oxidation of the KVF resulted from interaction with highly oxidizing groundwaters between *ca.* 2.06 and 1.75 Ga ago.

Title: A Theory of Archean Oxygen Stability

Presenter/First Author: Daniel P Schrag, Harvard Univ, Cambridge, MA

Presenter/First Author Email: schrag@eps.harvard.edu

Co-authors: Thomas Laakso, Harvard University, Cambridge, MA

Abstract Body: Though much attention has been given to the Great Oxidation Event of ~2.4 Ga, there is still no mechanistic model for what controls the steady-state levels of atmospheric O_2 in the late Archean or the early Proterozoic. Here we discuss the major controls on pO_2 during various stages of the Archean, using a simple model that describes the biogeochemical of oxygen, hydrogen, carbon, iron, sulfur and phosphorus in the ocean and atmosphere. In the prebiotic era, the redox balance was dominated by the input of reduced species derived from the mantle and from water-crust interactions, compensated by the escape of hydrogen to space. Based on a simple energy balance model of the thermosphere, we find the escape rate may have been slower than the diffusion-limited rate often assumed, leading to elevated hydrogen concentrations. The appearance of chemoautotrophic life altered this balance by adding an additional sink for hydrogen, drawing down the concentration of H_2-bearing species in the atmosphere. In our model the drop in hydrogen concentrations can be as large as several orders of magnitude, with a similarly large increase in pO_2 due to slowed reaction rates between atmospheric reductants and photochemically-derived oxygen. Such large changes in the composition of the atmosphere may have implications for detecting the origin of life, at least as a geochemically significant force, in the rock record. Our model results show that an atmosphere with pO_2 of 10^{-10} PAL would have been stable even after the evolution of oxygenic photosynthesis, provided that the rates of outgassing and serpentinization were sufficiently large in the Archean relative to the organic carbon burial, which was likely limited by alternative sinks for phosphorous.

Title: Alkalinity, Snowball Glaciations, and the Great Oxidation Event

Presenter/First Author: Thomas Laakso, Harvard University, Cambridge, MA

Presenter/First Author Email: laakso@fas.harvard.edu

Co-authors: Daniel P Schrag, Harvard Univ, Cambridge, MA

Abstract Body: The cause of the rapid rise in atmospheric oxygen at 2.4 Ga remains controversial. Using a model of biogeochemical cycling , we identify a new positive feedback that greatly increases the rate at which pO_2 rises across the GOE compared to simpler models. Increasing pO_2 strips ferrous iron from the oceans, reducing alkalinity and the precipitation of calcium carbonate. This is supplemented by sulfide oxidation, which also leads to a reduced flux of alkalinity. To compensate, pCO_2 rises, leading to additional silicate weathering and alkalinity production. This also increases the release of phosphate via apatite weathering, which must be balanced by increased organic carbon burial and further production of oxygen. We show that this positive feedback leads to multiple equilibria in pO_2. In an otherwise steady state, low-oxygen Archean with oxygenic photosynthesis, a transient increase in pCO_2 leads to increased oxygen production via the alkalinity feedback. If this pulse is sufficiently large, the ratio of oxygen to production to electron outgassing can pass the critical threshold without any change in mantle processes, and a permanent transition to high oxygen occurs. Otherwise, the pulse of oxygen is overwhelmed by reductants from the mantle, and pO_2 decays back to its Archean values. These dynamics may explain why the GOE appears to be associated with one of the Paleoproterozoic Snowball events.

Title: Multiple Sulfur Isotopes in Neoproterozoic Pyrite: Implications for Links Between the Sulfur Cycle and Atmospheric Oxygen

Presenter/First Author: Marcus Kunzmann, McGill University, Montreal, QC

Presenter/First Author Email: marcus.kunzmann@mail.mcgill.ca

Co-authors: Thi Hao Bui, McGill University, Montreal, QC, Canada; Boswell A Wing, McGill University, Montreal, QC, Canada; Galen P Halverson, McGill University, Montreal, QC, Canada; Clinton T Scott, , ,

Abstract Body: The size of the seawater sulfate reservoir (SSR) depends on the oxidation state of Earth's surface because riverine sulfate supply is controlled by oxidative weathering of sulfide minerals on the continents and burial of sulfur as pyrite is controlled by the amount of dissolved oxidants in the ocean. The sulfur isotopic composition of pyrite can provide information on sulfate availability and isotopic properties during bacterial sulfate reduction (BSR). However, only pyrites that formed in direct communication with the SSR, i.e. in an euxinic water column or at the sediment-water interface, will reliably record its properties. We present a pyrite-multiple sulfur isotope record coupled to a numerical model from a Neoproterozoic succession in Svalbard, which was deposited on a thermally subsiding continental shelf between 835 and 620 Ma. $\delta^{34}S$ values throughout the succession are highly variable and range from -30 to +40‰, akin to published data from other coeval basins. These data suggest substantial variation in sulfate availability to BSR. However, redox proxies and pyrite contents suggest that BSR during deposition of pre-Sturtian units was restricted to pore waters. In contrast, BSR likely occurred at the sediment-water interface during deposition of the interglacial and post-Marinoan units. The interglacial units show $\delta^{34}S$ values up to +40‰, equal to estimates of coeval seawater sulfate, suggesting collapse of the SSR while post-Marinoan $\delta^{34}S$ values are lower than estimates for contemporaneous seawater sulfate, indicating a larger SSR. The post-Marinoan samples follow a Rayleigh-like trend in $\Delta^{33}S$-$\delta^{34}S$ space. Modeling suggests that sulfate is not the limiting factor during BSR and that some of the H_2S generated during BSR was lost, probably by migration into the overlying water column. A larger post-Marinoan SSR compared to the interglacial period is consistent with a rise in atmospheric O_2 concentration, supporting recent trace metal studies.

Title: What influenced the rise and fall of atmospheric oxygen during the Phanerozoic?

Presenter/First Author: Ralf Tappert, University of Alberta, Edmonton, AB

Presenter/First Author Email: rtappert@ualberta.net

Co-authors: Karlis Muehlenbachs, University of Alberta, Edmonton, AB, Canada; Alex P Wolfe, University of Alberta, Edmonton, AB, Canada; Ryan C McKellar, Royal Saskatchewan Museum, Regina, SK, Canada; Martin Schoell, Retired, Washington, DC

Abstract Body: A new reconstruction of atmospheric oxygen, which is based on the $\delta^{13}C$ of terrestrial organic matter, indicates that pO_2 varied considerably during the Phanerozoic, but reached its maximum of 21% only in the recent geologic past. Throughout much of the Phanerozoic, variations in pO_2 closely followed variations in $^{87}Sr/^{86}Sr$ of marine carbonates, which indicates that pO_2 was primarily influenced by the rates of continental weathering and the associated burial of organic carbon and pyrite. During episodes of increased weathering, *i.e.*, during orogenetic cycles, more sedimentary carbon and sulfur was deposited, causing a rise in pO_2. Episodes of declining pO_2, on the other hand, were primarily the result of reduced continental weathering and continuous seafloor alteration, which resulted in a constant removal of oxygen through oxidation and hydration processes. High-pO_2 episodes, including the Late Carboniferous-Early Permian and Neogene-Quaternary were characterized by low global temperatures and the presence of extensive glaciations, whereas low-pO_2 episodes were typically linked to hothouse conditions. Assuming that atmospheric carbon dioxide is the main factor that controls global temperatures, this indicates that pO_2 and pCO_2, on a long-term scale, are inversely correlated. However, short-term fluctuations of pCO_2 may have been caused by processes, such as volcanism, that had only a limited effect on the global oxygen cycle. In addition to geological factors, Phanerozoic pO_2 was also influenced by the biological evolution. The appearance of lignin in the tissue of vascular plants, for example, allowed for more efficient soil carbon storage, which ultimately led to a considerable rise in pO_2 during the Paleozoic.

Title: Ordovician climate simulations with an earth system model: Focus on the impact of atmospheric O_2 and CO_2 on deep ocean oxygen concentrations

Presenter/First Author: Daniel Frank D'Amico, Ohio State University Main Campus, Columbus, OH

Presenter/First Author Email: damico.43@buckeyemail.osu.edu

Co-authors: Alvaro Montenegro, The Ohio State University, Columbus, OH; Michael Eby, , ,

Published Material: N/A

Abstract Body: Stratigraphic evidence from the Ordovician suggests that widespread oceanic anoxia existed during the late-Middle to Late Ordovician (460-443 million years ago). While numerous observational studies have examined this issue, there have been relatively few numerical experiments attempting to model the conditions that might have contributed to the recorded low oxygen levels during the period. Previous Ordovician modeling efforts have focused on atmospheric concentration of CO_2 and its impacts on extreme climate change, including a short lived glaciation during the Hirnantian (~445 million years ago). Here we utilize the University of Victoria Earth System Climate Model, a model of intermediate complexity, to simulate the impacts of paleogeography and atmospheric CO_2 and O_2 concentrations on Ordovician deep ocean oxygen. Simulations were performed with two different CO_2 levels (14 and 20 times the preindustrial atmospheric level) and two distinct atmospheric O_2 concentrations (5 and 12% by volume). Modeled meridional overturning transport, sea surface and surface air temperatures are in general agreement with previous simulations of the period. The overturning is dominated by two cells with maximum transports ranging from -42 Sv around 20°N to 58 Sv around 10°S. While atmospheric CO_2 variability influences both ocean temperature and overturning, it has no significant impact on modeled deep ocean O_2. Experiments with the lower atmospheric O_2 concentration show fairly widespread anoxia, here defined as O_2 concentrations below 10 µmol L^{-1}, for the northern hemisphere with an average oxygen concentration of 4.39 µmol L^{-1}. Counter to many of the observations, the majority of the deep ocean in the southern hemisphere, where most continents are located, remains well oxygenated. Future simulations will further evaluate the impact of changes in biological activity and nutrient input on deep-ocean anoxia during the period.

Title: Episodic Organic Carbon Burial During the Phanerozoic Indicated by a New Atmospheric pO_2 Record resources.

Presenter/First Author: Martin Schoell, Retired, Washington, DC

Presenter/First Author Email: mschoell@gas-consult.com

Abstract Body: A new reconstruction of Phanerozoic atmospheric pO_2, which is based on the $\delta^{13}C$ of terrestrial organic matter, indicates that at least four major episodes of continuous pO_2 increase occurred over the last 450 million years. Each of these episodes lasted between 20 and 50 million years. The increase in pO_2 during these episodes allowed us to estimate of the amount of organic carbon (OC) that needed to be buried in order to account for the pO_2 increases. The combined total for all four burial episodes is ~$4.4x10^{19}$ moles of OC. Using the accumulation of bitumen in the Athabasca tar sands deposit as a measure of scale (1 AE ~1.8 $x10^{12}$ barrels), we estimate the amount of OC burial during the burial events to be equivalent to ~2600 Athabasca deposits (see Table).

The timing of the four predicted OC burial events coincides with the formation of economically important coal, oil, and gas deposits. However, the amount of carbon stored in known deposits is ~2-3 orders of magnitude smaller than the amount of OC burial required to account for the pO_2 changes. This suggests that the vast majority of OC buried during the Phanerozoic still remains within its sedimentary host rocks, either as dispersed material, or as undiscovered resources.

Burial event	Time (ma)	% O2 change
OBE 1 Tertiary	40-0	13-21
OBE 2 Cretaceous	140-120	7-15

Title: Using co-produced water and disposal wells to assess the geothermal potential of sedimentary basins

Presenter/First Author: Grant A G Ferguson, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: grant.ferguson@usask.ca

Published Material: Co-produced and injection figures have been presented. The geothermal analysis is new.

Abstract Body: Rich datasets from the oil and gas industry can reduce the level of uncertainty for geothermal developments. 700,000 wells have been drilled in the Western Canada Sedimentary Basin (WCSB) allowing for the creation of detailed geological models. In addition to this geological knowledge, extensive hydraulic characterization and fluid production and injection has occurred in the WCSB. Approximately 20 billion m^3 of water has been produced from this basin during oil and gas production and 23 billion m^3 has been injected. Here, hypothetical geothermal developments are explored using historical production and and injection rates and known temperatures. The ability to predict hydraulic performance of geothermal developments based on long-term records is not normally possible in other geothermal developments. This could be a key advantage to developing these lower temperature resources.

Title: Electricity generation performance from low-grade heat in enhanced geothermal systems

Presenter/First Author: Marc-André Richard, Hydro-Québec, Shawinigan, QC

Presenter/First Author Email: richard.marc-andre@ireq.ca

Published Material: Eastern Canada and the North East U.S., with typical average temperature gradients of less than 30 °C/km, will be low-grade resources for Enhanced Geothermal Systems (EGS). Geothermal electricity generation must cope with significant power plant cooling, geothermal fluid pumping and temperature drop in production wells. The negative impact of these aspects is even more important if the power conversion efficiency is low due to the low resource temperature. The production lifetime of conduction dominated geothermal reservoirs may also be problematic. To analyse the potential for a geothermal electricity generation system from low grade resources, we developed a tool that takes into account electrical plant gross efficiency, energy spent in cooling, pumping of the geothermal fluid and temperature drop in the production wells. To simulate the geothermal reservoir, we represent reservoir fracture systems by an equivalent equidistant fracture network that provides a numerical solution linking reservoir properties, fluid temperature at the exit of the reservoir and time. Then, we analysed the impact of the most important parameters and explored strategies for the optimisation of electric generation from low grade EGS resources. Different scenarios were analysed (optimistic, realistic, and pessimistic). The results suggest that the initial reservoir temperature should be at least 150°C. The power plant must also be able to tolerate a large geothermal fluid temperature drop through the system lifetime. It is suggested that although the power plant efficiency optimisation is important, the reservoir engineering is critical when accessing low grade heat.

Abstract Body: Eastern Canada and the North East U.S., with typical average temperature gradients of less than 30 °C/km, will be low-grade resources for enhanced geothermal systems (EGS). Title: Interstage Heating Strategies for Double-Flash Geothermal Power Plant

Presenter/First Author: François Mathieu-Potvin, Laval University, Quebec,

Presenter/First Author Email: francois.mathieu-potvin@gmc.ulaval.ca

Published Material: The results were reported and published in the journal "Geothermics, 2015, vol. 54, pp. 82-95"

Abstract Body: More than 60% of the electricity generated by geothermal power plants in the world is produced from the heat of high temperature hydrothermal reservoirs. These high temperature power plants are typically of the Flash category (Single, Double or Triple-Flash), and it is well known that their efficiency is relatively low. Hence, to ensure economic sustainability of these power plants, it is desirable to improve their design

so that they can provide more energy with the same amount of geothermal fluid.

Recently, we proposed a novel strategy to improve Double-Flash power plants, which consists in extracting heat present in warmer parts of the thermodynamic cycle in order to use it in colder parts of the system, by means of an additional heat exchanger. These new designs are named "Interstage Heating", and are inspired from the work of DiPippo and Vrane (1991).

A numerical model was developed to simulate Interstage Heating processes in Double-Flash thermodynamic cycles, and the model was validated with results reported in literature. That numerical model was then used to optimize the operating parameter values (i.e., separator pressures) and to maximize the specific work output of the geothermal power plants.

Numerical results showed that by using Interstage Heating in Double-Flash designs, the specific work output of power plants may be increased by about 5%, the liquid content in the low pressure turbines may be decreased by about 50%, and the waste heat to power output ratio of power plants may be reduced by about 10 %. In other words, Interstage Heating provides a higher energy output from the same geothermal wells, it reduces the erosion rate of turbine blade, and it may reduce the initial cost of cooling systems in Double-Flash power plants. To summarize, Interstage Heating has the potential to provide significant benefits to owners of Double-Flash power plants.

Title: PRELIMINARY FINDINGS INTO SPECIFIC STRATIGRAPY AND HYDRAULIC PROPERTIES FOR GEOTHERMAL ENERGY PROSPECTING ALONG THE WILLISTON BASIN

Presenter/First Author: Randy Rajiv Koon Koon, University of the West Indies, Arouca,

Presenter/First Author Email: randykoonkoon88@hotmail.com

Co-authors: Lotanna Ufondu, , ,

Published Material: The Mathematical model used within this paper is currently under review by the Editor-in-Chief Professor Soteris Kalogirou, D.Sc.. at the Renewable Energy Journal titled, "MATHEMATICAL MODELLING OF THE GEO-MECHANICAL & THERMAL STRAIN ON FRACTURE WALLS WITHIN A CONVENTIONAL GEOTHERMAL SYSTEM".

Abstract Body: Geothermal energy exploration is becoming a sustainable modification from the conventional hydrocarbon industry. Canada shows possible potential for this form of energy widely distributed across the Provinces. The paper serves to present the analysis of well core data within four wells in regards to their temperatures, permeability enhancements, and its dominant hydraulic flow paths. The area of Weyburn is chosen as the target region within the scope of the prominent Williston Basin. From these four wells, five cores are investigated and results generated as a means to display a criteria to analyse other well core data. Through bottom-hole temperature values, temperature vs depth plots are generated and assist to yield insight into favourable depths having suitable temperatures for potential binary systems. Through the use of a mathematical model that describes the deformation of fracture walls as a function of the fracture radius due to the effect of the geothermal fluid, analytical solutions for each core sample is generated that reveals which core structures deform the greatest in response to the fluid. Results are illustrated graphically via MATLAB plots and Excel Histograms. However, through COMSOL Multiphysics 4.3a software the Darcy's Law module is utilized to model the core geometry and the relevant Physics are implemented to generate 3D pressure isosurface models illustrating maximum flow paths. In addition, important 1D plots such as: Darcy's velocity flow, permeability, porosity and pressure along the core sample length are extracted to further analyse the system. Hence the geological cores of the identified wells of interest are modelled to show the extent of velocity flow magnitude and isosurfaces through these cores.

Co-authors: Maher Nasr, Institut national de la recherche scientifique (INRS), Québec, QC, Canada; Michel Malo, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, Canada

Published Material: The portion of the reasearch concerning BHT corrections has been partially presented to the Geothernal Ressources Concil 2014 annual conference as a poster (september 2014, Portland, Oregon).

Abstract Body: The Cambrian-Ordovician St. Lawrence Lowlands sedimentary basin covers approximately 20 000 km^2 in southern Quebec, Canada. Deep saline aquifers contain warm water that could potentially be used for geothermal energy. The thickness of the sedimentary cover reaches more than 3000 meters in the south-eastern part of the basin, offering significant thermal insulation. Basal sandstones of the Potsdam Group are prospective targets for natural reservoirs and the crystalline basement of the Grenville province may be a suitable host for enhanced geothermal systems.

The thermal state of the sedimentary basin has been assessed with a 3D geological model to evaluate the potential for geothermal power generation and direct use. The data used to create the 3D model included the geological map of the area, the interpreted basement structural map as well as oil and gas exploration well data. The bottom hole temperature (BHT) data available for 93 of those wells were corrected to estimate equilibrium temperatures that were integrated to the model. Thermal conductivity analyses of 56 outcrop rock samples were performed with a needle probe to determine properties of the modelled geological units. The temperature and conductivity results were then used to calculate the surface heat flow and estimate temperature at depth, assuming a purely conductive heat transfer.

In the 3D model, results indicate heat flow in the range of 36x10^{-3} to 107x10^{-3} W/m^2 with an average of 67x10^{-3} W/m^2. Local areas of higher heat flow (68x10^{-3} to 85x10^{-3} W/m^2) situated in the eastern part of the basin, close to Logan's Line, have sedimentary cover thickness of 3000 to 5500 meters. The equivalent thermal conductivity of the insulating caprocks in this area ranges from 2.4 to 2.7 W/mK. At a depth of 4 km, temperature above 120°C could be expected for the most promising areas.

Power production potential appears to be mostly associated to the deep basement whereas temperature of the basal sandstones indicates potential for direct use.

Title: Comparing permeability of fault zones of geothermal and non-geothermal regions, compiled in a global fault zone permeability database.

Presenter/First Author: Jacek Scibek, McGill University, Montreal, QC

Presenter/First Author Email: jacek.scibek2@mail.mcgill.ca

Co-authors: Jeffrey M McKenzie, McGill University, Montreal, QC, Canada; Tom Gleeson, McGill University, Montreal, QC, Canada

Published Material: An update of this project was presented at the AGU 2014 by Scibek et al in abstract titled "How fault zones impact regional permeability and groundwater systems: insights from global database of fault zone studies."

Abstract Body: Fault zones are important fluid conduits in geothermal reservoirs, and the permeability of fault zones is also an important parameter in models assessing deep groundwater flow in sedimentary basins. In this study we conducted a review and compilation of existing fault zone hydrogeological data in various regions of the world, including many faulted sedimentary basins. The database focusses on fault zone permeability and conceptual permeability models published in multidisciplinary literature (structural- and hydro-geology, engineering geology, and geothermal projects among others). In regions with the largest data clusters, the occurrence of different dominant hydrogeologic effects of fault zones (barrier / conduit), and the locally estimated permeability magnitudes, were tabulated and compared for different geologic regions, lithologies, depths. Various data biases, as related to tests of fault zones, are also explored and compared.

The data from developed geothermal projects are compared to other fault permeability estimates at thermal springs (analytical and numerical solution of Darcy flux driven by convective heat flow). Starting with the methodology applied in Japan by Hanano and Kajiwara (1999) and regional mapping by Muraoka et al. (2006), a similar methodology is applied to other regions where hot thermal springs occur. 2D numerical flow models of heat+water flow are used to explore the assumptions and parameter sensitivities of these methods. Fault permeability data from sedimentary basins are compared globally with geothermal heat flux, depth, reservoir size and scale of measurement, number of wells drilled, and other parameters. These results are also compared to non-geothermal hydrogeological data of fault zone permeability in these regions.

The research result lead to a key question - are fault permeability data from developed geothermal fields transferable and/or scalable, or useful in any way, to exploration in geothermally undeveloped sedimentary basins?

Title: Geothermal Potential of an Emergent Na-Cl Thermal Spring, Clarendon Plains Basin , Jamaica

Presenter/First Author: DeBonne Natalie Wishart, Central State University, Beavercreek, OH

Presenter/First Author Email: dwishart@centralstate.edu

Abstract Body: Analyzed chemical compositions of emergent low-temperature, Na-Cl type mineral waters from Milk River (MKR) spring situated in the Miocene Age limestone of central Jamaica were combined with a multicomponent geothermometric approach to estimate the geothermal reservoir temperature and depth of fluid circulation. Geochemical data provide interesting information on the origin, circulation, and temperature of this thermal fluid. Boron (B), lithium (Li), and strontium (Sr) concentrations reveal important information about mixing between seawater and geothermal fluids. Cationic ratios of Li/B vs. SO_4^{2-}/Cl^- indicate deep circulating fluid signatures derived mainly from water/rock interactions involving clastic rocks with water essentially resulting from seawater-derived brine. The drastic shift of $\delta^{18}O$ and δ^2H isotopes from the global meteoritic water line (GWML) indicates significant depletion of $\delta^{18}O$ in the region of influence from seawater. Log(Q/K) curves show a cluster of equilibrium temperatures over a range of 150-170°C for MKR. Quartz silica solubility geothermometers underestimated reservoir temperatures. A comparison of temperatures estimated from cation-exchange (Na/K, Na-K-Ca and Na-K-Mg) geothermometers computed from SOLGEO and geothermometric equations range between 153 to 197°C. The higher temperatures estimated for the fluids at depth compared to the emergence temperatures may be due to the circulation of seawater in permeable fractures serving as conduits supporting the upward flow of the geothermal fluids along a major tectonic structure-the east-west trending South Coast Fault (SCF). Chemical and isotopic data suggest the up-flow of deep, thermal, saline brines along fractures of the SCF. Based on hydrochemical, isotopic, geological, and structural data, a hydrogeological conceptual model for the circulation of geothermal fluids at Milk River spring is proposed.

Title: Behavior of Marine Sulfate in Variably Sulfidic Oceans

Presenter/First Author: Linda C Kah, University of Tennessee, Knoxville, TN

Presenter/First Author Email: lckah@utk.edu

Co-authors: Miles A Henderson, , , ; Cara K Thompson, , ,

Published Material: Related abstract investigating only the Ordovician material was presented at GSA 2014. All of this is currently in preparation for publication.

Abstract Body: Our understanding of the oxygenation history of ancient oceans commonly derives from reservoir modeling of marine S-isotopes. Traditional modeling of S-isotopes has emphasized a single-reservoir model, in which the composition of the marine sulfate reservoir depends only on the magnitude and isotopic composition of input fluxes and output fluxes. An inherent assumption in this model is that bacterially reduced HS^- is either immediately extracted by reaction with available iron (e.g., within anoxic waters or sediment pore space) or immediately reoxidized, through a range of intermediate sulfur phases, to sulfate (e.g., within a well-oxygenated waters).

Much of the Proterozoic and early Paleozoic, however, preserves independent data that indicates persistent marine euxinia, wherein Fe^{2+} was at least locally insufficient to strip the water column of bacterially produced HS^-. Such conditions demand modeling the marine sulfur cycle as a dual-reservoir system, wherein marine SO_4^{2-} and HS^- are treated as distinct, reactive reservoirs, with their own input and output fluxes that affect both the behavior of the individual reservoirs as well as the degree of linkage between the two reservoirs. In this case, the isotopic composition of marine sulfate is affected directly by the magnitude and isotopic composition of traditional input and output fluxes that act over long time scales, as well as a suite of transitory input and output fluxes,

including bacterial sulfate reduction and a combination of chemical and biological sulfide oxidation.

Here we examine patterns of behavior in the marine sulfur cycle from Mesoproterozoic through Ordovician-aged strata (from China, Mauritania, Argentina, and Newfoundland), and interpret these patterns in terms of a dual-reservoir model. We show how systematic changes in sulfur isotope behavior related to the protracted oxygenation of the Earth's biosphere and growth of the marine sulfate reservoir over nearly 1 billion years of Earth history.

Title: Epiclastic Versus Pyroclastic: Revised Age Constraints on Cryogenian Glacial Deposits in the Pocatello Formation, Idaho, U.S.A.

Presenter/First Author: Mark David Schmitz, Boise State University, Boise, ID

Presenter/First Author Email: markschmitz@boisestate.edu

Co-authors: Vincent Isakson, , , ; Carol M Dehler, Utah State Univ, Logan, UT; Adolph Yonkee, Weber State University, Ogden, UT; Francis A Macdonald, Harvard University, Cambridge, MA

Published Material: Cordilleran Tectonics Workshop, University of British Columbia-Okanagan

Abstract Body: Neoproterozoic glacial successions are recognized worldwide, and interpreted to record global glaciations as part of the 'Snowball Earth' model (Kirschvink, 1992; Hoffman et al, 1998). Although a fundamental tenet of the Snowball Earth hypothesis is a global synchrony of glaciogenic deposits, the number, timing, and correlation of these glacial episodes remain controversial, due to incomplete successions and limited geochronologic constraints.

The Neoproterozoic Pocatello Formation of southeastern Idaho exposes a thick (>1km), well-preserved stratigraphic succession containing glaciogenic strata and a cap dolostone with Marinoan characteristics (Dehler et al, 2011). Stacked diamictite-bearing intervals appear to record two glacial episodes, but absolute ages and relation to other Neoproterozoic glacial events are uncertain. Published ages from the lower Scout Mountain Member of the Pocatello Formation (Fanning and Link, 2004) are now known to be maximum depositional ages from epiclastic volcanic detritus (Keeley et al, 2013). We present new high-precision (CA-IDTIMS) U-Pb zircon ages of ~697 Ma from two felsic pyroclastic flows within the lower diamictite of the Pocatello Formation, which place the first robust constraints on the 'Sturtian' glaciation in this sector of the Laurentian margin. Exposures of the lower Pocatello Formation in Idaho thus appear to record only the latter half of the long Sturtian Snowball Earth glaciation (Rooney et al, 2014). By contrast, we will also introduce new data that falsify the earlier identification of a green argillite bed in the upper Scout Mountain Member as a ~667 Ma "reworked fallout tuff bed" (Fanning and Link, 2004), and demote its significance to a maximum depositional age from epiclastic detritus. Without a firm minimum age bracket, the correlation of the upper diamictite and associated cap carbonate in the Pocatello Formation to the Marinoan deglaciation remains tenable.

Title: Oxygen, Facies, and Secular Controls on the Appearance of Cryogenian and Ediacaran Body and Trace Fossils in the Mackenzie Mountains, Northwestern Canada

Presenter/First Author: Erik A Sperling, Scripps Institution of Oceanography, Cambridge, MA

Presenter/First Author Email: sperling@fas.harvard.edu

Co-authors: Calla Carbone, , , ; Justin Vincent Strauss, Harvard University, Cambridge, MA; David T Johnston, Harvard-Earth & Planet Science, Cambridge, MA; Guy Narbonne, , , ; Francis A Macdonald, Harvard University, Cambridge, MA

Published Material: Presented at the 2014 Palaeontological Association meeting, Leeds, United Kingdom.

Abstract Body: The causes behind the appearance of abundant macroscopic body and trace fossils at the end of the Neoproterozoic Era remain debated. Iron geochemical data from fossiliferous Ediacaran successions in Newfoundland suggested that the first appearances at that locality appeared to correlate with an oxygenation event. A similar relationship was claimed to exist in the Mackenzie Mountains, Canada, although later stratigraphic studies indicated that the stratigraphic sections analyzed for geochemistry were incorrectly correlated with those hosting the fossils. To directly connect fossil occurrences with geochemistry in the Mackenzie Mountains, we conducted a multi-proxy iron, carbon, sulfur, and trace element geochemical analysis of stratigraphic sections hosting both the Cryogenian 'Twitya discs' at Bluefish Creek as well as the Ediacaran fossils and simple bilaterian traces at Sekwi Brook. There is no clear oxygenation event correlated with the appearance of macroscopic body fossils or simple bilaterian burrows; however, some change in environment – a potential partial oxygenation – is correlated with increasing burrow width higher in the Blueflower Formation. Data from Sekwi Brook suggest that these organisms were periodically colonizing a predominantly anoxic and ferruginous basin. This seemingly incongruent observation is accommodated through accounting for differing timescales between the characteristic response-time of sedimentary redox proxies versus that for ecological change. Thus, hypotheses directly connecting ocean oxygenation with the appearance of macrofossils need not apply to all areas of a heterogeneous Ediacaran ocean. At least in the Mackenzie Mountains, the appropriate facies for fossil preservation appears to be the strongest control on the stratigraphic distribution of macrofossils.

Title: Late-Ediacaran Resumption of Extension on the Western Laurentian Margin near Jasper, Alberta, Canada

Presenter/First Author: Thomas James Maguire, McGill University, Montréal,

Presenter/First Author Email: thomas.maguire@mail.mcgill.ca

Co-authors: Galen P Halverson, McGill University, Montreal, QC, Canada

Abstract Body: The timing and nature of renewed latest-Ediacaran extension on the western Laurentian margin remains controversial after decades of study. Lower-greenschist facies sedimentary rocks with *Namacalathus-Cloudina* fossils near Jasper, Alberta, Canada present an attractive prospect for improving geochemical understanding of the key end-Proterozoic time, yet remain poorly studied due to correlation difficulties. Two pulses of sedimentation have been interpreted to record major episodes of extension: 1) Cryogenian intracontinental rift sediments, the Miette Group of the Windermere Supergroup, a 9km thick siliciclastic-dominated shallowing-up succession; 2) late-Ediacaran extension resumption accommodating 6km of carbonate-dominated passive margin sediments through the lower-Paleozoic, beginning with fluvio-marine and fluvial coarse-grained sandstones of the >2.2km thick Hamill-Gog (locally Gog) Group. At it's base, an erosional hiatus of widespread extent and non-uniform stratigraphic removal, the sub-Gog Unconformity, has complicated correlations of upper Miette strata, as have the lack of biostratigraphic clues in the Gog, indications of extension diachroneity, and a paucity of rocks suitable for absolute-dating methods. In the Jasper area, however, extension contemporaneous with the sub-Gog surface provides a locally-continuous record of Miette through Gog sedimentation in fault-bounded basins. Our sequence-stratigraphic correlations, complemented by biostratigraphic and high-resolution carbonate chemostratigraphic data, permit study area correlation across a complex paleotopography with several hundreds of meters of stratigraphic variability, and to age-constrained rocks globally. We establish a new age-constraint on Jasper-area margin collapse: it begins no earlier than ~552Ma and before 542 ± 0.3Ma, at odds with the sole regional U-Pb radiometric date of 569.6 ± 5.3Ma from the 150km-distant Hamill Group, confirming strong diachroneity along the margin.

Title: Ediacaran soft-tissue preservation

Presenter/First Author: Marc Laflamme, University of Toronto, Mississauga, Mississauga, ON

Presenter/First Author Email: marc.laflamme@utoronto.ca

Co-authors: James D. Schiffbauer, , , ; SImon Alastair Francis Darroch, Smithsonian Institution, Washington, DC

Published Material: Preseneted similar results at the International Paleontological Congress in October 2014. Paper presently being written for publication.

Abstract Body: Biases in the fossil record must be considered before any meaningful signals can be retrieved. *Konservat-Lagerstätten,* sites that preserve soft-bodied organisms, represent the richest fossil source of anatomical information and offer more complete views of organismal diversity and disparity patterns in deep time. Understanding the early evolution and diversification of animals, as written in the Ediacaran fossil record, is reliant on our understanding of the preservational constraints affecting the fossilization of soft tissues in Ediacaran *Lagerstätten*. We have employed a two-pronged approach to aid in unraveling the geobiological intricacies in Ediacaran preservation. On the one hand, advanced instrumentation such as environmental scanning electron microscopy (ESEM), energy dispersive X-ray spectroscopic elemental mapping analyses (EDS)x-ray, photoelectron spectrometry (XPS), and electron probe microanalyzer wavelength dispersive X-ray spectroscopy (EPMA-WDS), was performed on sectioned Ediacaran fossils from Newfoundland and Namibia, revealing the importance of clay minerals and the precipitation of iron sulfides such as pyrite in casting the external morphology of the organisms. On the other hand, decay experiments conducted under controlled laboratory settings allowed for investigations into the replication of soft-tissue preservation, which identified controls on rates of tissue decay and early mineralization. This combined two-pronged approach provides a conceptual framework for understanding the distribution of Ediacaran-style preservation in time and space, and will help frame the paleoenvironmental settings and conditions where body fossils are preserved in the Neoproterozoic.

Title: Biodiversity in the Precambrian Fossil Record: Constructing a Digital Database of the Ediacara Biota and Closing the Precambrian-Cambrian Evolutionary Gap.

Presenter/First Author: Thomas Howard Boag, University of Toronto, Toronto,

Presenter/First Author Email: thomas.boag@mail.utoronto.ca

Co-authors: Marc Laflamme, University of Toronto, Mississauga, Mississauga, ON, Canada; SImon Alastair Francis Darroch, Smithsonian Institution, Washington, DC

Abstract Body: Large, complex life first appears in the latest Ediacaran (579-541 Ma), characterized by globally distributed marine soft-bodied organisms colloquially called the Ediacara biota. Although it is well documented that these organisms went extinct prior to the Cambrian explosion of bilaterian animals, the ultimate cause is still unclear. Three hypotheses are proposed: 1) gradual and evolutionarily mediated biotic turnover in response to the appearance of metazoan 'ecosystem engineers'; 2) a taphonomic artifact produced by the disappearance of conditions required for preservation; and 3) a sudden, coeval mass extinction driven by perturbations to global geochemical cycles. Critical testing of these hypotheses requires a detailed understanding of Ediacaran biodiversity in both paleogeographic space and stratigraphic time. Here, I present preliminary results from an exhaustive integrated paleontological database that summarizes the known distributions of Ediacaran taxa, combined with geological characterization of Ediacaran depositional and taphonomic settings as compiled from both literature research and recent fieldwork. I include additional data on chronostratigraphy, lithostratigraphy, preservational mode, and mineralogy of local-scale diagenetic alteration. I find that the Ediacaran fossil record displays a distinct bias towards moldic-style preservation in coarse-grained siliciclastic lithologies – with comparatively little preserved in carbonate facies or as compressions in shales. I also find strong correlation between worker effort and genus richness among major localities worldwide. These data illustrate that accurately quantifying changes in Ediacaran biodiversity through time requires a variety of sample standardizing techniques. Ultimately, these findings will guide future fieldwork in targeting under-studied strata, paleoenvironments, and preservational windows, helping to resolve the tempo and mode of early animal evolution preluding the Cambrian explosion.

Title: New Precambrian Trace Fossils, the End of the Ediacara Biota, and First Mass Extinction of Complex Life

Presenter/First Author: SImon Alastair Francis Darroch, Smithsonian Institution, Washington, DC

Presenter/First Author Email: simon.darroch@yale.edu

Co-authors: Marc Laflamme, University of Toronto, Mississauga, Mississauga, ON, Canada

Published Material: These findings are currently in review as part of two submitted manuscripts in peer-reviewed journals.

Abstract Body: The precambrian-Cambrian transition (542 Ma) marks perhaps the most dramatic geobiological change in the last billion years of Earth history, and yet remains poorly understood. This interval marks the extinction of the enigmatic Ediacara biota (a collection of multicellular eukaryotes whose affinities with modern metazoans are unknown), the Cambrian 'explosion' of modern animal groups, and a shift from stratified, microbially-dominated 'matgrounds', to more recognizable Phanerozoic 'mixgrounds' colonized by a wide variety of infaunal metazoans. Key to understanding this transition is unraveling the causes behind the extinction of the Ediacara biota, as these made way for the proliferation of modern animal groups. Here, we present new data from latest Ediacaran sections in southern Namibia that preserve both Ediacaran soft-body fossils, and trace fossils that represent the activity of Cambrian-type animals. We show that: 1) latest Ediacaran communities had low evenness and species richness, consistent with interpretation as 'stressed' ecosystems; and, 2) these Ediacaran communities co-existed with cnidarian grade trace-makers that may represent some of the earliest evidence for passive predation. Together, these findings provide support for a 'biotic replacement' model of the extinction of the Ediacara biota, in which extinction was protracted, and ultimately caused by the evolution of Cambrian-style predators and 'ecosystem engineers'. These findings also suggest that the first mass extinction of complex life was likely biologically caused and mediated, in stark contrast to the subsequent Phanerozoic 'Big Five' events.

Title: Nitrogen isotopes across a late Mesoproterozoic basin transect, Arctic Bay Formation, Nunavut

Presenter/First Author: Malcolm Hodgskiss, McGill University, Montreal,

Presenter/First Author Email: mhodgskiss@gmail.com

Co-authors: Pierre Sans-Jofre, Université de Bretagne Occidentale, Brest, France; Marcus Kunzmann, McGill University, Montreal, QC, Canada; Devon Cole, Yale University, New Haven, CT; Timothy Gibson, McGill University, Montreal, QC, Canada; Peter William Crockford, McGill University, Montreal, QC, Canada; Galen P Halverson, McGill University, Montreal, QC, Canada

Published Material: A poster featuring an incomplete dataset will be presented at the Northeastern Geobiology Symposium at Princeton University. Similarly, an incomplete dataset will be used in an oral presentation at the GEOTOP Congress.

Abstract Body: Proterozoic ocean oxygenation is poorly understood, with various geochemical proxies resulting in seemingly contradictory models. Nitrogen isotope compositions of sedimentary organic matter, while regionally heterogenous, reflect the redox state of the global ocean. The late Mesoproterozoic Arctic Bay Formation, Nunavut, comprises hundreds of meters of organic-rich shales (up to 20 weight % TOC) deposited below storm wave base in a marine setting. Two sections were measured along a basin-shelf transect and analysed for nitrogen isotopes in bulk sediment and kerogen, organic carbon isotopes, and iron speciation. Within the more basinal section, $\delta^{15}N$ values range from 1.6-4.7‰, with a modal value of 2.0‰. In the more proximal (shelf break) section, $\delta^{15}N$ values range from 0.8-4.4‰, with a modal value of 2.2‰. A small offset is also seen in organic carbon isotopes, with the basinal section recording a modal $\delta^{13}C_{org}$ of -30.2‰, compared to -29.7‰ in the shelf break section. The offset between basinal and shelf break $\delta^{15}N$ values is interpreted to be a result of decreased nitrate stability, and therefore decreased oxygen concentrations, at depth. The lowest $\delta^{15}N$ values in the shelf break section (0.82‰) occur at a flooding surface, and may indicate the presence of an oxygen minimum zone adjacent to the shelf break. The measured range of $\delta^{15}N$ values (0.8-4.7‰) implies a relatively stabile nitrate reservoir consistent with the early Mesoproterozoic (~2‰). However, the modal values (2.4‰) are distinctly lower than the late Neoproterozoic (~4‰) or Phanerozoic (~5‰), suggesting that the ocean was not yet dominantly oxic.

Published Material: I already presented some of these I/[Ca+Mg] data frrom the Akademikerbreen Group in Svalbard at the Goldschmidt Conference 2014. I also presented my preliminary results as a poster.

Abstract Body: The ca. 810 Ma Bitter Springs carbon isotope anomaly is an abrupt and long-lived (5–10 m.y.) departure from the high $\delta^{13}C$ values that otherwise characterize early-middle Neoproterozoic seawtaer. This isotope anomaly, which reflects a -8‰ shift in mean seawater DIC carbon isotope composition, has been documented globally, but is perhaps best represented in carbonates from Svalbard and East Greenland. Given increasing evidence that Neoproterozoic oxygenation and eukaryotic diversification began well before the Ediacaran Period, the Bitter Springs anomaly is a logical interval to explore for geochechemical evidence of early Neoproterozoic redox change. To this end we have applied the I/[Ca+Mg] to carbonate rocks spanning the anomaly as a novel proxy for seawater redox potential that is highly sensitive to changes in oxygen content. These data are further compared with other trace element data on carbonates.

Iodine exists almost exclusively as iodide (I^-) and iodate (IO_3^-) in seawater, with the balance shifted towards iodate under more oxidizing conditions. Because IO_3^- can be incorporated in calcite crystal during carbonate precipitation, variations in I/[Ca+Mg] in carbonate may reflect fluctuations in seawater redox. The proxy has previously been applied to Cretaceous Ocean Anoxic Events (OAEs) and the Great Oxidation Event (GOE). Our data, available so far, from Svalbard and Greenland reveal two prominent features. First, the Bitter Springs anomaly is associated with low I/[Ca+Mg] ratios compared to carbonates above and below. Secondly, two spikes in I/[Ca+Mg] are associated with $\delta^{13}C$ recoveries (positive shifts), including the end of the Bitter Springs event and the smaller anomaly proceding it. We interpret these results to indicate that the Bitter Springs anomaly coincided with periods of expanded basin anoxia.

Title: Lost and found: the Islay carbon isotope excursion in Namibia is nearly 746 Ma in age

Presenter/First Author: Paul F Hoffman, Organization Not Listed, Washington, DC

Presenter/First Author Email: paulfhoffman@gmail.com

Co-authors: Eric J. Bellefroid, Yale University, New Haven, CT; Benjamin W Johnson, University of Victoria, Victoria, BC, Canada; Daniel P Schrag, Harvard Univ, Cambridge, MA

Abstract Body: Before 2014, the Islay carbon isotope excursion (I-CIE) was assumed to directly predate the early Cryogenian Sturtian glaciation (717-659 Ma), notwithstanding a return to enriched $\delta^{13}C$ values before glaciation observed in some areas. On this assumption, a fruitless search for the I-CIE was conducted in northern Namibia for 20 years. There, Sturtian glacial deposits (Chuos Fm) are underlain by 1.0 km of mixed carbonate and clastic strata (OSG, Ombombo Subgroup) on the Northern Platform (Congo craton), and by a comparable sequence (USG, Ugab Subgroup) in the Northern Zone of the Damara orogen, directly south of the platform. OSG carbonate $\delta^{13}C$ increases stratigraphically upward from 1 to 8 permil VPDB, before falling to 3 permil at the top. A tuff in midsection was previously dated at 759±1 Ma (U-Pb). USG carbonate decreases upward from 6 permil in midsection to 0 permil at the top. The lower 140 m of USG carbonate, which conformably overlies rhyolite ash-flow tuff dated at 746±2 (U-Pb), was not previously sampled. In 2014, Re-Os isochron ages of 739.9±6.5 and 732.2±4.7 Ma were reported from black shales associated with the fall and rise of the I-CIE, respectively, in NW Canada (Rooney et al. PNAS 111(1), 51-6; Strauss et al. Geology 42(8), 659-62). These dates imply that the I-CIE is unrelated to Sturtian glaciation and ~20 Myr older then earlier assumed. Given this lead, we sampled the previously neglected lower USG carbonate interval. We find that $\delta^{13}C$ falls steeply from −1 to −5 permil in the first 30 m of section, after which it rises to 4 permil at the top of the lower carbonate interval. This CIE is too young to be the Bitter Springs stage and is the only negative CIE younger than ~760 Ma known in Namibia. Pending confirmation in correlative sections, we infer that the long-sought I-CIE occurs in the lower USG, in which case its age is a little less 746±2 Ma, compatible with Canadian Re-Os data and unrelated to Sturtian glaciation.

Title: Expanded records of early Ediacaran marine carbonate $\delta^{13}C$ from Namibia: synchronous foredeep initiation bordering the Kaoko and Damara orogens?

Presenter/First Author: Paul F Hoffman, Organization Not Listed, Washington, DC

Presenter/First Author Email: paulfhoffman@gmail.com

Co-authors: E. Blake Hodgin, , , ; Eric J. Bellefroid, Yale University, New Haven, CT; Peter William Crockford, McGill University, Montreal, QC, Canada; Glenn R. Jasechko, Simon Fraser University, Burnaby, BC, Canada; Benjamin W Johnson, University of Victoria, Victoria, BC, Canada; Pierre Sans-Jofre, Université de Bretagne Occidentale, Brest, France; Daniel P Schrag, Harvard Univ, Cambridge, MA

Abstract Body: Shelf carbonates of the Tsumeb Subgroup (TSG) exposed in the Otavi fold belt (Namibia) offer an expanded record of early Ediacaran surface seawater chemistry. TSG includes late Cryogenian (Marinoan) glacial deposits and the global syndeglacial cap dolostone marking the base of the Ediacaran Period. The TSG shelf occupied the SW promontory of the Congo craton, the western margin of which collided with the east-facing Ribeira arc (SE Brazil) at 600-590 Ma, forming the Kaoko orogen (KO). In the west, the TSG ends with shelf drowning and foredeep clastic sedimentation. To the south, the TSG shelf faces the Damara orogen (DO), where a south-facing magmatic arc in the Central Zone (CZ), established by 560 Ma, collided with the Kalahari craton at ~550 Ma. The CZ is traditionally viewed as an attenuated extension of the Congo craton, but between them lies the most deep-seated and continuous total magnetic intensity anomaly in the country. We present new high-resolution $\delta^{13}C$ records for TSG from sites bordering the KO in the west and the DO nearly 400 km to the east at Tsumeb. The TSG can be divided into three chemostratigraphic units (T1-T3). T1 (0.2-1.0 km) was a 'catch-up' stage in which accommodation created during Marinoan glaciation was filled. It coincides with the Maieberg CIE, a steep fall from −1 to −6 permil VPDB, followed by gradual recovery to −1 permil. T2 (0.5-1.0 km) was a 'keep-up' stage, defined by a gradual smooth decline to −3 permil followed by a smooth but steeper climb to 2 permil. 'Keep-up' continued in T3 (0.4-0.8 km), defined by a sharp rise to unstable heavy values of 3-7 permil (west) and 5-11 permil (east), followed by a decline to 2 permil at the top of TSG in both areas. We infer that either clastic input from the KO ended carbonate sedimentation in the east, well beyond the limit of KO foredeep subsidence, or that clastic input in the east is related to tectonism in the DO 40-50 Myr before the terminal Congo-Kalahari collision.

Title: Dolomite Marine Cements Record Marine Anoxia During the Late Cryogenian

Presenter/First Author: Ashleigh van Smeerdijk Hood, Yale University, New Haven, CT

Presenter/First Author Email: ashleigh.hood@yale.edu

Co-authors: Malcolm William Wallace, , ,

Published Material: Some findings published in a short summary paper:Hood, Ashleigh VS, and Malcolm W. Wallace. "Marine cements reveal the structure of an anoxic, ferruginous Neoproterozoic ocean." *Journal of the Geological Society* 171.6 (2014): 741-744.More detailed finding have been accepted for publication (pending revisions) in Precambrian Research

Abstract Body: The Neoproterozoic was a time of great changes in the Earth's surface and marine environments, including a significant 'step' in the evolution and oxygenation of the oceans. However, the timing of this ocean oxygenation remains uncertain, particularly in regards to Cryogenian seas, which were disrupted by large periods of global glaciation. The recent recognition of primary dolomite marine cements in Cryogenian sequences of Namibia and Australia may help resolve the complex ocean chemical history of this time. These cements show well-preserved cathodoluminescence growth zonation and have optical properties indicating they preserve their original marine chemistry and can therefore be used as geochemical proxies for Late Cryogenian paleooceanography. In particular, the interglacial Cryogenian Oodnaminta Reef Complex, (Adelaide Fold Belt, Australia) contains abundant primary marine dolomite cements, which cover a significant palaeo-depth range. Analysis of these cements from nearshore facies (~0-2m), to deep framework facies (~1km) of the reef complexes reveals significant geochemical gradients with palaeo-depth. Iron is present in high concentrations in cements from deep and shallow reef facies, but is present only as Fe-oxides in nearshore facies. Chalcophile elements (Cu, Cd, Pb, Zn) are abundant in the nearshore and shallow cements, but decrease in concentration with depth. Rare earth element profiles are unusual, with shallow and deep facies showing convex profiles with negligible Ce/Ce* anomalies and positive Eu/Eu* anomalies.

Constrained by sedimentology, this carbonate geochemistry provides a detailed window into the structure and chemistry of an interglacial Cryogenian ocean. The marine cements reveal a pronounced chemical stratification, where a thin veneer of oxic surface waters existed over increasingly anoxic and Fe-rich seawater at depth. The distribution of strongly chalcophile elements (e.g. Cd and Cu) across this chemocline suggests that although ferruginous, deeper anoxic waters probably contained minor dissolved sulfide. These conditions describe a ferro-sulfidic ocean and encompass some of the most extreme anoxia yet documented during the late Precambrian.

Title: Testing Snowball Earth: Subsurface Sedimentology of the Neoproterozoic Kamoa Subbasin, Democratic Republic of Congo

Presenter/First Author: Kirsten Kennedy, University of Toronto, Toronto,

Presenter/First Author Email: kirstkennedy@gmail.com

Co-authors: Nicholas Eyles, University of Toronto, Claremont, ON, Canada; David Broughton, , , ; David Edwards, , ,

Abstract Body: Systematic drilling of over 1100 wells representing some 300 km of core through a world-class stratiform copper deposit in the Kamoa Subbasin (Katanga Supergroup, Democratic Republic of Congo) has been undertaken, providing data for an unusually thorough examination of facies during a putative Snowball Earth event. The stratigraphy in the Kamoa region is composed of basement Kibaran Supergroup quartzites and basalts, interdigitating Poudingue conglomerates and Mwashya Subgroup sandstones (up to 1600 m thick), Grand Conglomerat diamictites (1600 m thick), and Kakontwe Formation stromatolitic dolomites. The basin documents a complex extensional tectonic history that presents the primary control on sedimentation via syndepositional faulting, rapid subsidence, and volcanism. The geometry of faulted basement blocks is tracked through the distribution of basement-derived breccia and fan-delta conglomerates (Poudingue). These data indicate that the subbasin was bounded to the west and the east by basement blocks which partially separated the Kamoa Subbasin from the larger Katanga Basin, leaving an outlet to the south. The transition from relatively oxidized Mwashya sandstones to a stratigraphically complex slope-toe debrite-turbidite association (Grand Conglomerat Fm.) was accompanied by faulting, cannibalization of Poudingue gravels, minor volcanism, and an influx of mud. Grand Conglomerat diamictites have long been attributed to the Sturtian glacial event, yet display frequent changes in textural styles and composition and are interbedded with deepwater heterolithic strata, indicating that sediment sources and depositional lobes fluctuated over time. While the influx of mud at the Mwashya-Grand Conglomerat transition may be related to the onset of regional glaciation, the localized effects of sediment focussing, coeval volcanism, and the dynamic topography of an extensional basin should not be understated.

Title: New Age Constraints on Middle Ediacaran Chemostratigraphy, Biostratigraphy, and the East African Orogeny from the Arabian Shield

Presenter/First Author: Galen P Halverson, McGill University, Montreal, QC

Presenter/First Author Email: galen.halverson@mcgill.ca

Co-authors: Mark David Schmitz, Boise State University, Boise, ID; Grant M Cox, McGill University, Montreal, QC, Canada; Peter R Johnson, , Portland, OR; Marcus Kunzmann, McGill University, Montreal, QC, Canada; Thomas James Maguire, McGill University, Montréal, Canada; Alan S Collins, University of Adelaide, Adelaide, Australia

Published Material: Some of the stratigraphy and fossil claims are previously published in a 2013 paper in Terra Nova by Nettle et al. The current abstract, however, is based on new radiometric age data.

Abstract Body: The middle Ediacaran Jibalah Group fills a series of small, isolated, and minimally deformed sedimentary basins in the eastern and northern Arabian Shield. These mixed volcanic-siliciclastic-carbonate basins lay along strands of the Najd Fault System, an array of transpressional structures related to lateral escape during the late stages of the East African Orogeny (EAO). The abundance of tuffs and occurrence of putative Ediacaran fossils within the Jibalah Group present the potential to calibrate the middle Ediacaran Period. Here we report new U-Pb zircon ID-TIMS age constraints from two of the Jibalah basins: the Antaq and the Jifn. Three silicified tuffs in the cyclic, shallow marine to fluvial Muraykhah Formation, the uppermost of three formations in the Antaq basin, yield ages of 599.1±0.2, 593.7±0.2, and 593.6±0.2 Ma. These tuffs span the range from which possible *Charniodiscus* and *Aspidella* fossils have been reported. The new ages also suggest that the well-defined, 10m-scale Muraykhah cycles represent ~110–130 thousand years, consistent with orbital forcing. Ages from volcanic clasts and tuffaceous siltstones in the Jifn basin suggest that it is coeval with the Antaq basin, with a maximum age constraint of 585.5±0.5 Ma on the calcareous upper member of the Umm al'Aisah Formation. This member comprises a single shoaling upward sequence with turbidites and debrites at the base and grainstones and microbialaminites at the top. Isotopic data suggest that the Jifn basin was dominantly restricted, but intermittently connected to the open ocean. These data enable us to constrain the onset of the Shuram negative carbon isotope anomaly to <585.5 Ma and the rise in seawater $^{87}Sr/^{86}Sr$ to ≥0.7085 by this time. Collectively, these new ages indicate that the Najd Fault System and the Jibalah basins initiated between 618–600 Ma, prior to final closure of the Mozambique Ocean and terminal collision of the EAO.

Title: Uncovering late Ediacaran kinematics of the Avalonia terrane using paleomagnetism

Presenter/First Author: Ross Peter Anderson, Yale University, New Haven, CT

Presenter/First Author Email: ross.anderson@yale.edu

Co-authors: David AD Evans, Yale University, New Haven, CT; Phil J A McCausland, University of Western Ontario, London, ON, Canada; Bin Wen, Nanjing University, New Haven, CT

Abstract Body: Recently published paleomagnetic data from the Avalonia terrane, Newfoundland (Pisarevsky et al., 2012) show a 70° discordance between paleomagnetic mean directions from the Bull Arm Fm. (~570 Ma) and the Crown Hill Fm. (~550 Ma), which the authors attributed to local vertical-axis rotation between sampling sites, rotation of the entire terrane between 570 and 550 Ma, or rapid apparent plate motions possibly due to true polar wander. In this study, we collected 319 samples from 7 localities around Trinity and Bonavista Bays from the Bull Arm – Crown Hill stratigraphic interval. At Duntara, Bonavista Bay, Crown Hill Fm. redbeds are very stable to demagnetization and reproduce the moderate NW-down/SE-up direction from Pisarevsky et al. (2012). The 55m section has at least 7 reversals, implying (if primary) that the late Ediacaran geodynamo was in a rapidly reversing state. Crown Hill rocks at the nearby Tickle Cove record the same direction as the Duntara rocks at three sites, including two with a structural attitude similar to Bull Arm volcanics in the same area. If primary, this would show that the remanence discordance between Crown Hill and Bull Arm Fms. is stratigraphic rather than structural. A fold test at this locality is currently inconclusive but further analyses may

clarify. On the eastern margin of Trinity Bay, redbeds from the Maturin Pond Fm. (thought to be slightly older than Crown Hill Fm.), sampled over 260m at Heart's Content, yield a 2-polarity direction that is very steep NW-down/SE-up in geographic coordinates or shallow NW-down/SE-up in tilt-corrected coordinates. Additional localities and tests are needed to determine the age of remanence in these strata. Overall, our initial dataset suggests that variations in paleomagnetic remanence directions in the Bull Arm - Crown Hill sections of the Bonavista/Trinity Bay area are not due to local structural rotations, but instead indicate rapid apparent polar wander of the Avalonia terrane.

Title: Cycles of Nutrient Trace Elements in the Phanerozoic Ocean and Relationship to Atmosphere-Ocean Oxygenation

Presenter/First Author: Ross Raymond Large, University of Tasmania, Hobart, TAS

Presenter/First Author Email: ross.large@utas.edu.au

Co-authors: Jacqueline Halpin, University of Tasmania, Hobart, Australia; Elena Lounejeva, , , ; Leonid V Danyushevsky, University of Tasmania, Hobart, TAS, Australia

Published Material: A version was presented at Goldschmidt 2014, but new data and interpretation has considerably changed the presentation

Abstract Body: Redox sensitive and nutrient trace element (TE) concentrations in the palaeo-ocean have commonly been interpreted to rise abruptly toward the end of the Neoproterozoic, and remain relatively constant through the Phanerozoic. This pattern has been considered to relate to a second stage of Earth oxygenation, resulting in, or a consequence of, the Cambrian explosion of life. Here we present a comprehensive dataset on the trace element content of marine sedimentary pyrite that defines several TE concentration cycles, on 70 to 120 million year wavelengths, with amplitude variations of several orders of magnitude. The cycles, which start in the Neoproterozoic and are best developed through the Paleozoic, have a similar pattern to the ocean $^{87}Sr/^{86}Sr$ record, suggesting that continental erosion and nutrient supply maybe a first order driver of the TE cycles. Molybdenum, thallium, selenium, cadmium, antimony and $^{87}Sr/^{86}Sr$ show cycles with a positive statistical correlation, whereas cobalt shows a negative correlation with this TE group and the $^{87}Sr/^{86}Sr$ pattern. The contrasting pattern of cobalt, which is demonstrated on all scales from a few million to a billion years is most probably due to its decrease in solubility under conditions of increasing oxidation. This opposite behavior to the other TE, implicates oxygenation as a second order driver of the redox sensitive TE cycles, and enables the tentative construction of an oxygenation curve for the Phanerozoic.

First Author Email: karlis.muehlenbachs@ualberta.ca

First Author Student?: No

Co-authors: Ralf Tappert, University of Alberta, Edmonton, AB, Canada; Ryan C McKellar, Royal Saskatchewan Museum, Regina, SK, Canada; Martin Schoell, Retired, Washington, DC

Published Material: 50% at AGU 2014 & GSA 2014.

Abstract Body: A new reconstruction of Phanerozoic atmospheric oxygen concentrations has been developed from terrestrial organic matter $d^{13}C$, revealing trends that correlate positively and significantly to those of marine carbonate-hosted $^{87}Sr/^{86}Sr$. However, the structure of this correlation is highly time-dependent, and is strongest during the upswings of Phanerozoic pO_2, in the range of 13 to 20% atmospheric O_2, that occur in the Late Paleozoic, the Jurassic, the Late Cretaceous, and the Cenozoic. We interpret these intervals to reflect combinations of orogenesis, weathering, and sedimentation that simultaneously raise ocean $^{87}Sr/^{86}Sr$ while enhancing burial of organic matter and pyrite, with the net effect of rapid and efficient oxygenation of the ocean-atmosphere system. During intervening intervals, the correlation between reconstructed atmospheric O_2 and ocean $^{87}Sr/^{86}Sr$ is much weaker, intimating that processes of O_2 removal are more complicated, temporally lagged, and inherently hysteretic. For example, deep-sea hydrothermal processes including Fe(II) oxidation and hydrous alteration of the ocean floor, while highly effective overall, produce a more sluggish response with respect to ocean-atmosphere deoxygenetion than the reverse process of O_2 re-supply mediated by burial. In support of the conceptual model that relates atmospheric pO_2 to the same processes that control ocean $^{87}Sr/^{86}Sr$, this linkage does not appear restricted to the Phanerozoic. Vanishingly low pO_2 inferred for much of the Meso- and Neoproterozoic is matched by $^{87}Sr/^{86}Sr$ ratios lower than any interval of the last 500 Ma, signifying particularly strong sea-floor O_2 sinks during the billion-year interval that presaged the Ediacaran oxygen spike, itself associated with an abrupt increase of $^{87}Sr/^{86}Sr$ and the rise of Metazoa.

Title: Intermittent Scaling of the Solar Wind Data from Ulysses: Multifractal Analysis

Presenter/First Author: Anna Wawrzaszek, Space Research Center Polish Academy of Sciences, Warsaw,

Presenter/First Author Email: sanna@cbk.waw.pl

Co-authors: Wieslaw Marian Macek, Polish Academy Sciences, Warsaw, Poland; Marius Echim, Institute of Space Sciences, Bucharest, Romania

Abstract Body: We study the evolution of intermittency in interplanetary magnetic fields with the heliocentric distance and latitude by using large amount of data from Ulysses spacecraft measured during two solar minima (1995-1997, 2007-2008) and solar maximum (1999-2001). In particular, we consider small-scale fluctuations of the magnetic field embedded in the "pure" slow and fast solar wind. To distinguish different types of solar wind we use the following parameters: radial velocity, proton density, proton temperature, the distribution of charge states of oxygen ions, and compressibility of magnetic field. We exclude from our analysis any solar wind transients (shocks, CME, magnetic clouds), thus our analysis is relevant for the "pristine" state of the wind, fast and slow. In the next step we consider the chosen intervals for fast and slow solar wind and perform multifractal analysis of components of the fluctuating magnetic field. More precisely, to quantify the degree of multifractality (intermittency) we

determine about 500 multifractal spectra of the selected data sets (magnetic field components and intensity) and fit the observations with models of the intermittent turbulence.

The multifractal characteristics of the solar wind turbulence depend on the heliographic latitudes, heliocentric distance, and phase of the solar cycle. In general, we observe a somewhat smaller degree of multifractality at high latitudes during solar minimum for the fast solar wind, where turbulence evolves more slowly as compared with that at the ecliptic plane. Moreover, it seems that the multifractality exhibits a latitudinal dependence with some symmetry with respect to the ecliptic plane. The performed analysis provide a supporting evidence that the small-scale magnetic field fluctuations observed by Ulysses exhibit a multifractal behavior that is a persistent feature of fast and slow wind, at solar maximum and minimum.

Title: Local Fluctuations and Correlations in Turbulent Cascade Rates in the Solar Wind

Presenter/First Author: Miriam A Forman, Dept of Physics & Astronomy, Stony Brook, NY

Presenter/First Author Email: miriam.forman@stonybrook.edu

Co-authors: Jesse T. Coburn, University of New Hampshire Main Campus, Durham, NH; Charles William Smith, University of New Hampshire Main Campus, Durham, NH; Bernard John Vasquez, University of New Hampshire Main Campus, Durham, NH; Julia E Stawarz, University of Colorado at Boulder, Boulder, CO

Published Material: part in Coburn, et al. in Astrophysical Journal last year

Abstract Body: Politano and Pouquet showed in two 1998 papers that the turbulent heating rate in stationary homogeneous plasmas is proportional to the slope of certain signed third moments of fluctuations in Elsasser variables with scale distance. Using plasma data from the ACE spacecraft at L_1, we found that the required third moments are highly variable, so that months of data were needed to get the third moments at each scale to converge, so we could get a meaningful heating rate. These heating rates compared well with the in-situ heating of the solar wind deduced from the non-adiabatic decay of proton temperature from the corona to 1 AU. We thought the need for large amounts of data was due to intermittency. Lately, however, we discovered that in more local 1 to 12 hour ACE data sets, the third moment of fluctuations in Elsasser variables are in practically all cases proportional to scale, with correlation coefficients close to ±1. However, the slopes and inferred local cascade rates (we hesitate to call these heating rates) are highly variable among these shorter data sets. Combining many such local cascade rates converges on meaningful heating rates as before. Furthermore, the cascade rates for outward- and inward-travelling pseudo-energies (in each Elsasser variable) in these smaller data sets tend to be anti-correlated according to the local cross-helicity. Evidence of this will be presented in this talk. We are left with the questions: Is this variation in local behavior of the third moments in solar wind another aspect of intermittency? and What do the observed anti-correlation, its dependence on cross-helicity, and the negative local cascade rates mean?

Title: Solar Wind Turbulence: the Effects of Spherical Expansion on II and III Order Structure Functions

Presenter/First Author: Andrea Verdini, University of Florence, Firenze,

Presenter/First Author Email: verdini@arcetri.astro.it

Published Material: Some of the result will be also presented at EGU 2015 meetingPart of the results are contained in a paper currently under review

Abstract Body: The Expanding Box Model (EBM) is a framework for numerical simulations of turbulence that is able to capture the effect of spherical expansion while retaining the resolution for turbulence dynamics. We have recently shown that it can reproduce two important feature of solar wind turbulence, namely the component anisotropy and the emergence of jets at large scales. We present now an analysis of the simulated solar wind turbulence in terms of II-order and III-order structure function (SF).
We find that EBM simulations are able to reproduce the observed II-order SF anisotropy with respect to the local mean field (eddy shape) and further show that the overall anisotropy depends on the direction of increments on which SF are calculated. We finally present preliminary results on III-order SF in the EBM and compare them to homogenous turbulence simulations (MHD and Hybrid-PIC) in order to highlight the effects of expansion on the III-order SF anisotropy and the resulting cascade rate.

Title: External Versus Internal Triggering of Substorms: An Information-Theoretical Approach

Presenter/First Author: Jay Johnson, Princeton Plasma Physics Lab, Princeton, NJ

Presenter/First Author Email: jrj@pppl.gov

Co-authors: Simon Wing, Johns Hopkins University, Laurel, MD; Peter A Damiano, Princeton Plasma Physics Lab, Princeton, NJ

Published Material: published in Geophysical Research Letters

Abstract Body: The role of external triggering of substorms through northward turning of the interplanetary magnetic field has been examined in a number of recent studies. While Hsu and McPherron (2002, 2004) argue that the strong association between external triggers defined by Lyons et al. (1997) and substorm onsets could be responsible for most substorms, Morley and Freeman (2007) argue that the association between northward interplanetary magnetic field (IMF) turnings and substorm onsets are coincidental rather than causal, because the same external triggers are also closely associated with an artificial list of substorm onsets generated with the Minimal Substorm Model, which has no requirement of northward IMF turning. We examine an expanded list of substorms using conditional redundancy, an entropy-based measure of conditional dependency, to examine whether northward IMF turning as an external trigger provides any additional information about substorm onset beyond knowing that there has been a period of sustained loading of energy flux (southward IMF). Our analysis reveals that only a few percent additional information is provided by the northward turning criterion, which is consistent with the statistics of surrogate data sets of external triggers constructed to coincide with 2% of substorms. We therefore conclude that northward turning of the IMF is, in general, coincidentally, rather than causally, associated with substorm onsets.

Title: Dynamical Critical Scaling of Space Storms

Presenter/First Author: James A Wanliss, Presbyterian College, Clinton, SC

Presenter/First Author Email: jawanliss@presby.edu

Co-authors: Vadim M Uritsky, NASA Goddard Space Flight Center, Greenbelt, MD

Published Material: JOURNAL OF GEOPHYSICAL RESEARCH, VOL. 115, A03215, doi:10.1029/2009JA014642, 2010

Abstract Body: Energy dissipation in the terrestrial magnetosphere often follows an intermittent temporal pattern consisting of periods of high activity with sharply increased convection, compressional pulses, intensified fluctuations of field aligned, currents and many other bursty processes, separated by periods of quiescence. Although physical mechanisms of individual activity bursts in the inner magnetosphere have been investigated in numerous studies, in this paper we explore ensemble-averaged statistical properties of these events. We examine statistical properties of bursty multiscale energy dissipation in the inner magnetosphere of Earth based on the dynamics of the SYM-H index, a global marker of low-latitude geomagnetic fluctuations. We show that on average, and for time scales shorter than 2 h, temporal development of SYM-H bursts follows an algebraic form consistent with the predictions from the theory of nonequilibrium phase transitions. The power law exponents describing the probability distributions suggest that the main energy dissipation in the inner magnetosphere takes place because of large activity bursts such as major space storms as opposed to smaller activations whose contribution is less significant despite their much higher relative occurrence. The results obtained provide statistical evidence that the energy dissipation mechanisms associated with magnetospheric activity in the inner magnetosphere are essentially “scale-free,” displaying dynamical and statistical self-similarity.

Title: On the Role of Long-Range Connectivity in Space Plasma Complexity

Presenter/First Author: Giuseppe Consolini, National Institute of Astrophysics, Roma,

Presenter/First Author Email: giuseppe.consolini@inaf.it

Co-authors: Simone Benella, , ,

Abstract Body: In many frameworks space plasmas display a self-similar dynamics in response to external driving. This is, for instance, the case of the Earth’s magnetotail plasma sheet during magnetospheric substorms in response to solar wind changes. This behavior has been interpreted in terms of a near Forced and/or Self-Organized Criticality dynamics. However, there are some aspects of the event statistics that depart from what is expected for a near criticality dynamics, resembling features more similar to extremum statistics. Here, we investigate the role that long-range connectivity plays in the space plasma avalanching systems, presenting the results of a sandpile model on network. A discussion of the similarity and differences between classical SOC models and our network model is presented with reference to the criticality behavior and the intermittent nature of the dynamics.

Title: Forecasting Solar Wind Streams from Quiescent Solar Corona and Recurrent Geomagnetic Activity

Presenter/First Author: Ljubomir Nikolic, Natural Resources Canada, Ottawa,

Presenter/First Author Email: Ljubomir.Nikolic@NRCan-RNCan.gc.ca

Co-authors: Lorne McKee, , , ; Hing-Lan Lam, Natural Resources Canada, Ottawa, ON, Canada; Larisa Trichtchenko, NRCan, Ottawa, ON, Canada

Abstract Body: The interaction of solar wind disturbances with the Earth’s magnetosphere often drives geomagnetic storms which can have adverse effects on technology and human activities. While fast transient solar disturbances, such as coronal mass ejections (CMEs), can produce the most intense geomagnetic storms, increases in geomagnetic activity are frequently associated with changes in the solar wind induced by coronal holes in the relatively quiescent corona. High-speed solar wind streams (HSS) emanating from coronal holes, which can survive several solar rotations, correlate well with geomagnetic activity; as observed in Canadian polar cap, auroral and sub-auroral zones. Forecasting solar wind disturbances represents one of the focal points of space weather research and operational activities. To forecast HSS, we use a solar wind speed forecast model based on an empirical relation (Wang-Sheeley-Arge type) between open coronal magnetic field lines and the solar wind speed. To derive the global coronal magnetic field we employ a potential source surface model and GONG magnetograms. Investigation of the short-term (5 day) solar wind forecast performance shows in general a good agreement between forecasted and observed solar wind speed during 2007-2013. To examine the disagreements, excluding CMEs, we follow an equatorial coronal hole through six solar rotations starting from its central meridian crossing on June 25, 2013. The results suggest that the inclusion of additional parameters related to numerically derived coronal holes into the empirical solar wind speed relation is necessary to improve the forecast. Furthermore, we examine the potential of a long-term (27 day) recurrent HSS forecast based on forecasted and observed solar wind from two previous solar rotations. In the quest to better forecast geomagnetic activity, we compare and discuss these results with a long-term forecast of recurrent geomagnetic activity derived only from Canadian ground magnetic observations.

Title: Study of the Formation and Topology of Flux Transfer Events using Global Numerical Simulation

Presenter/First Author: Germán Fariñas Pérez, National Institute for Space Research, Sao Jose dos Campos, SP

Presenter/First Author Email: german.farinas@gmail.com

Co-authors: Flavia R Cardoso, INPE, Sao Jose Dos Campos, SP, Brazil; Walter D Gonzalez, INPE National Institute for Space Research, Sao Jose dos Campos, Brazil

Abstract Body: We have analyzed a global magnetohydrodynamic (MHD) simulation of the magnetosphere to study the formation and magnetic topology of flux transfer events (FTEs) for reconnection during assumed interplanetary plasma and magnetic field conditions. All the interplanetary conditions have been kept constant during the simulation time. The interplanetary magnetic field (IMF) had a large southward-duskward component. The grid resolution at the subsolar magnetopause is sufficiently high to allow the formation of FTEs. We observe the spontaneous formation of FTEs under constant solar wind conditions and

zero dipole tilt. Five FTEs with clear magnetic perturbations have been detected. The characteristics of these five FTEs are identified, among them, the beginning and end of their magnetic signature, sense of propagation, speed of propagation and time onset of their movement. The first, second and fourth FTEs travel northward, while the others two move southward. The bipolar B_N signature and the intensification of the core magnetic field (B_M) are presented in all FTEs. The sense of propagation is mainly northward-dawnward in the Northern Hemisphere and southward-duskward in the Southern Hemisphere, which is consistent with the orientation of flows for a southward-duskward IMF case. The cross section of the first FTE has been analyzed in terms of the projected magnetic field, thermal pressure and core magnetic field. The typical magnetic characteristics of a flux rope were found. However, the analysis of the magnetic topology reveals that this structure is not a typical flux rope. Instead it is formed by two interlinked flux tubes which together seem to present similar characteristics of a flux rope. The magnetic topology over the magnetopause was calculated to study the generation mechanism of this event. Flow vortices have been observed in every FTE event. The flow vortices bring together regions of different magnetic topologies, which drive subsequent processes of magnetic reconnection. This could be the cause of the increased complexity in the topology observed after the interlinked flux tubes occurrence.

Title: The Global Structure and Time Evolution of Dayside Magnetopause Surface Eigenmodes

Presenter/First Author: Michael Hartinger, Virginia Polytechnic Institute and State University, Hampton, VA

Presenter/First Author Email: mdhartin@vt.edu

Co-authors: Ferdinand Plaschke, IWF ÖAW, Graz, Austria; Martin Owain Archer, Imperial College London, London, United Kingdom; Dan Welling, University of Michigan, Ann Arbor, MI; Mark Moldwin, University of Michigan, Ann Arbor, MI; Aaron J Ridley, University of Michigan, Ann Arbor, MI

Abstract Body: Theoretical work and recent observations suggest that the dayside/subsolar magnetopause may support its own eigenmode, consisting of propagating surface waves which reflect at the northern and southern ionospheres forming a standing wave. These magnetopause surface eigenmodes (MSE, also called Kruskal-Schwarzchild modes) have been proposed as source of magnetospheric Ultra-Low Frequency (ULF) waves with frequencies less than 2 mHz. Due to their large wavelengths and long periods, it is difficult to observe these waves in situ and characterize their global structure. Theoretical predictions exist for their global structure, but these are based on models with idealized geometries and zero flow shear. We use BATS-R-US global magnetohydrodynamic (MHD) simulations to study the magnetospheric response to impulsive solar wind dynamic pressure increases. Resonantly excited waves are observed whose global properties are largely consistent with the theoretical predictions for MSE and cannot be explained by other known ULF wave modes. These results demonstrate MSE can exist in realistic magnetic field geometries with nonzero flow shear.

Title: Shape of the terrestrial plasma sheet in the near-Earth magnetospheric tail as imaged by the Interstellar Boundary Explorer (IBEX)

Presenter/First Author: Maher A Dayeh, Southwest Research Institute San Antonio, San Antonio, TX

Presenter/First Author Email: maher.aldayeh@swri.org

Co-authors: Stephen Fuselier, Southwest Research Institute San Antonio, San Antonio, TX; Herbert O Funsten, Los Alamos Natl Laboratory, Los Alamos, NM; David J McComas, Southwest Research Institute San Antonio, San Antonio, TX; Keiichi Ogasawara, Southwest Research Institute, San Antonio, TX; Steven M Petrinec, Lockheed Martin Corporation, Sunnyvale, CA; Nathan Schwadron, University of New Hampshire, Durham, NH; Philip W Valek, Southwest Research Inst, San Antonio, TX

Abstract Body: We present remote, continuous observations from the Interstellar Boundary Explorer (IBEX) of the terrestrial plasma sheet location up to ~16 earth radii (R_E) back in the magnetospheric tail using energetic neutral atom (ENA) emissions. The time period studied includes two orbits near the winter and summer solstices, thus associated with large negative and positive dipole tilt respectively. Continuous side-view images reveal a complex shape that is dominated mainly by large-scale warping due to the diurnal motion of the dipole axis. Superposed on the global warped geometry are short-time fluctuations in plasma sheet location that appear to be consistent with plasma sheet flapping and possibly twisting due to changes in the interplanetary conditions. We conclude that the plasma sheet warping due to the diurnal motion dominates the average shape of the plasma sheet. Over short times, the position of the plasma sheet can be dominated by twisting and flapping.

Title: The Role of Multiple Atmospheric Reflections in the Formation of Electron Distribution Functions in the Diffuse Aurora Region

Presenter/First Author: George V Khazanov, NASA Goddard Space Flight Center, Greenbelt, MD

Presenter/First Author Email: george.v.khazanov@nasa.gov

Co-authors: Alex Glocer, NASA/GSFC, Greenbelt, MD; David G Sibeck, NASA/GSFC, Greenbelt, MD

Abstract Body: The precipitation of high-energy magnetospheric electrons ($E > 500$-600 eV) in the diffuse aurora contributes significantly to the energy flux into the Earth's ionosphere. It has been found [Khazanov et al., JGR, 2014] that quantifying this flux at the upper boundary of the ionosphere requires a consideration of the entire coupled ionosphere-magnetosphere system. In the diffuse aurora, precipitating electrons initially injected from the plasmasheet via wave-particle interaction processes degrade in the atmosphere toward lower energies and produce secondary electrons via impact ionization of the neutral atmosphere. These precipitating electrons can be reflected back into the magnetosphere from the conjugate atmospheres, leading to a series of multiple reflections that can greatly influence precipitating flux at the upper ionospheric boundary (700-800 km) and the resultant secondary electron population. We present a solution of the Boltzman-Landau kinetic equation that uniformly describes the entire electron distribution function in the diffuse aurora, including the affiliated production of secondary electrons ($E < 600$ eV). This solution takes into account, for the first time, the role of multiple atmospheric reflections of the precipitated electrons that were initially moved into the loss cone via wave-particle interaction processes in the Earth's plasmasheet. Our results will be compared with the THEMIS observations.

Title: Investigation of the Causes of Anomalous Ionosphere Electron Density Variations

Presenter/First Author: Philip G Richards, George Mason University Fairfax, Dunn Loring, VA

Presenter/First Author Email: pgrichds@gmail.com

Co-authors: Robert R Meier, George Mason University Fairfax, Fairfax, VA; Shihping Chen, NCU National Central University of Taiwan, Jhongli, Taiwan

Abstract Body: This research investigates the causes of anomalous diurnal behavior of the mid latitude ionospheric electron density known as the Weddell Sea Anomaly. Our approach is to use the FLIP ionosphere model together with measurements of electron density from ground based ionosondes, electron density profiles from the COSMIC satellites, neutral densities from TIMED-GUVI, and in situ ion and neutral densities from the Atmosphere Explorer-C satellite. This paper demonstrates the inadequacy of previously proposed explanations of these unusual nighttime enhancements, and investigates the hypothesis that neutral density variations play a key role in their formation. In particular, we demonstrate that the magnetic declination effect on neutral winds is not the main cause of Weddell Sea Anomaly.

Reeves (2015),Characterization of the energy-dependent response of riometer absorption, J. Geophys. Res. Space Physics, 120, doi:10.1002/2014JA020027.http://onlinelibrary.wiley.com/doi/10.1002/2014JA020027/abstract

Abstract Body: Ground based riometers provide an inexpensive means to continuously remote sense the precipitation of electrons in the dynamic auroral region of Earth's ionosphere. The energy-dependent relationship between riometer absorption and precipitating electrons is thus of great importance for understanding the loss of electrons from the Earth's magnetosphere. In this study, statistical and event-based analyses are applied to determine the energy of electrons to which riometers chiefly respond. Time-lagged correlation analysis of trapped to precipitating fluxes shows that daily averaged absorption best correlates with ~ 60 keV trapped electron flux at zero-time lag, although large variability is observed across different phases of the solar cycle. High-time resolution statistical cross-correlation analysis between signatures observed by riometer stations, and assuming electron motion due to gradient and curvature drift, results in inferred energies of 10-100 keV, with a clear maximum in occurrence for 40-60 keV
electrons. One event is considered in detail utilizing riometer absorption signatures obtained from several stations. The mean inferred energies for the initial rise time and peak of the absorption after correction for electric field effects were ~ 70 keV, and ~ 60 keV, respectively. The analyses presented provide a means to characterize the energy of electrons to which riometers are responding in both a statistical sense, and during the evolution of individual events.

Title: New Perspectives on Small-Scale and Rapidly Varying Auroral Structures from CASSIOPE e-POP Fast Auroral Imager (FAI) Observations

Presenter/First Author: Leroy Cogger, Retired, Calgary,

Presenter/First Author Email: yau@ucalgary.ca

Co-authors: Andrew David Howarth, University of Calgary, Calgary, AB, Canada; Andrew W Yau, University of Calgary, Calgary, AB, Canada

Abstract Body: The Fast Auroral Imager (FAI) on the CASSIOPE Enhanced Outflow Probe (e-POP) consists of two CCD cameras, which measure the atomic oxygen emission at 630 nm and prompt auroral emissions in the 650 to 1100 nm range, respectively, using a fast lens system and high quantum-efficiency CCDs to achieve high sensitivity, and a common 26 degree field-of-view to provide nighttime images of about 650 km diameter at apogee (1500 km). The FAI is capable of operating in four viewing modes: nadir viewing, for imaging over a large latitude range; Earth-target viewing, for pointing at an emission target of fixed altitude, latitude and longitude; limb viewing, for measurement of altitude profiles; and inertial pointing; for imaging of an inertial target such as a star field. The near infrared camera provides up to two images of 0.1 sec exposure per second, with a spatial resolution of a few km in the nadir viewing mode, while the 630-nm camera provides one image of 0.5 sec exposure every 30 seconds. The four viewing modes make possible the observations of a variety of auroral and airglow phenomena, such as transpolar arcs and drifting polar patches, rapidly varying and small-scale auroral structures in the auroral oval, and detached and stable auroral red (SAR) arcs as well as airglows at lower latitudes. We will focus on new features in the observed data and the resulting new perspectives on auroral structures in the context of high-resolution studies of the ionosphere.

Title: Imaging the Dynamic Auroral Ionosphere and Polar Ionosphere Using Incoherent Scatter Radar and All-Sky Imaging

Presenter/First Author: Stephen Roland Kaeppler, SRI International, Menlo Park, CA

Presenter/First Author Email: stephen.kaeppler@sri.com

Co-authors: Michael J Nicolls, SRI International Menlo Park, Menlo Park, CA; Russell B Cosgrove, SRI International San Luis Obispo, San Luis Obispo, CA; Anja Stromme, SRI International Menlo Park, Menlo Park, CA; Donald Hampton, University of Alaska Fairbanks, Fairbanks, AK

Abstract Body: Advanced Modular Incoherent Scatter Radar (AMISR) systems have enabled multi-dimensional observations within the nightside auroral zone (PFISR) and deep within the polar cap (RISR). AMISR systems are phased-array radars capable of beam steering on a pulse-to-pulse cadence. Heinselman and Nicolls [2008] described a technique for determining the horizontal plasma flow pattern from AMISR measurements and applied this method to the estimation of E-region neutral winds. More recently, Nicolls et al., [2014] enhanced this technique to determine the electrostatic potential at F-region altitudes using a minimum curvature estimator [Cosgrove et al., 2014]. We present results of studies that have made use of the velocity field imaging applied to auroral electrodynamics in the nightside region and polar cap.

A next step forward in ISR imaging is to fold in complimentary data sources that can be used with the ISR data to improve estimates of ionospheric parameters. All-sky color imagers, collocated with ISRs, make line-of-sight measurements of the visible light emission at a variety of different wavelengths corresponding to different physical processes. Given an incident electron spectrum, forward electron transport models have been used to predict visible auroral emission and volume ionization rate, which can be indirectly observed by ISR. The all sky imagers generally provide measurements over a larger field-of-view and at much higher time cadence than ISR, thus the measurements contain useful information that can be used to enhance the spatial and temporal resolution of the 3-D electron density estimation. We present a new technique for merging photometric and ISR observations to generate improved estimates of the 3-D electron density structure in the auroral ionosphere. The improved electron density estimate can be used to determine the 3-D conductivity, and, when combined with vector electric field images, the 3-D current structure can be determined in a localized region. We discuss the applicability of this technique to monostatic ISR and the AMISR system. We use this technique to investigate currents systems and energy transfer in the auroral ionosphere, and for studies of high latitude auroral conductivity to ingestion into models.

Title: Source and evolution of the ionospheric F-region tongue of ionization and patches

Presenter/First Author: Wenbin Wang, High Altitude Observatory, Boulder, CO

Presenter/First Author Email: wbwang@ucar.edu

Co-authors: Jing Liu, , , ; Alan Geoffrey Burns, National Center for Atmospheric Research, Boulder, CO; Stanley C Solomon, National Center for Atmospheric Research, Boulder, CO

Abstract Body: The high-resolution NCAR Thermosphere-Ionosphere-Electrodynamics General Circulation Model (TIE-GCM) has been employed to numerically study the source and evolution of the ionospheric F-region tongue of ionization (TOI) and patches, which are electron density enhancements in the polar region with fine structures. The model is run for different interplanetary magnetic field (IMF) conditions. It is found that the formation of TOI and patches is critically dependent on the Universal Time (UT). TOI and patches occur preferentially at the UT when the high latitude ion convection pattern is closer to the daytime high middle latitude ionosphere so more plasma can be transported into the polar region. This UT dependence is different between the northern and southern hemispheres because of the different separations of the magnetic poles from the geographic poles in the two hemispheres. Furthermore, the effect of subauroral polarization streams (SAPS) on the formation of TOI and patches is examined by running the TIEGCM with and without the SAPS in the model.

Title: Spatial characteristics of pulsating aurora as a function of latitude

Presenter/First Author: Robert Michell, Southwest Research Institute, San Antonio, TX

Presenter/First Author Email: rmichell@swri.edu

Co-authors: Marilia Samara, NASA Goddard Space Flight Center, Greenbelt, MD; Donald L Hampton, University of Alaska Fairbanks, Fairbanks, AK

Abstract Body: We will present an analysis of the spatial characteristics of pulsating aurora from 3 different latitudes where pulsating auroral features have been observed using green line all-sky imaging at 3 frames per second. At higher latitudes---near the polar cap boundary at 74 degrees geomagnetic latitude---the auroral patches of pulsating appear larger and more spread out longitudinally. At auroral latitudes of 66 degrees geomagnetic latitude---where we have the most observations--the patches are smaller and irregularly shaped. At lower latitudes--sub-auroral, 55 degrees geomagnetic latitude--the auroral patches are even smaller. We will quantify the differences between the spatial characteristics of pulsating aurora at these three different latitudes. An understanding of these differences in spatial characteristics will be used to gain insight into the magnetospheric processes causing the electron precipitation for these three distinctly different latitude regimes.

Title: Small-scale Structure and Variability in Mid-Latitude Ionospheric Plasma Convection

Presenter/First Author: J. Michael Ruohoniemi, Virginia Tech, Blacksburg, VA

Presenter/First Author Email: mikeruo@vt.edu

Co-authors: Joseph B. H. Baker, Virginia Polytechnic Institute and State University, Blacksburg, VA; Evan G Thomas, Virginia Polytechnic Institute and State University, Blacksburg, VA; William Bristow, University of Alaska Fairbanks, Fairbanks, AK; Simon G Shepherd, Dartmouth College, Hanover, NH

Abstract Body: The plasma of the mid-latitude ionosphere is perturbed by strong electric fields that extend equatorward of the usual auroral zone during disturbed periods. The resulting plasma density irregularities and plasma convection are observed with the radars of the new mid-latitude SuperDARN chain. In addition, the radars regularly observe backscatter from the ionosphere on the nightside during quiet times at subauroral latitudes; these velocities measure only tens of meters per second and appear to be well organized. The fields of view of the mid-latitude radars overlap extensively forming common volumes in the North American sector that make it possible to map the structure and variability of the convection with high confidence at the smallest resolutions afforded by the radar measurements, namely, tens of seconds in time and tens of kilometers in distance. We describe early results from a study of the characteristic scales of velocity variation in mid-latitude plasma convection and the connection to effects in Magnetosphere-Ionosphere-Thermosphere coupling.

Title: Enhanced N2 and O Neutral Densities as an Explanation of Rapid Electron Density Decay Following Ionization Surges in the Ionosphere

Presenter/First Author: Dmytro Sydorenko, University of Alberta, Edmonton, AB

Presenter/First Author Email: sydorenk@ualberta.ca

Co-authors: Robert Rankin, University of Alberta, Edmonton, AB, Canada

Published Material: Preliminary results of the study were presented at 2014 AGU Fall Meeting, poster SM43A-4258, "The interaction of high-m guided poloidal alfven waves with magnetospheric electrons and the ionosphere".

Abstract Body: On April 21, 1993, between 0320 and 0400 UT, the EISCAT radar and ground based magnetometers recorded evidence of intense Pc5 waves and electron precipitation with a wide energy spectrum [*Lester, Davies, and Yeoman*, 2000]. The high-energy (40 keV) part of the precipitation started about an hour earlier and created dense plasma at an altitude near 100 km. Immediately before the event, the plasma density was monotonically decaying above 100 km with no maximum in the F-layer. The flux of electrons with energies below a few keV was pulsating with the wave frequency (5.2 mHz) and produced a sequence of strong but short-lived plasma density enhancements at altitudes between 150 km and 300 km. The dense plasma produced during each precipitation pulse decayed completely within just two minutes. The event is analyzed using a numerical model of the coupled ionosphere and magnetosphere developed by [*Sydorenko and Rankin*, 2013]. When MSIS thermospheric neutral densities were used in the model, the rate of plasma density decay was more than two times lower than is necessary to explain the observations, and the density maximum in the F-layer appears. The reason for this is an abundance of oxygen atoms and, correspondingly, atomic oxygen ions, which have no direct recombination process. In order to achieve the required plasma density decay rate and altitude profile in the simulation, the density of nitrogen and oxygen molecules is increased by a factor ranging from 7 to 18 in an altitude range between 100 and 320 km, while the density of oxygen atoms is decreased by a factor of 3.5 below 350 km. A qualitatively similar modification of the composition of neutrals in the thermosphere during periods of intense magnetospheric activity is known from observations and numerical models [*Prolss and Fricke,* 1976; *Mikhailov and Foster*, 1997].

Title: Characteristics of short-range HF echoes in the presence of sporadic E layers

Presenter/First Author: Alexandre V Koustov, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: sasha.koustov@usask.ca

Co-authors: Kateryna Yakymenko, University of Saskatchewan, Saskatoon, SK, Canada

Abstract Body: SuperdARN HF radars often detect echoes at short ranges. These are traditionally associated with the E region irregularities generated through the electrojet plasma instabilities. However, determination of the real height of echo detection or irregularity location is difficult; this severely limits possibility of relating echo characteristics with specific electroject instability processes. We investigate a special class of SuperDARN echoes observed in the presence of strong sporadic E layers that block HF radio wave penetration deep into the ionosphere so that the echoes are very likely received from the lower E region, below 100 km. Joint data of the Clyde River (CLY) HF radar and Pond Inlet (PI) CADI ionosonde are considered. We give statistics on typical echo power, Doppler velocity and spectral width of such echoes and compare them with the same characteristics for non-Es cases. We conclude that the only clearly identifiable difference of Es-related CLY echoes is their generally smaller velocities although, occasionally, values close to the nominal ion-acoustic speed can be seen. We also compare CLY velocities at short ranges with simultaneous CLY measurements at far ranges as well as with the velocity data from other SuperDARN radars and the PI ionosonde.

Title: High-Resolution Observations of Ionospheric Plasma from Swarm and ePOP

Presenter/First Author: David J Knudsen, University of Calgary, Calgary, AB

Presenter/First Author Email: knudsen@ucalgary.ca

Co-authors: Johnathan K Burchill, University of Calgary, Calgary, AB, Canada; William Edward Archer, University of Calgary, Calgary, Canada; Taylor Grant Cameron, University of Calgary, Calgary, AB, Canada; Matthew Patrick, University of Calgary, Calgary, AB, Canada; Yangyang Shen, , ,

Abstract Body: The ionosphere has been probed extensively at scales of 1 km and larger, both from the ground and in situ. However, numerous observations have shown that ionospheric structuring on finer scales is widespread, and that the most highly structured events are often also the most intense. This talk will present new observations on sub-kilometer scales from ion and electron distribution imaging sensors currently flying on two satellite missions launched in late 2013, namely the European Space Agency's Swarm mission and Canada's Enhanced Polar Outflow Probe. Swarm's Thermal Ion Images are used to produce on-board velocity moments at a rate of 16 per s, with a corresponding spatial resolution of approximately 500 m. The ePOP Surpathermal Electron Imager captures 2-D distributions of electron fluxes at having energies up to 350 eV, on spatial scales as small as 70 m in bursts lasting 5-10 minutes. This talk will present Swarm and ePOP observations of highly structured ionospheric plasma including fast flow channels and associated Poynting flux and anisotropic ion heating, structured ion upflow, and velocity-dispersed suprathermal electron bursts in the auroral zone.

Title: Low-Altitude Cusp Ion Upflow and Downflow at Kilometer Scales

Presenter/First Author: Johnathan K Burchill, University of Calgary, Calgary, AB

Presenter/First Author Email: j.burchill@ucalgary.ca

Co-authors: David J Knudsen, University of Calgary, Calgary, AB, Canada; Stephan C Buchert, IRF Swedish Institute of Space Physics Uppsala, Uppsala, Sweden

Abstract Body: We present detailed observations from the Swarm Electric Field Instruments of vertical ion flow, ion temperature, electron

temperature, and electron density structured on scales of a few to tens of kilometers in the vicinity of Earth's magnetic cusps. Swarm measures upflow and downflow and plasma heating on scales as small as the measurement resolution of ~4 km (<0.1° of magnetic latitude). Structured upflows are at times observed in association with electron heating, frictional ion heating, both, or neither. Structured ion downflows with warm ion temperatures are often observed poleward of the upflow. We test the hypothesis that these downflows are populations of poleward-convecting heated upflows that, not having attained escape velocity, splash into the polar cap ionosphere.

Title: High resolution observations of plasma properties around sporadic E layers at low latitude in the evening sector: evidence for unexpected electrodynamic feedback and parallel currents.

Presenter/First Author: Jean-Pierre St-Maurice, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: jp.stmaurice@usask.ca

Co-authors: Aroh Barjatya, Embry-Riddle Aeronautical University, Daytona Beach, FL; Matthew D Zettergren, Embry-Riddle Aeronautical Univ, Daytona Beach, FL

Published Material: The presentation is based on results initially presented in a JGR paper published in 2013.

Abstract Body: Rocket observations of the low latitude E region were carried out near the Kwajalein atoll during the EQUIS II campaign. The observations took place in the early evening sector, but well after sunset. High spatial resolution (100 m) observations were made of the electron density and temperature, together with the two perpendicular electric field components and the two neutral wind components (zonal and meridional) that are known to be able to drive sporadic E (Es) layers. Two Es layers were indeed observed. Two well-defined electron temperature (Te) peaks were also recorded above each Es layer. The Te peaks reached of the order 1000 K, which is very large when compared to the expected 300 K expected for the E region. Our analysis of the data revealed that the electric field played a strong role in the formation of the top Es layer while the bottom layer appeared to match expectations from the observed neutral winds. Undulations in the perpendicular electric field triggered by the impact on the F region dynamo field of the Es layers themselves was also such that the evolution of the top Es layer was affected by its own location. The Te peaks were found to be consistent with field-aligned currents (FAC) of the order of a few micro-amp per meter square. It was also noted that Te in the Es layers was hotter than expected, suggesting that even more intense FAC were involved in those locations. The FAC responsible for the Te peaks had to be related to the bottom-side of the F region nighttime dynamo while the FAC associated with the Es layer peaks were due to diverging Hall currents related to the steep changes in the conductivities in conjunction with a relatively strong zonal electric field. These observations suggest that parallel currents are an important part of the night-time electrodynamics around Es layers and that the formation of Es layers can be more complicated than normally thought. Results from first calculations will be presented.

Title: Some New Results in Solar Terrestrial Coupling

Presenter/First Author: David J Thomson, Queen's University, Kingston, ON

Presenter/First Author Email: djt@mast.queensu.ca

Published Material: Studies of solar modes in terrestrial and spacecraftdata continue to surprise and I discuss several new results.First, both p--modes and low frequency g-modes are detectablein geomagnetic data. Below ~1 mHz the magneticsignal to noise ratio is better than that of optical data.Second, at frequencies above the Sun's 5.1 mHz acoustic cutoff frequency,spectra of geomagnetic data have many high-Q lines with the characteristic 136uHzspacing of solar modes. This should allow better characterizationof solar pseudo (pp) modes.Third, because ACE is in a synodic orbit and Ulysses' orbitis nearly sidereal, one can test the identification ofsolar g-modes by looking at frequency agreement on theazimuthal quantum numbers.This gives several g-modes with all the expected singletsdetected and in agreement.

Abstract Body: Studies of solar modes in terrestrial and spacecraft data continue to surprise and I discuss several new results.
First, both p--modes and low frequency g-modes are detectable in geomagnetic data. Below ~1 mHz the magnetic
signal to noise ratio is better than that of optical data.
Second, at frequencies above the Sun's 5.1 mHz acoustic cutoff frequency, spectra of geomagnetic data have many high-Q lines with the characteristic 136uHz
spacing of solar modes. This should allow better characterization of solar pseudo (pp) modes.
Third, because ACE is in a synodic orbit and Ulysses' orbit is nearly sidereal, one can test the identification of solar g-modes by looking at frequency agreement on the
azimuthal quantum numbers. This gives several g-modes with all the expected singlets detected and in agreement.
Because these modal signatures are seen in interplanetary space, in the magnetospere, and in the solid earth, they must traverse the ionosphere and should be seen there as well.

Title: Modulation of the Ionospheric Total Electron Content by ULF Waves

Presenter/First Author: Viacheslav Pilipenko, Space Research Institute RAS, Moscow,

Presenter/First Author Email: pilipenk@augsburg.edu

Abstract Body: An intriguing effect was found while analyzing the small-scale variations of total electron content (TEC) derived from global positioning system (GPS) signals. We found a response in TEC variations to intense global Pc5 pulsations with periods of a few mHz covering the CGM latitudes ~58°-75° during the recovery phase of the strong magnetic storms on Oct. 2003. The GPS-TEC technique has turned out to be a powerful method to study the interaction of ULF waves with the ionosphere. During periods with intense Pc5 geomagnetic wave activity distinct pulsations with the same periodicity were found in the TEC data from high-latitude GPS receiving stations in Scandinavia. Wavelet and cross-spectral analysis showed a high coherence between the periodic geomagnetic and TEC variations. Combined usage of magnetometers and GPS/TEC is a very promising way to reveal the physical mechanism of disturbances. The relative amplitude of TEC periodic fluctuations DTEC/TEC was about or even larger than the relative amplitude of geomagnetic variations DB/B. The effect of TEC modulation by Pc5 waves is not well understood and is still a challenge for the MHD wave theory. Various possible modulation mechanisms have been estimated, but no mechanism has been firmly identified.

Title: Probing Ionosphere-Magnetosphere coupling with the combination of in-situ and ground based measurements: the GREECE mission

Presenter/First Author: Marilia Samara, NASA Goddard Space Flight Center, Greenbelt, MD

Presenter/First Author Email: marilia.samara@nasa.gov

Co-authors: Robert Michell, Southwest Research Institute, San Antonio, TX; Guy Alan Grubbs, University of Texas at San Antonio, San Antonio, TX; Donald L Hampton, University of Alaska Fairbanks, Fairbanks, AK; John W Bonnell, University of California Berkeley, Berkeley, CA; Keiichi Ogasawara, Southwest Research Institute, San Antonio, TX

Published Material: The specific findings were not reported but an overview of the GREECE mission was given at the Fall AGU in San Francisco, December 2014.

Abstract Body: The Ground-to-Rocket Electrodynamics-Electrons Correlative Experiment (GREECE) sounding rocket successfully launched from Poker Flat, Alaska on 03 March 2014 reaching an apogee of 335 km. GREECE launched into a dynamic post-midnight auroral arc event—rich in particle and wave signatures—that occurred directly over the downrange imaging site of Venetie, AK. The onboard electron detectors measured the precipitating electrons, which were then compared to the optical auroral structures that they were responsible for. The ground-based auroral imaging consisted of 6 different imagers with a total of 3 separate fields of view, providing information about the aurora on both the large-scale (>10 km) and the small scale (~100 m). This yielded multi-emission line intensities of the auroral brightness at the magnetic footprint of the rocket critical for our main goal of exploring the correlation of the sheer flows—often observed in high resolution imagery during aurora—and the in situ signatures of precipitating particles and waves. The emission line brightness data correlate well with electron characteristics taken by the Acute Precipitating Electron Spectrometer (APES). The ultimate goal is to characterize the auroral emissions produced from a known precipitating electron distribution, such that we can more accurately use ground-based imaging and photometry to infer the characteristics of the precipitating electrons. These techniques can then be applied over larger scales and longer times, when only multi-spectral imaging data are available with no corresponding in situ data. Moreover, using both electron detectors and the electric field instrument on board GREECE we were able to determine that the auroral flows are not caused by large-amplitude electric fields in the low altitude (<400 km) ionosphere. The nature of the electron precipitation reveals that the flow structure is caused by motions of the electron source region, occurring much farther out in the near-Earth space environment.

Title: Relativistic electron precipitation and substorm auroras

Presenter/First Author: Joshua L Semeter, Boston Univ, Boston, MA

Presenter/First Author Email: jls@bu.edu

Abstract Body: We report evidence for relativistic electron precipitation in substorm auroras. Multi-beam measurements by the electronically steerable Poker Flat Incoherent Scatter Radar (PFISR) reveal transient patches of ionization extending below 70 km altitude. These regions are restricted to the poleward edge of the auroral expansion phase. Reconstructed vertical density profiles, analyzed using a particle penetration model, suggest that the primary electron spectrum contains a significant population in the 300-600keV range. Proton precipitation is ruled out due to the limited horizontal extent of these regions and the extreme energies required for protons to penetrate to these altitudes. This electron population is not likely produced by near-Earth acceleration mechanisms. The likely source lies in the magnetotail, where substorm dipolarization can readily energize electrons to the relativistic range. Our interpretation is supported by magnetically conjugate measurements from the THEMIS satellite for one of these events, which reveal a remarkably impulsive reconfiguration of the magnetotail preceding one of these events. These results exemplify the unique scientific capability of common volume measurements by electronically steerable ISR and wide-field cameras.

Title: Electrodynamic Coupling Between Inertial Scale Alfven Waves and the High-latitude Auroral Ionosphere

Presenter/First Author: Dmytro Sydorenko, University of Alberta, Edmonton, AB

Presenter/First Author Email: sydorenk@ualberta.ca

Published Material: The model description and several aspects of ion upflow formation were published in JGR in 2012 and 2013; some details of feedback instability and wave emission were presented at 2011 AGU Chapman conference, Fairbanks, ALaska.

Abstract Body: Small scale inertial Alfven waves (IAWs) can accelerate auroral electrons and are considered to be an important part of energy coupling between the magnetosphere and high latitude ionosphere. The coupling of IAWs with the ionosphere is affected by wave and background precipitation, heating due to wave and convection electric fields, and strong vertical nonuniformity of the bottom layers of the ionosphere. We have developed a comprehensive two-dimensional numerical model of the coupled magnetosphere and ionosphere that includes these effects. The model considers torsional Alfven waves in the presence of an externally imposed convection electric field, chemical reactions between ions and neutrals, various cooling and heating processes, and a parametric model of electron precipitation. The model's spatial resolution in the E-layer can be as fine as tens of meters in the horizontal direction, and hundreds of meters in the vertical direction. We present applications of the model that are designed to understand reflection of waves with short transverse wavelength from the ionosphere, formation of ion upflows, feedback instabilities, and emission of Alfven waves by convecting plasma nonuniformities in the E-layer. The results are compared with observations from the Canadian ePOP satellite, and ground-based instruments of the GO-Canada observatory.

Title: Small-scale secondary electron features and FACs in diffuse and pulsating aurora

Presenter/First Author: Sarah Jones, NASA Goddard Space Flight Center, Greenbelt, MD

Presenter/First Author Email: sarah.l.jones@nasa.gov

Co-authors: Marc Lessard, University of New Hampshire Main Campus, Durham, NH; Leroy Cogger, Retired, Calgary, Canada; Andrew W Yau, University of Calgary, Calgary, AB, Canada; David J Knudsen, University of Calgary, Calgary, AB, Canada; Kristina A Lynch, Dartmouth College, Hanover, NH; Dirk Lummerzheim, University of Alaska Fairbanks, Anchorage, AK; Hans Stenbaek-Nielsen, , , ; Allison N Jaynes, University of Colorado Boulder, Boulder, CO

Published Material: The preliminary findings were presented in poster format at previous AGU conferences. Currently a manuscript is in preparation.

Abstract Body: Observations of small-scale structures in the secondary and backscattered populations associated with diffuse and pulsating aurora have been observed by several spacecraft including ePOP, REIMEI, and the ROPA sounding rocket. We present in situ observations of such sub-keV electron precipitation mapped into the THEMIS GBO all-sky images, with evidence of field aligned currents and acceleration through parallel electric fields. These observations are consistent with Sato et al. (2002, 2004) who show FAST measurements of sub-keV inverted-V structures collocated with pulsating aurora. In the case of ROPA, the sub-keV electron signatures appear to be the result of secondary / backscattered electrons that are accelerated downward through a potential at an altitude above the spacecraft. Thus the intermittency of the sub-keV signatures seen in the ROPA measurements would reflect structure in the accelerating potential, suggesting small scale, local electric field structure above the spacecraft. A lack of velocity dispersion in these accelerated, secondary electron signatures is consistent with an acceleration region that is not far from the spacecraft, or may suggest a lack of temporal variation in the associated accelerating field structure during the measurement. PFISR observations of similar pulsating aurora show, in some directions, high altitude electron density enhancements that likely correspond to sub-keV electron signatures. The higher altitude density enhancements associated with the sub-keV electron signatures more or less align with gaps between lower altitude density enhancements presumably caused by the pulsating patches. This raises questions as to the role of the ionosphere in the generation of pulsating aurora.

Title: Correlated ULF Waves, Whistler-mode Chorus and Pulsating Aurora Observed by the Van Allen Probes and Ground-based Systems

Presenter/First Author: Allison N Jaynes, University of Colorado Boulder, Boulder, CO

Presenter/First Author Email: allison.jaynes@lasp.colorado.edu

Co-authors: Marc Lessard, University of New Hampshire Main Campus, Durham, NH; Kazue Takahashi, Applied Physics Laboratory Johns Hopkins, Laurel, MD; Ashar Ali, University of Colorado at Boulder, Boulder, CO; David Malaspina, University of Colorado, Boulder, Boulder, CO; Craig Kletzing, University of Iowa, Iowa City, IA; John R Wygant, University of Minnesota Twin Cities, Minneapolis, MN; Eric Donovan, University of Calgary, Calgary, AB, Canada; J Bernard Blake, Aerospace Corporation Santa Monica, Santa Monica, CA; Robert Michell, Southwest Research Institute, San Antonio, TX; Marilia Samara, NASA Goddard Space Flight Center, Greenbelt, MD; Emma Spanswick, University of Calgary, Calgary, AB, Canada

Published Material: Preliminary findings reported at LWS meeting (Oct 2014) and more analysis reported at AGU (Dec 2014). Final work is expected to be published before Joint Assembly in the Pulsating Aurora special issue of JGR.

Abstract Body: Theory and observations have linked equatorial VLF waves with pulsating aurora for decades, invoking the process of pitch-angle scattering of 10's keV electrons in the equatorial magnetosphere. Recent satellite studies have strengthened this argument, by showing strong correlation between pulsating auroral patches and (1) lower-band chorus observed by THEMIS and (2) 30-100 keV electron modulation in the vicinity of geosynchronous orbit observed by GOES. Additionally, a link has been made between Pc4-5 compressional pulsations and modulation of whistler-mode chorus using THEMIS. Here we present simultaneous in-situ observations of structured chorus waves and an apparent field line resonance as a result of a substorm injection, observed by Van Allen Probes, along with ground-based observations of pulsating aurora. We demonstrate the possible scenario being one of substorm-driven ULF pulsations modulating chorus waves, and thus providing the driver for pulsating particle precipitation into the Earth's atmosphere. We also show, for the first time, a particular 3-Hz modulation of individual chorus elements. Such modulation has been noticed as a high-frequency component in camera data of pulsating aurora for decades, and is possibly a result of nonlinear chorus wave interactions.

Title: Dynamics of auroral particle acceleration by kinetic Alfvén waves

Presenter/First Author: Robert L Lysak, University of Minnesota Twin Cities, Minneapolis, MN

Presenter/First Author Email: bob@fields.space.umn.edu

Abstract Body: It is now generally believed that there are at least two forms of auroral particle acceleration: a nearly monoenergetic acceleration through quasi-static parallel electric fields, and a broad-band acceleration associated with the propagation of kinetic Alfvén waves along auroral field lines. This Alfvénic acceleration also takes on two forms. In the low-β region at low altitudes, the electrons can be accelerated in bulk by the parallel electric field. At higher altitudes, where the plasma β is larger than the electron-to-ion mass ratio, electrons can be accelerated due to a Landau damping process. Furthermore, the precipitation of electrons due to Alfvénic acceleration leads to conductivity enhancements in the ionosphere, which can provide a positive feedback in structuring auroral currents. In addition, the production of secondary and backscattered electrons modifies the structure of the auroral flux tube and can set up conditions conducive to the formation of plasma double layers. These interactions will be illustrated through numerical simulations of the interaction of kinetic Alfvén waves with the auroral ionosphere.

Title: New Features of Substorm and Storm Dynamics Revealed by Coordinated ISR-ASI Measurements of Auroral Dynamics

Presenter/First Author: Larry R Lyons, University of California Los Angeles, Los Angeles, CA

Presenter/First Author Email: larry@atmos.ucla.edu

Co-authors: Toshi Nishimura, University of California Los Angeles, Los Angeles, CA; Donald Hampton, University of Alaska Fairbanks, Fairbanks, AK; Vassilis Angelopoulos, University of California Los Angeles, Los Angeles, CA; Eric Donovan, University of Calgary, Calgary, AB, Canada; Michael J

Nicolls, SRI International Menlo Park, Menlo Park, CA; Steven Chen, SRI International Menlo Park, Menlo Park, CA

Abstract Body: Coordinated imager and radar observations of the auroral oval have previously revealed that bursts of enhanced flow within the plasma sheet lead to most magnetosphere-ionosphere disturbances (i.e., PBIs, streamers, substorms). Using incoherent-scatter radar and all-sky-imager observations, we have identified weak, azimuthally moving auroral features near the equatorward boundary of the auroral oval. We find that they are associated with large azimuthal flow bursts in the SAPS region, and we find evidence that they originate from tail flow bursts that are guided to the SAPS by the large-scale evening side convection. We have evidence that some of these flow bursts can extend earthward of the pre-existing SAPS region, leading to ring current earthward injections and proton aurora. We have previously seen that localized flow enhancements from the polar cap can contribute significantly to plasma sheet flow bursts and substorm expansion phase activity. We now have found striking new evidence that these polar cap flow enhancements feed new plasma into the head of the westward traveling surge, and thus may play a critical in driving the surge.

Title: Ion Temperature Anisotropy Measured in Regions of Strong Electric Fields Adjacent to Auroral Arcs

Presenter/First Author: William Edward Archer, University of Calgary, Calgary,

Presenter/First Author Email: archer@phys.ucalgary.ca

Co-authors: David J Knudsen, University of Calgary, Calgary, AB, Canada; Johnathan K Burchill, University of Calgary, Calgary, AB, Canada; Matthew Patrick, University of Calgary, Calgary, AB, Canada; Jean-Pierre St-Maurice, University of Saskatchewan, Saskatoon, SK, Canada

Published Material: Some of these findings were recently accepted pending minor review in "ESA's Swarm Mission, One Year in Space", a special edition of GRL.

Abstract Body: The Swarm satellites observe strongly anisotropic ion temperatures at 500 km altitude with temperature anisotropy ratios varying from 2 to 10. Coincident measurements with THEMIS All-Sky imagers suggest that these highly localized regions of ion heating are associated with strong electric fields at the edge of auroral precipitation. The ion temperature enhancements appear to depend on electric field strength and are comparable to what is expected from ion frictional heating theory. However, the observed perpendicular-to-parallel temperature ratios exceed the values predicted by existing calculations of collisional heating by as much as a factor of 2 in the strongest flows. If these observations are an accurate representation of the steady state collisional environment, they suggest that the collisional cross-sections currently used in collisional heating calculations should be revised. However it is also possible that the measurements are not made in a steady state environment, in which case a velocity distribution dispersion associated with vertical transport and occurring on a scale of minutes would also be able to affect the observed anisotropies.

Title: Simulations of the Dynamics of the Radiation Belts using VERB 4D Diffusion-convection code

Presenter/First Author: Yuri Shprits, Massachusetts Institute of Technology, Cambridge, MA

Presenter/First Author Email: yshprits@atmos.ucla.edu

Co-authors: Adam C Kellerman, University of California Los Angeles, Los Angeles, CA; Alexander Drozdov, University of California Los Angeles, Los Angeles, CA; Ksenia Orlova, University of California Los Angeles, Los Angeles, CA

Published Material: 60% of these resuls were presented at the fall AGU meeting.

Abstract Body: Modeling and understanding of ring current and radiation belt coupled system has been a grand challenge since the beginning of the space age. In this study we show long term simulations with a 3D VERB code of modeling the radiation belts with boundary conditions derived from observations around geosynchronous orbit. We also present 4D VERB simulations that include convective transport, radial diffusion, pitch angle scattering and local acceleration. VERB simulations show that the lower energy inward transport is dominated by the convection and higher energy transport is dominated by the diffusive radial transport. We also show that at energies of 100s of keV a number of processes work simultaneously including convective transport, radial diffusion, local acceleration, loss to the loss cone and loss to the magnetopause.

Title: Observations of a Global Coherence Scale Modulating Electron Loss Due to Plasmaspheric Hiss

Presenter/First Author: Aaron W Breneman, The University of Minnesota, Minneapolis, MN

Presenter/First Author Email: awbrenem@gmail.com

Published Material: Talk presented at Fall AGU 2014.

Abstract Body: Over 40 years ago it was suggested that electron loss in the region of the radiation belts that overlaps with the high density plasmasphere is largely due to interaction with an electromagnetic plasma wave called plasmaspheric hiss. Motivated by the difficulty of observing this loss process on satellites alone, the Balloon Array for Radiation Belt Relativistic Electron Losses (BARREL) mission was designed to provide complementary observations of bremsstrahlung x-rays generated by hiss-scattered electrons colliding with atmospheric neutrals after removal from the radiation belts. In addition to providing direct evidence that hiss causes electron loss, we have discovered that 1-20 min period fluctuations of x-rays and hiss amplitude are coherent on spatial scales comparable to the size of the plasmasphere, far exceeding the few km scale on which wave-particle interactions operate. Our results established a new correlation scale and indicate that electrons as far inwards as the electron slot region may be more strongly influenced by dynamics of the magnetosphere than previously thought. These effects have not been currently incorporated into global radiation belt electron loss models.

Title: Electron and proton precipitation during a solar storm: Observations of a SEP and CME-shock arrival by BARREL.

Presenter/First Author: Alexa Halford, Dartmouth College, Hanover, NH

Presenter/First Author Email: Alexa.Halford@gmail.com

Published Material: The precipitation due to the CME-Shock arrival and subsequent magnetosphereic phenomena has been submitted to JGR. Portions of this work have been presented at the AGU fall meeting and the LWS meeting in November 2014.

Abstract Body: The Balloon Array for Radiation belt Relativistic Electron Losses (BARREL) observed X-rays from precipitating electrons as well as Solar energetic proton events (SEPs) in the Earth's atmosphere. During the second campaign in January 2014 two SEP events were detected in the BARREL payloads as they produced atmospheric X-rays, ɣ-rays, and directly injected protons observed by the scintillator on the BARREL payloads. A total of 6 payloads were up during the solar storm beginning 7 January with an X-class flare at 1832 UT, spread across a wide range of L and MLT. Payload 2I was on open field lines for the entire event while 2T (2W) crossed from open (closed) to closed (open) field lines over the course of the three days. Payloads 2K and 2L were moving from the inner magnetosphere (L ~ 4) to higher field lines (L>6.6) while 2X stayed within the inner magnetosphere (L<6.6). Throughout this time, there were multiple conjunctions with the Van Allen Probes and good agreement with when and at what L- values the energetic protons were observed. As the SEP subsided, the CME-shock originating from the active region reached the magnetosphere, compressing it and ultimately generating an electric field impulse and chorus waves leading to precipitation of lower energy electrons (10's – 100's of keV) observed by 2 payloads located near noon and in close conjunction with the Van Allen Probes and GOES. The electron precipitation was observed to be due to a combination of the electric field impulse and ultimately chorus waves. This is a unique event as BARREL observed portions of the entire solar/geomagnetic storm process.

Title: Precipitating Solar Energetic Particles and Higher Latitude Geomagnetic Environment

Presenter/First Author: Sharad Chandra Tripathi, Barkatullah University, Bhopal,

Presenter/First Author Email: risingsharad@gmail.com

Co-authors: Pramod Kumar Purohit, National Institute of Technical Teachers' Training and Research, Bhopal, India; Parvaiz Ahmad Khan, , , ; Ashok Kumar Gwal, , ,

Abstract Body: Solar Energetic Particles the most devastating Solar Transients disturbes completely the high latitude electrical systems after precipitation. They are responsible for the aurora and infact drive the geomagnetic storms as well in some way. In the present analysis the spectral behavior of Solar Energetic Particles have been investigated with respect to the current systems and geomagnetic storms. The ionospheric responses in different hemispheres have also been investigated. The Geomagnetic disturbance indices Dst and PC have been used in the present study and fairly good correlation has been found between particle spectral indices and PC index. In accordance different ionospheric responses have been observed in the different hemispheres during geomagnetic storms.

Title: Particle Precipitation in the Thermosphere-Ionosphere

Presenter/First Author: Stanley C Solomon, National Center for Atmospheric Research, Boulder, CO

Presenter/First Author Email: stans@ucar.edu

Abstract Body: Energetic particles from the magnetosphere ionize the high-latitude thermosphere at altitudes above about 100 km, causing auroral displays to occur, and contributing to formation of the ionosphere. During geomagnetic disturbances, the number and energy of these particles intensifies, leading to dramatic increases in ionization, conduction of magnetospheric currents, and significant heating and disturbance of the thermosphere-ionosphere system. Chemical changes accompany these increases, driven primarily by dissociation of molecular nitrogen and formation of odd-nitrogen compounds. This presentation will give an overview of processes driven by this particle "precipitation" into the thermosphere/ionosphere, and discuss some of the uncertainties involved in measuring and modeling the magnitude and variability of ionized and dissociated gases produced in the aurora.

Published Material: A preliminary version of this in AOGS2014

Abstract Body: Recent studies have shown that chorus waves are responsible for scattering energetic electrons that drive the pulsating aurora. While some of the chorus intensity modulation events are correlated with <~100 eV electron density modulation, most of the chorus intensity modulation events in the post-midnight sector occur without apparent density changes. Although it is generally difficult to find evolution of low-energy (<~20 eV) electron fluxes due to constraints imposed by the spacecraft potential and ESA energy range limit, we identified using THEMIS satellite data that low-energy ions of ~100 eV show density modulation that is correlated with chorus intensity modulation. Those low-energy ions and electrons are field-aligned with major peaks in 0 (for northern hemisphere winter event) and 180 (for northern hemisphere summer event) deg pitch angle, indicating that outflowing plasma from the sunlit hemisphere is the source of the low-energy plasma density modulation near the equator. Plasma sheet plasma density and ambient electric and magnetic fields do not show modulations that are correlated with the chorus intensity modulation. Assuming charge neutrality, the low-energy ions can be used to represent cold plasma density in wave growth rate calculations, and the enhancements of the low-energy plasma density are found to contribute most effectively to chorus linear growth rates. These results suggest that chorus intensity modulation is driven by a feedback process where outflowing plasma due to energetic electron precipitation increases the equatorial density that drives further electron precipitation.

Co-authors: Andrew W Yau, University of Calgary, Calgary, AB, Canada; David J Knudsen, University of Calgary, Calgary, AB, Canada; Johnathan K Burchill, University of Calgary, Calgary, AB, Canada; Andrew David Howarth, University of Calgary, Calgary, AB, Canada; David M Miles, University of Alberta, Edmonton, AB, Canada; Philip G Richards, George Mason University Fairfax, Dunn Loring, VA; Robert J Redmon, Natl Geophysical Data Ctr, Boulder, CO

Abstract Body: On July 28, 2014 at 00:48:14 the Canadian ePOP and DSMP F17 satellites were in near magnetic conjunction over a weak arc feature in the southern polar cap. They were near the same altitude (DSMP: 876km ePOP:1175 km). The precipitating electron flux estimated at DMSP was ~2 ergs/s-cm2) almost all of it coming from electrons with energies significantly greater than 100 eV. The Suprathermal Electron Imager (SEI) on ePOP observed a weak precipitating flux of low energy (less than 100 eV) electrons associated with a field aligned current system observed on both satellites. Here we present detailed observations and compare them with calculations made using the Field aligned interhemispheric plasma (FLIP) code.

Title: Contribution of Ion Velocity Shears in the Direct Generation of Small-Scale Irregularities in the High-Latitude F Region

Presenter/First Author: Patrick Perron, Royal Military College of Canada, Kingston, ON

Presenter/First Author Email: patrick.perron@rmc.ca

Co-authors: Jean-Marc Arthur Noel, , , ; Jean-Pierre St-Maurice, University of Saskatchewan, Saskatoon, SK, Canada; Konstantin Kabin, Royal Military College of Canada, Kingston, ON, Canada

Published Material: Part of this research was presented at the DASP meeting in February 2014. These results have not been published yet.

Abstract Body: Plasma instabilities play an important role in producing small-scale irregularities in the ionosphere. In particular, current-driven electrostatic ion-acoustic (CDEIA) instabilities contribute to high-latitude F-region electrodynamics. CDEIA instabilities are affected by ion velocity shears. Ion velocity shears are observed near auroral arc edges, sometimes coexisting with thermal ion upflow processes and field-aligned currents (FAC). The detection of naturally enhanced ion-acoustic lines (NEIALs) near the edges of auroral structures, often linked with ion upflows and parallel FACs, suggests that shear-modified CDEIA instabilities could take place in these regions. These observations led us to investigate whether these shears could enhance the incoherent scattering from CDEIA waves in the high-latitude F-region. We studied the effects of ion velocity shears on the theoretical incoherent scatter radar (ISR) spectrum density function (SDF) for stable plasmas. We found that, under the right conditions, small shears produce significant enhancements in ISR spectra, especially for directions near perpendicular to the geomagnetic field. This could lead to overestimations in the interpreted electron to ion temperature ratio and electron density when using standard ISR fitting procedures.

Title: Improved Techniques for Monitoring and Investigating Polar Cap Absorption

Presenter/First Author: Robyn A Fiori, Natural Resources Canada, Ottawa, ON

Presenter/First Author Email: rfiori@nrcan.gc.ca

Co-authors: Donald W Danskin, Organization Not Listed, Washington, DC; Larisa Trichtchenko, NRCan, Ottawa, ON, Canada

Abstract Body: Shock waves produced in front of coronal mass ejections can accelerate solar energetic protons Earthward where they are guided by the Earth's magnetic field into the high-latitude polar cap region. Energetic >10 MeV protons can penetrate into the ionosphere increasing ionization in the D-region causing a polar cap absorption (PCA) event potentially blocking out high frequency (HF) radio communications at high latitudes. This is of direct importance to the safety of transpolar flights which communicate using the affected radio signals. Riometer instruments are able to monitor variations in ionospheric absorption by observing background cosmic radio noise. This paper presents a newly developed two-dimensional display for viewing riometer-derived absorption on a Canada-wide scale. Two display options are examined: (1) displaying observations at the coordinates of riometers stations, and (2) modeling absorption across the entire high-latitude region. Such visualization tools will greatly enhance the monitoring and investigation of ionospheric effects on HF radio communication allowing system operators to optimize system performance thereby contributing to the reduction of economic losses during PCA events.

Title: Effect of solar flare and solar wind on space weather variation

Presenter/First Author: Balveer Singh Rathore, Jiwaji University Gwalior, Gwalior,

Presenter/First Author Email: balveer_singhra@yahoo.co.in

Co-authors: Dinesh Chandra Gupta, , ,

Published Material: this contained published in Research in astronomy and astrophysics in volume 15, number 1, 2014. and some part underproses in other journals

Abstract Body: Today's challenge for space weather research is to quantitatively predict the
dynamics of the magnetosphere from measured solar wind and interplanetary magnetic
field (IMF) conditions. Correlative studies between geomagnetic storms (GMSs)
and the various interplanetary (IP) field/plasma parameters have been performed to
search for the causes of geomagnetic activity and develop models for

predicting the
occurrence of GMSs, which are important for space weather predictions. We find a
possible relation between GMSs and solar wind and IMF parameters in three different
situations and also derived the linear relation for all parameters in three situations.
On the basis of the present statistical study, we develop an empirical model. With the
help of this model, we can predict all categories of GMSs. This model is based on the
following fact: the total IMF Btotal can be used to trigger an alarm for GMSs, when
sudden changes in total magnetic field Btotal occur. This is the first alarm condition
for a storm's arrival. It is observed in the present study that the southward Bz component
of the IMF is an important factor for describing GMSs. A result of the paper is
that the magnitude of Bz is maximum neither during the initial phase (at the instant
of the IP shock) nor during the main phase (at the instant of Disturbance storm time
(Dst) minimum). It is seen in this study that there is a time delay between the maximum
value of southward Bz and the Dst minimum, and this time delay can be used
in the prediction of the intensity of a magnetic storm two-three hours before the main
phase of a GMS. A linear relation has been derived between the maximum value of
the southward component of Bz and the Dst, which is Dst =
(¡0:06)+(7:65)Bz +t.
Some auxiliary conditions should be fulfilled with this, for example the speed of the
solar wind should, on average, be 350 km s¡1 to 750 km s¡1, plasma ¯ should be low
and, most importantly, plasma temperature should be low for intense storms. If the
plasma temperature is less than 0:5£106 K then the Dst value will be greater than the
predicted value of Dst or if temperature is greater than 0:5£106 K then the Dst value
will be less (some nT).

Abstract Body: Effect of low-latitude D-region ionosphere is examined during the space weather events of solar flare and the geomagnetic storm, occurred on 9 March 2012, by means of the associated perturbations of several subionospheric VLF/LF signals. VLF data recorded at the time of solar flare show an amplitude enhancement of 2.5dB and a strong fluctuation in the amplitude of the VLF signals during the recovery phase of the flare event, which is due to geomagnetic storm and persisted through the end of the data-recording period. Further, signal absorption is seen during recovery. We suggest that both the subsequent fluctuations and signal absorption were associated with variations in the precipitation flux of energetic electrons onto the upper atmosphere due to storm. The occurrence rate of lightning-induced electron precipitation (LEP) events, as recorded on several VLF/LF signals as well as tweek analysis results were seen to be highly variable with geomagnetic activity on the day. Quantitative modeling of subionospheric VLF/LF wave propagation incorporating energetic electron flux measurements yield results consistent with the variations in the VLF signal amplitude observed.

Title: Investigation of correlation between the lower ionospheric perturbations with seismic anomaly as detected by subionospheric VLF signals

Presenter/First Author: Ashutosh K Singh, Banaras Hindu University, Varanasi,

Presenter/First Author Email: ashutoshksingh.bhu@gmail.com

Co-authors: Uma Pandey, R.B.S. Engineering Technical Campus Bichpuri, Agra, India; O.P. P. Singh, R.B.S. Engineering Technical Campus Bichpuri, Agra, India; Birbal Singh, Raja Balwant Singh Engineering Tech. Campus, Bichpuri Agra, Agra, India

Abstract Body: The seismogenic lower ionosphereic perturbations in association with the earthquakes are being investigated here, using subionospheric VLF propagation. As the target to find correlation between the VLF propagation anomaly (average nighttime amplitude, nighttime fluctuation) and earthquakes we have analyzed a long period of data over 5 years from 2010 to 2014. VLF data analysis is done for the propagation path from NWC (in North West Cape, Australia) to Agra, India. As the latest advancements in the VLF method analysis we have used the fluctuation power spectra in the frequency range of atmospheric gravity waves (period = 10 min to 100 min) to confirm the presence of seimo-ionospheric perturbations. Further superimposed epoch analysis has been undertaken, in order to find the correlation of the ionospheric perturbations with seismic activity. Analysis results show that there occur significant anomalies in VLF propagation few days (3 and 5 days) before the earthquake, indicating significant correlation with the earthquakes. Finally we have discovered an important correlation between number of pre/after shocks and anomalous signal i.e. ionospheric anomalies.

Title: Solar flare induced sudden amplitude/phase anomalies as a consequence of ionospheric D-region perturbation

Presenter/First Author: Uma Pandey, Banasthali University, Tonk,

Presenter/First Author Email: pandeyuma68@rediffmail.com

Co-authors: Ashutosh K Singh, Banaras Hindu University, Varanasi, India; Birbal Singh, Raja Balwant Singh Engineering Tech. Campus, Bichpuri Agra, Agra, India; O.P. P. Singh, R.B.S. Engineering Technical Campus Bichpuri, Agra, India; V K Saraswat, Bansthali University, Bansthali, India

Published Material: Submitted in "Astrophysics and Space Science" and the manuscript is under review.

Abstract Body: The results of solar flare induced D-region perturbation studies along a short great circle path (GCP = 6690 km) lying entirely in the low and equatorial latitude region are presented. We use SoftPAL receiver at Agra (Geograph. lat. 27.2°N, long. 78°E), India and monitor NWC signal (f= 19.8 kHz) transmitted from Australia. We analyze the data for the year

2011 and find that the results of amplitude and phase perturbations, time delay, zenith angle independence, and electron density variation in the lower ionosphere are consistent with those observed along similar paths at low and high latitudes. The new work includes; (i) the distribution of peak X-ray flares in the mixed solar cycle period 2011 responsible for clear and measurable sudden phase anomalies (SPAs) is different from that in minimum solar cycle period, though the cut off hardening factor is the same; (ii) the phase anomalies are evaluated in terms of X-ray fluence (J/m^2); (iii) the perturbation due to X-class of flare is used to calculate the electron densities in 70-60 km height range which are found to be 60-80 % lower than those in the polar region where X-ray flare is followed by solar proton event.

Title: Localization and Turbulent Spectrum of 3-D Kinetic Alfvén Wave in Intermediate Beta Plasma

Presenter/First Author: Prachi Sharma, Indian Institute of Technology Delhi, New Delhi,

Presenter/First Author Email: ps5739@gmail.com

Co-authors: R P Sharma, Indian Institute of Technology Delhi, India, Delhi, India; Nitin Yadav, IIT Delhi, New Delhi, India

Abstract Body: Numerical simulation of the coupled normalized equations guided by the 3-D kinetic Alfvén wave (KAW) and slow magnetosonic wave dynamics in the intermediate beta plasma have been demonstrate in the present study. We have examined the localization/filamentation and power spectrum of 3-D kinetic Alfvén wave for this nonlinear interaction. Pump KAW exerts a ponderomotive force on the slow magnetosonic wave and thereby results in localization of the wave. The coupling between KAW and slow magnetosonic wave has been studied numerically and the results were found to be consistent with the observation of THEMIS spacecraft in magnetopause.

Title: Role of Kinetic Alfvén Wave in Energy Transportation in Magnetopause

Presenter/First Author: Neha Pathak, Indian Institute of Technology Delhi, Delhi,

Presenter/First Author Email: npsneha90@gmail.com

Co-authors: R P Sharma, Indian Institute of Technology Delhi, India, Delhi, India; Nitin Yadav, IIT Delhi, New Delhi, India

Abstract Body: The transportation of energy is the vital subject in space physics. Magnetohydrodynamic waves are known to play very important role in plasma transportation. In the present work, we have studied the localization of kinetic Alfvén wave (KAW), which is three dimensionally propagating. These localized structures might be a possible candidate for transported energy at small scales in dissipation range of turbulent spectra. For this scenario, governing dynamical equation of KAW has been derived taking ponderomotive nonlinearity into account. Furthermore, these equations are solved numerically using pseudo spectral method in magnetopause regime to analyse the localized structures of KAW and corresponding turbulent spectrum. Spectrum shows steeper scaling followed by inertial range and this steepening is due to the transportation of energy from large to small scale, which eventually contributes to heating of plasma. The present mechanism may be useful for explaining the plasma heating and particle acceleration in magnetopause.The present study is correlated with the observations made by Chaston et al. [2008] using THEMIS data.

Title: 1/k-Spectrum in the Sub-Inertial Domain of Turbulence: A Shell-Model Approach.

Presenter/First Author: Giuseppe Consolini, National Institute of Astrophysics, Roma,

Presenter/First Author Email: giuseppe.consolini@inaf.it

Co-authors: Rossana De Marco, INAF-Istituto di Astrofisica e Planetologia Spaziali, Roma, Italy; Vincenzo Carbone, Departmento de Fiscia, Arcavacata di Rende, Italy

Abstract Body: Many physical and astrophysical fluid and plasma turbulent systems display the presence of a 1/f (or 1/k assuming Taylor's hypothesis) spectral domain at temporal (or spatial) scales above the inertial range, whose origin is still not understood. Here, we investigate the formation of a 1/k spectral domain in fluid and MHD turbulence systems in the sub-inertial range (k < k0 where k0 is the injection scale) by means of shell-model simulations. Our results suggest that the 1/k domain emerges as a consequence of competing direct and inverse cascading process. The relevance of our results for observations in space and astrophysical contexts is briefly discussed.

Title: Circularly Polarized Dispersive Alfvén Wave In Solar Wind Turbulence

Presenter/First Author: Swati Sharma, Indian Institute of Technology Delhi, New Delhi,

Presenter/First Author Email: swati.sharma704@gmail.com

Co-authors: R P Sharma, Indian Institute of Technology Delhi, India, Delhi, India

Published Material: No, the present article is to be submitted in a scientific journal soon.

Abstract Body: ***Abstract***

The physical properties of solar wind turbulence and its evolution have been an intense topic of exploration for decades. The inertial range of Solar wind turbulence can be described by a magnetohydrodynamic model. The dispersive range of the solar wind turbulence likely consists of several kinds of waves. The obliquely propagating waves, e.g., the kinetic Alfvén wave and whistler wave, are considered to be an important factor in the solar wind turbulence. On the other hand, parallel propagating right(R) and left(L) circularly polarized Alfvén/ ion cyclotron wave in the framework of Hall MHD are also thought to be essential ingredients of the solar wind turbulence. Recently, He et.al[1] have used the magnetic field data from the STEREO spacecraft to calculate the magnetic helicities in the solar wind turbulence. Their analysis indicates the possible existence of Alfvén -cyclotron waves and their coexistence with the right handed polarized fluctuations (kinetic Alfvén waves or whistler waves). In the present article we intend to study the temporal evolution of right and left circularly polarized dispersive Alfvén wave (DAW) and their role in the solar wind turbulence. Dispersion is considered on account of the finite frequency (frequency comparable to ion gyro frequency) of the pump wave. The individual DAW dynamics of two modes in the presence of the density fluctuations (ion acoustic/magnetosonic) is obtained and simulated numerically. We have then studied the transient evolution of DAW when transverse density perturbations are present in the background. The power spectrum is investigated which shows a steepening for scales larger than the proton inertial length. This is consistent with the recent work by Meyrand et.al[2]. The observations in the solar wind also indicate that L and R modes coexist uptil the pump wave frequency remains less than or comparable to the ion cyclotron frequency[1].

Title: Multi-scale Structural Analysis of Magnetosheath Turbulence with Rank Ordered Fractals

Presenter/First Author: Marius Echim, Institute of Space Sciences, Bucharest,

Presenter/First Author Email: marius.echim@gmail.com

Co-authors: Costel Munteanu, University of Oulu, Oulu, Finland; Tom Chang, Massachusetts Institute of Technology, Cambridge, MA

Abstract Body: In-situ measurements of magnetic field fluctuations in the terrestrial magnetosheath revealed fundamental differences between the quasi-perpendicular and quasi-parallel geometries. In the quasi-parallel case the fluctuations are strongly intermittent as suggested by the scale dependent non-Gaussian wings of the probability distribution functions (PDFs) and the scale dependent behaviour of their fourth order moment. A previous study of the intermittent magnetosheath turbulence for a quasi-parallel geometry (Sundkvist et al., PRL, 2007) discussed the energy dissipation in terms of reconnecting thin current sheets scaling with the local Larmor radius. The Rank Ordered Multifractal Analysis (ROMA) is a data analysis method constructed with the aim of identifying the various individual fractal behaviour of multifractal fluctuations (Wu and Chang, Phys Rev E, 2008). ROMA is capable of disentangling the ranges of fluctuations that exhibit the same fractal (self-similar) dimension in terms of the local invariant property based on the scaled amplitude of fluctuations and thereby identifying the different regimes of fluctuations (e.g., persistency) and physical processes (e.g., kinetic/MHD). A ROMA analysis of the intermittent turbulence in the magnetosheath describing the multiscale and dissipation behaviour over ranges of scales, in the coarse-grained sense, will be presented. We will also discuss the relevance of the analysis for general studies of turbulence in solar system plasmas.

Title: Statistical Analysis of Intermittency in the Solar Wind using Rank-Ordered Multifractal Analysis of Ulysses data

Presenter/First Author: Herve Lamy, Belgian Institute for Space Aeronomy, Brussels,

Presenter/First Author Email: herve.lamy@aeronomie.be

Co-authors: Marius Echim, Institute of Space Sciences, Bucharest, Romania; Tom Chang, Massachusetts Institute of Technology, Cambridge, MA

Abstract Body: The intermittent properties of the turbulence in the solar wind are investigated using Ulysses data and the direct Rank-Ordered Multifractal Analysis (ROMA) developed by Chang & Wu (2008). Ulysses databases were carefully selected previously in the framework of the STORM project (http://www.storm-fp7.eu/) in order to use only pure slow and fast solar wind data. They correspond to 3 time periods : 1997-1998 and 2007-2008 for the solar minimum and 1999-2001 for solar maximum.

We start by illustrating the key-features of ROMA applied on Ulysses magnetic field data recorded in the fast solar wind and explain the usefulness of the method to understand plasma complexity and turbulence. Then we provide the multifractal (ROMA) spectra s(Y) obtained for different heliographic latitudes, radial distances and types of wind (fast versus slow). We discuss the statistical properties of the intermittency for each data set as resulting from ROMA analysis.

Title: Non linear effects associated with kinetic Alfvén wave in solar wind plasmas.

Presenter/First Author: Nidhi Gaur, Indian Institute of Technology Delhi, New Delhi,

Presenter/First Author Email: nidhiphysics@gmail.com

Co-authors: R P Sharma, Indian Institute of Technology Delhi, India, Delhi, India

Published Material: These findings will be shortly submitted after minor revisions in a scientific journal.

Abstract Body: The nonlinear phenomena are of striking importance in understanding the particle acceleration, heating and turbulence in the interplanetary space. Alfvén waves are known to be the exact solution of the ideal magnetohydrodynamic (MHD) system and when this MHD Alfvén wave develops a large perpendicular wave number transverse to the ambient magnetic field it creates kinetic Alfvén wave (KAW). These waves may be responsible for accelerating the solar wind and powering the solar wind turbulence. Plasma contains a variety of low frequency modes like ion acoustic, magnetosonic mode and even the low frequency KAW. The ponderomotive force of (relatively high frequency, high power) pump KAW may be used to excite the low frequency KAW. This is the motivation of the present work to analyze the nonlinear dynamics of relatively high frequency pump KAW in the presence of comparatively low frequency KAW perturbation and its effect on the solar wind turbulence. For this purpose the dynamical equations to analyze the nonlinear dynamics of relatively high frequency pump KAW in the presence of comparatively low frequency KAW perturbation are derived. The numerical solution has been carried out for the coupled system of equations by using the pseudospectral method for space integration and finite difference method along with the predictor corrector scheme for the evolution in time. The coupled system of nonlinear dynamical equations is analyzed to study the nonlinear effects associated with pump KAW and the resulting turbulent spectra at 1 AU. The averaged power spectrum in the quasisteady state (ensemble contains 10 spectra) obtained follows the Kolmogorov scaling which further steepens after k>1. Therefore, this nonlinear interaction due to KAWs may lead to the distribution of energy among the large and intermediate wavenumbers at k>1[Saharoui et al., 2010; Howes et al. 2008]. Energy transfer is implicated by the spectral index followed by the turbulent energy spectrum. The process of filamentation attributed to the energy transfer amongst the nonlinearly interacting modes is also studied. The present model may have some applicability to understand the initiation of turbulence in the solar wind.

[1]Centre for Energy Studies, Indian Institute of Technology Delhi, Delhi-110016, India

ABSTRACT

We have studied the effect of background density fluctuations on the formation of localized large amplitude structures and turbulent spectrum of kinetic Alfvén wave (KAW) applicable to magnetopause. Numerical simulation has been performed to study these structures. Localization becomes more intense with the growth of numerous structures at later times. From the results, we found that background fluctuations affect the localization process of KAW. Simulation results reveal that power spectrum deviates from Kolmogorov scaling at the transverse size of KAW, equal to ion gyroradius. Steepening of power spectrum at shorter wavelengths may be accountable for heating and acceleration of the plasma particles. Thus the presented coupling suggests a mechanism of energy transfer from larger length-scales to smaller length-scales. The relevance of present investigation with observations collected from the THEMIS spacecraft in magnetopause is also discussed [Chaston et al., 2008].

Title: Small-scale Turbulence in The Terrestrial Magnetosheath by Cluster Observations

Presenter/First Author: Emiliya Yordanova, IRF Swedish Institute of Space Physics Uppsala, Uppsala,

Presenter/First Author Email: eya@irfu.se

Co-authors: Hugo Breuillard, LPC2E/CNRS, Orleans, France; Zoltan Voros, Space Research Institute, Graz, Austria; Olga Alexandrova, Paris Observatory, Paris, France

Abstract Body: Terrestrial magnetosheath is the interface region between the solar wind and the Earth's magnetosphere. The interaction between the solar wind plasma and the magnetospheric plasma results in the formation of a very complex and turbulent region associated with intensive and highly variable fluctuations in all plasma parameters. By using different approaches we attempt to identify and characterize the quasi-linear waves and coherent structures arising from the dynamical behavior of magnetosheath plasma at scales around the proton scale. The data analysis is based on Cluster spacecraft measurements.

The research leading to these results has received funding from the European Community's Seventh Framework Programme ([FP7/2007-2013]) under grant agreement n 313038/STORM.

Published Material: This is already in under review in the SCI journal.

Abstract Body: This paper is devoted to the study of the nonlinear interaction and propagation of high frequency pump inertial Alfvén wave (IAW) with comparatively low frequency inertial Alfvén wave (IAW) with emphasis on nonlinear effects and applications within space plasma and astrophysics for low - plasma. We have developed the set of dimensionless equations in presence of ponderomotive nonlinearity due to high frequency pump IAW in the dynamics of comparatively low frequency IAW. Stability analysis and numerical simulation has been carried out for the coupled system comprising of pump IAW and low frequency IAW to study the localization and turbulent spectra, applicable to auroral region. The result reveals that localized structures becomes more complex and intense in nature at the quasi steady state. From the obtained result, we found that the present model may be useful to study the turbulent fluctuations in accordance with the observations of FAST/THEMIS spacecraft.

Title: Motion of the Polar Cap Arcs and Associated Plasma Flows

Presenter/First Author: Kateryna Yakymenko, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: kay431@mail.usask.ca

Co-authors: Alexandre V Koustov, University of Saskatchewan, Saskatoon, SK, Canada; Keisuke Hosokawa, University of Electro-Communications, Tokyo, Japan

Abstract Body: Arc-like auroral structures in the polar cap often move in the dawn-dusk direction. Speeds of such motions vary between ~100 m/s and 2 km/s depending on the magnetic local time of observations. In the midnight sector, typical speeds of 300-500 m/s have been reported. We show that these values are somewhat larger than plasma flow speeds in the zonal direction typically observed by the Clyde River SuperDARN HF radar. This raises a question whether the zonal motion of the polar cap arcs is consistent with the projection of the ExB plasma velocity on the direction of the shift. In this study, we consider several events of the polar cap arc monitoring with the Resolute Bay 630 nm all-sky imager and concurrent measurements of the plasma flow with the PolarDARN/SuperDARN HF radars and Resolute Bay–North AMISR incoherent scatter radar to assess typical plasma flows established in the ionosphere while the arcs move through the common field-of-view. We show that the optical arcs zonal speed is close to the ExB velocity component. We also investigate the microstructure of plasma flows in the arcs' vicinity by adding to the large-scale SuperDARN convection patterns data from localized AMISR measurements. For one event, plasma density and magnetometer measurements on the SWARM satellite are added to estimate the location and intensity of the field-aligned currents.

Title: Auroral Response to Sudden Changes in the Solar Wind and IMF

Presenter/First Author: Emma Spanswick, University of Calgary, Calgary, AB

Presenter/First Author Email: elspansw@ucalgary.ca

Co-authors: Eric Donovan, University of Calgary, Calgary, AB, Canada; Eric M. Grono, University of Calgary, Calgary, AB, Canada; Brian J Jackel, University of Calgary, Calgary, AB, Canada

Abstract Body: Sudden changes in the solar driver of magnetospheric activity provide us with exciting opportunities to study the physics of the aurora. In this talk, we focus on how sudden impulses, where the solar wind dynamic pressure changes significantly and quickly, affect the auroral distribution. In particular, we look at polar cap aurora observed in the Oxygen redline with the new Geospace Observatory (GO) Canada REdline Geospace Observatory (REGO) network of imagers, focusing on a sudden impulse that occurred around 11 UT on December 23, 2014. During this event, clearly as a result of the sudden impulse, numerous pre-existing transpolar arcs brighten significantly and stay bright for hours following. The pre-existence, multiplicity, and brightening of the transpolar arcs all speak to their origin.

Title: Electron Energy Dispersion as seen by the ePOP Suprathermal Electron Imager

Presenter/First Author: Taylor Grant Cameron, University of Calgary, Calgary, AB

Presenter/First Author Email: taylor987@gmail.com

Co-authors: David J Knudsen, University of Calgary, Calgary, AB, Canada; Johnathan K Burchill, University of Calgary, Calgary, AB, Canada; H Gordon James, Retired, Ottawa, ON, Canada

Published Material: Some of this work was reported in a poster at the CEDAR Workshop in 2014. Taylor Cameron*, David Knudsen, Jonathan Burchill. Electron Energy Dispersion as seen by the ePOP Suprathermal Electron Imager, CEDAR Workshop 2014, Seattle

Abstract Body: A candidate mechanism for accelerating auroral electrons is acceleration by Alfven waves. These waves can accelerate electrons to velocities of the order of the Alfven speed. Wave acceleration has been linked to energy dispersion, a distinct signature that can be seen in particle detectors. This signature is a burst of electrons where the higher energy ones appear first, followed by decreasing energies. Using data from the Suprathermal Electron Imager (SEI) onboard the enhanced Polar Outflow Probe (ePOP), we document instances of low energy electron dispersion. These events are supported by VLF electric field data, also from ePOP. We also report inverse electron dispersion events, where energy increases with time. This phenomenon has not been recorded in the literature. These observations are not consistent with transient Alfven wave acceleration alone. We explore an alternative explanation involving a slowly drifting source, and present results of a simple simulation of this.

Published Material: Some of the background to presentations at COSPAR SA 2014, Moscow, 2-10 August, 2014 and atURSI GASS2014, Beijing, 16-23 August 2014 will reappear here.

Abstract Body: The orbit of the Canadian small satellite CASSIOPE allows the Enhanced Polar Outflow Probe (ePOP) payload that it carries to directly observe ionospheric processes at a variety of altitudes and latitudes. The 325km x 1500km elliptical orbit at 81° inclination permits comparison of topside collisionless plasmas with denser plasmas below and of mid-latitude plasmas with polar-cap ones. In coordinated operations of the ePOP Radio Receiver Instrument (RRI) with measurements by the SuperDARN (SD) radars, the RRI has recorded HF signals originating at the Saskatoon and Rankin Inlet SDs. Here, the combination of both EM propagation directly incident from the radar emitters and of signals backscattered from nearby irregularities provides new insights into the nature of coherent backscatter. Transionospheric propagation through the F region modified by ionospheric heaters and detected by the RRI is used to image the structure therein, and to better understand electromagnetic propagation through irregular media. Spontaneous radio emissions at very low frequency and medium frequency borne of auroral-particle free-energy sources manifest a variety of spatial scales.

Title: Global Plasmaspheric Electron Density Simulations of Pre-dawn and Post-dusk Geomagnetic Events Observed by the Van Allen Probes

Presenter/First Author: Sebastian De Pascuale, University of Iowa, Iowa City, IA

Presenter/First Author Email: sebastian-depascuale@uiowa.edu

Co-authors: Vania Jordanova, Los Alamos National Laboratory, Los Alamos, NM; Jerry Goldstein, Southwest Research Institute San Antonio, San Antonio, TX; Craig Kletzing, University of Iowa, Iowa City, IA

Published Material: A poster on the content of this proposal was presented at the 2014 AGU Fall Meeting in San Francisco, CA under the Dawn-Dusk Asymmetries in Solar Wind-Magnetosphere-Ionosphere Systems session. The findings were also reported in an internal Los Alamos Space Weather Summer School Research Reports circulation at LANL, but have not yet been submitted for peer-review. That work is currently in preparation for submission to the Journal of Geophysical Research.

Abstract Body: We use in situ measurements by the Van Allen Probes (RBSP) to validate a globally applicable plasmaspheric electron density model (RAM-CPL), which is based on ionospheric outflow rates and electric field drivers as proxies for system refilling and erosion respectively. The model is a key component of the RAM-CPL suite in describing the temporal evolution of plasma density in the equatorial plane of the magnetosphere. In addition to considering absolute density values, this study employs a composite definition of the plasmapause boundary as a standard metric for comparison between observations and the model. Because the dynamics of the plasmasphere are governed on different timescales ranging from minutes to days, we consider geomagnetic events for which the RBSP satellites are at conjunction to sample fine-scale density variation as well as large-scale structure. Furthermore, the pre-dawn and post-dusk sectors of the observations provide adequate constraints on the candidate electric field drivers of the plasmasphere. The good agreement attained by the RAM-CPL plasmasphere model can be utilized to predict density conditions in magnetic local time and L-parameter sectors distant from an RBSP orbit of interest. These simulations reproduce plasmapause radial locations to within 0.6 Earth radii (RE) of RBSP observations and we investigate further the competing effects of plasmaspheric refilling and erosion on model performance.

Title: Long-Lived Plasmaspheric Drainage Plumes and the Plasma-Source Dilemma

Presenter/First Author: Joseph Borovsky, Space Science Institute Los Alamos, Los Alamos, NM

Presenter/First Author Email: jborovsky@spacescience.org

Co-authors: Dan Welling, University of Michigan, Ann Arbor, MI; Michelle F Thomsen, Planetary Science Institute, Los Alamos, NM; Michael Denton, Space Science Institute Boulder, Boulder, CO

Published Material: Journal of Geophysical Review 2014

Abstract Body: Long-lived (weeks) plasmaspheric drainage plumes during long-lived high-speed-stream-driven storms were explored. Geosynchronous-orbit spacecraft see the plumes as streams of dense plasmaspheric plasma continuously advecting sunward toward the dayside magnetopause. The standard assumption is that the plasmaspheric plumes are the drainage of plasma from a built-up outer plasmasphere. Computer simulations indicate that drainage from the outer plasmasphere can only supply a plume for about 2 days. Plumes that are 5 days old are common and plumes lasting 15 days have been seen. The question arises for long-lived plumes (and for any plume older than about 2 days): Where is the plasma coming from? Magnetospheric sources and ionospheric sources will be explored.

Domnin, Institute of Ionosphere, Kharkiv, Ukraine

Abstract Body: During the last solar minimum, anomalously high nighttime H^+ densities was observed over the Kharkiv, Ukraine incoherent scatter radar (49.6° N, 36.3° E, L=2.1). The standard physical model underestimates the H^+ densities by a factor of 2 in March 2006 and a factor of 3 in March 2009. The calculations indicate that the higher measured topside ionosphere H^+ densities are most likely due to higher neutral hydrogen densities. It could be the result of weaker than usual magnetic activity, which would reduce the energy input to high latitudes. Prolonged low activity periods could cause a global redistribution of hydrogen and also allow more neutral hydrogen to settle down from the exosphere into the mid latitude ionosphere. The finding of the need for higher H densities agrees well with recent H-alpha airglow measurements and it is important for accurate modelling of plasmasphere refilling rates. Our calculations with the FLIP model show that the refilling rate is increased by a factor of 2 when the NRLMSISE H density is increased by a factor of 3 and no other changes made to the model inputs. These refilling rates agree well with those observed at geosynchronous orbit (L=6.6) after a magnetic storm in June 2007. We have also found that the refilling rate varies significantly with longitude. Simulations in the American sector would underestimate the maximum refilling rate observed at geosynchronous orbit by more than 50%.

Title: The global distribution, energy source, and scattering effects of magnetosphic waves in the Earth's inner magnetosphere

Presenter/First Author: Qianli Ma, University of California Los Angeles, Los Angeles, CA

Presenter/First Author Email: qianlima@ucla.edu

Co-authors: Wen Li, University of California Los Angeles, Los Angeles, CA; Richard M Thorne, University of California Los Angeles, Los Angeles, CA; Jacob Bortnik, University of California Los Angeles, Los Angeles, CA

Published Material: Besides our new results first reported in this presentation, the previous findings in the following papers will be cited: Global distribution of equatorial magnetosonic waves observed by THEMIS, by Ma et al., Geophysical Research Letters, 2013; Magnetosonic wave excitation by ion ring distributions in the Earth's inner magnetosphere, by Ma et al., Journal of Geophysical Research, 2014; The trapping of equatorial magnetosonic waves in the Earth's outer plasmasphere, by Ma et al., Geophysical Research Letters, 2014.

Abstract Body: Equatorial magnetosonic waves are highly oblique whistler-mode electromagnetic emissions between the proton gyrofrequency and the lower hybrid resonant frequency, widely distributed in the Earth's inner magnetosphere, and may have potentially important effects in particle scattering in the radiation belts. Our global survey of magnetosonic waves using THEMIS fff data products has shown that the most intense magnetosonic waves are distributed on the dawn-noon sectors, with maximum root-mean-square averaged wave amplitudes ~50 pT and occurrence rates ~20%. Our instability analysis on a typical magnetosonic wave event has demonstrated that the unstable ion ring distributions could provide the free energy for the wave excitation outside the plasmapause or in the outer region of the plasmasphere. Although magnetosonic waves cannot be excited deep inside the plasmapause, the locally observed waves can be originated from the outer region and stay trapped in the plasmasphere, which is confirmed by our analysis on the wave perpendicular propagation. The magnetosonic waves can cause electron pitch angle and energy scattering via Landau resonance and transit time effects, and we further investigate their general influences on energetic electrons in the Earth's inner magnetosphere.

Title: Control of Energetic Ring Current Ion Spectra by EMIC Waves

Presenter/First Author: Danny Summers, Memorial University of Newfoundland, St John's, NL

Presenter/First Author Email: dsummers@mun.ca

Co-authors: Run Shi, Memorial University of Newfoundland, St John's, NL, Canada

Abstract Body: The dense thermal regions in the magnetosphere comprising the plasmasphere and plasmaspheric plumes play a key role in influencing the energetic ion and electron populations not least because electromagnetic ion cyclotron (EMIC) waves are typically generated inside or close to these thermal regions. Here we address the process of gyroresonant pitch-angle scattering of energetic ions by EMIC waves in the inner magnetosphere. Specifically we test the hypothesis that EMIC waves closely control the shapes and intensities of energetic ion spectra. The limiting energetic ion flux of a trapped population is assumed to be determined by a steady-state marginal-stability criterion in which a convective wave gain condition is applied over all frequencies for which EMIC wave growth occurs. We find that, assuming a multi-ion background plasma,the limiting energetic ion spectrum varies as 1/E for large energy E. We compare the numerical model solutions for the limiting spectra with observed energetic ion spectra at Earth measured by the Van Allen Probes.

Title: The Relation of Chorus, Hiss and the Plasmasphere

Presenter/First Author: Jacob Bortnik, University of California Los Angeles, Los Angeles, CA

Presenter/First Author Email: jbortnik@gmail.com

Co-authors: Wen Li, University of California Los Angeles, Los Angeles, CA; Richard M Thorne, University of California Los Angeles, Los Angeles, CA

Abstract Body: Recent work has shown strong theoretical support for the association of plasmaspheric hiss and whistler-mode chorus waves. In particular, it was shown that chorus waves originating in the low-density region outside the plasmasphere, are able to propagate away from their equatorial source region to higher latitudes, avoiding the effects of intense Landau damping, and enter into the plasmasphere where they merge into plasmaspheric hiss waves. In this talk, we review the chorus-hiss connection mechanism, and discuss the important role that the plasmasphere plays in this process. We discuss our method of modeling the plasmasphere, and show recent results based on THEMIS and Van Allen Probes data.

Title: Global Storm-Time Depletion of the Outer Electron Belt

Presenter/First Author: Aleksandr Y Ukhorskiy, Applied Physics Laboratory Johns Hopkins, Laurel, MD

Presenter/First Author Email: aleksandr.ukhorskiy@jhuapl.edu

Co-authors: Mikhail I. Sitnov, Applied Physics Laboratory Johns Hopkins, Laurel, MD; Robyn M Millan, Dartmouth College, Hanover, NH; Brian T Kress, Dartmouth College, Hanover, NH; Joseph Fennell, Aerospace Corporation, Los Angeles, CA

Published Material: A similar talk was presented in the 2014 Fall AGU meeting.

Abstract Body: The outer radiation belt consists of relativistic (>0.5 MeV) electrons trapped on closed trajectories around Earth where its magnetic field is nearly dipolar. During increased geomagnetic activity electron intensities in the belt can vary by orders of magnitude at different spatial and temporal scale. The main phase of geomagnetic storms often produces deep depletions of electron intensities over broad regions of the outer belt. Previous studies identified three possible processes that can contribute to the depletions: fully adiabatic inflation of electron drift orbits caused the ring current growth, electron loss into the atmosphere due to pitch-angle scattering by plasma waves (e.g., EMIC and whistler waves),

and electron escape through the magnetopause boundary. In this paper we investigate the relative importance of the magnetopause losses to the rapid depletion of the outer belt observed at the Van Allen Probes spacecraft during the main phase of March 17, 2013 storm. The intensities of > 1 MeV electrons were depleted by more that an order of magnitude over the entire radial extent of the belt in less than 6 hours after the sudden storm commencement. For the analysis we used three-dimensional test-particle simulations of global evolution of the outer belt in the Tsyganenko-Sitnov (TS07D) magnetic field model with the inductive electric field. The comparison of the simulation results with electron measurements from the MagEIS experiment shows that the magnetopause losses account for most of the observed depletion at L>5, while at lower L shells the depletion is adiabatic. Both the magnetopause losses and the adiabatic effect are controlled by the change in global configuration of the magnetic field due to storm-time development of the ring current; a simulation of electron evolution without a ring current produces a much weaker depletion.

Title: Simulation of Earth's Radiation Belt Electron Dynamics and Its Comparison to Van Allen Probes Observations

Presenter/First Author: Wen Li, University of California Los Angeles, Los Angeles, CA

Presenter/First Author Email: moonli@atmos.ucla.edu

Co-authors: Richard M Thorne, University of California Los Angeles, Los Angeles, CA; Qianli Ma, University of California Los Angeles, Los Angeles, CA; Jacob Bortnik, University of California Los Angeles, Los Angeles, CA

Abstract Body: The highly dynamical evolution of the Earth's outer radiation belt electron fluxes is due to a competition between various loss and acceleration processes. In this study, we focus on analyzing a few interesting events observed by the Van Allen Probes, including a very rapid electron acceleration event up to multi-MeV energies within ~12-16 hours, and a long-term slow decay event where MeV electrons slowly move towards the Earth in association with a slow decay in electron fluxes. Using the UCLA 3D particle diffusion code, we simulate the evolution of the electron phase space density by including important physical processes, such as electron energy diffusion and pitch angle scattering caused by whistler-mode chorus waves, plasmaspheric hiss, and electromagnetic ion cyclotron waves, and radial diffusion driven by ultra low frequency waves. By comparing the simulation results to Van Allen Probes observations, we quantify the role of each physical process in each event. We further discuss the preferential solar wind conditions that lead to the rapid electron acceleration up to multi-MeV and the gradual electron radial transport towards the Earth.

Title: ULF Wave Properties and Implications for Radiation Belt Interactions

Presenter/First Author: Michael Hartinger, Virginia Polytechnic Institute and State University, Hampton, VA

Presenter/First Author Email: mdhartin@vt.edu

Co-authors: Kazue Takahashi, Applied Physics Laboratory Johns Hopkins, Laurel, MD; Mark Moldwin, University of Michigan, Ann Arbor, MI; C. Robert Clauer, National Institute of Aerospace, Hampton, VA; John W Bonnell, University of California Berkeley, Berkeley, CA; Vassilis Angelopoulos, University of California Los Angeles, Los Angeles, CA

Abstract Body: Ultra Low Frequency (ULF) waves drive radial transport of radiation belt electrons, potentially leading to depletions or enhancements in relativistic electron fluxes. Rapid transport can occur via a drift-resonant interaction between azimuthal electron drift motion and large scale, coherent ULF wave fields. Several parameters affect transport timescales in addition to the radial phase space density profile; these include wave amplitude, frequency, propagation direction, and azimuthal structure. We report statistical results of the first three parameters using 6 years of THEMIS satellite observations, discussing their implications for drift-resonant interactions. We also discuss how ground-based/in situ observations of azimuthal structure could be added to these observations to better constrain transport timescales.

Published Material: N/A

Abstract Body: The high-latitude topside ionosphere is an important source of cold plasma for the Earth's inner magnetosphere. In this talk, we present initial Enhanced Polar Outflow Probe (e-POP) observations of ion outflows from the topside auroral and polar-cap ionosphere: we will focus on specific features in these observations, which reveal the occurrence of localized regions of enhanced ion up-flow velocities down to the F-region at different magnetic local times; the persistence of non-negligible up-flows at quiet times; and the larger-than-expected fluxes of atomic and molecular nitrogen ions in the observed up-flow. These observed features will be discussed in conjunction with recent outflow modeling results, and in the context of their implications on the composition and dynamics of the inner magnetosphere during both quiet and active times.

Baker, University of Colorado at Boulder, Boulder, CO

Abstract Body: In recent work we have discovered regimes of ultra-fast ULF wave diffusion which occur in response to specific solar wind drivers during magnetic storms. We review the impacts these periods of ultra-fast ultra-low frequency (ULF) wave power on the dynamics of ultra-relativistic electrons in the Van Allen belts. We place emphasis on the significance of using properly characterised time-series of ULF waves for accurately evaluating their impacts for both acceleration and loss. Specifically we compare results derived from observed wave power with those from more standard approaches using statistical characterisations based on geomagnetic indices such as Kp, revealing the importance of properly characterising the waves through the course of the main and recovery phases of geomagnetic storm-time Van Allen radiation belt dynamics. We find using the observed ULF wave power presents a remarkable explanation for the overall dynamics of the belts in terms of the impacts of inward and outward radial diffusion in association with plasmasheet sources and magnetopause shadowing. At ultra-relativistic energies the resulting dynamics demonstrate a remarkable simplicity which is controlled by the ULF wave power. Especially at ultra-relativistic energies, ULF wave power can explain the morphologies of the Van Allen belts in the form of either one, two or three belts.

Title: ULF wave power and radial diffusion during geomagnetic storms driven by different solar wind drivers

Presenter/First Author: Kyle R Murphy, NASA Goddard Space Flight Center, Greenbelt, MD

Presenter/First Author Email: kyle.r.murphy@nasa.gov

Co-authors: Ian Robert Mann, University of Alberta, Edmonton, AB, Canada; Louis Ozeke, University of Alberta, Edmonton, AB, Canada; David G Sibeck, NASA/GSFC, Greenbelt, MD; Jonathan Rae, University College London, London, United Kingdom

Abstract Body: ULF waves are recognized as playing an important role in the dynamics of the Earth's radiation belts through the action of ULF wave radial diffusion. ULF wave diffusion coefficients are typically defined using a statistical approach, parameterized by either geomagnetic indices or solar wind drivers such as solar wind velocity. However, during geomagnetic storms the ULF wave dependence on solar wind conditions may vary significantly from the solar cycle average. Consequently, accurately modelling the ULF wave response and their impact on the radiation belts during geomagnetic storms via radial diffusion is difficult even with a database of statistically defined radial diffusion coefficients. This is because ULF wave power during geomagnetic storms represents extreme values in the distribution and can vary significantly from one storm to another, thus deviating from any statistical characterization. Here we investigate ULF wave power during two different types of geomagnetic storms, those driven by coronal mass ejections (CMEs) and those driven by co-rotating interaction regions (CIRs), and demonstrate that the response of ULF wave power and the resulting derived diffusion coefficients is significantly different between these two types of storms, and from that inferred using solar cycle average ULF wave parameterizations. In addition, we model the response of the radiation belts during these different types of storms, characterizing how the dynamics of the radiation belts can vary during different storms and different ULF wave driving conditions including the overall transport rates and the penetration of the belts to low-L.

Title: Observations of Ultra-relativistic Electrons in the Earth's Radiation Belts: Recent Results from the Van Allen Probes Mission

Presenter/First Author: Shrikanth G Kanekal, NASA Goddard Space Flight Center, Greenbelt, MD

Presenter/First Author Email: shrikanth.g.kanekal@nasa.gov

Co-authors: Daniel N. Baker, University of Colorado at Boulder, Boulder, CO; Allison N Jaynes, University of Colorado Boulder, Boulder, CO; Xinlin Li, University of Colorado at Boulder, Boulder, CO; Ashley Diemer Jones, Catholic University of America, Washington, DC; Richard Selesnick, Air Force Research Laboratory Kirtland AFB, Kirtland AFB, NM; Binbin Ni, University of California Los Angeles, Los Angeles, CA

Abstract Body: The Earth's radiation belts are comprised of energetic trapped and transient charged particles and usually show an outer zone separated from an inner zone by a "slot region" bereft of energetic electrons. The outer zone comprises mostly of electrons and is home to a variety of physical processes, which energize as well as scatter these particles. These processes result in both enhanced and depleted flux levels depending upon whether energization or loss (due to scattering or escape through the magnetopause) dominates. These dynamics of outer zone electrons are driven by various interplanetary drivers, such as, shocks, coronal mass ejections and high-speed solar wind streams. At times the energized electron spectra can be quite hard and result in ultra-relativistic electrons of energies as high as ~10s of MeV. Here we report on a study of ultra-relativistic electron dynamics using data from the Van Allen probes mission. Van Allen probes comprises two identically instrumented spacecraft carrying a comprehensive suite of particle, plasma waves and fields instrumentation. The Relativistic Electron-Proton Telescope (REPT) experiment on board the Van Allen Probes measures electrons in the range ~2 to >10 MeV and provides both pitch angle and spectral information. In this study, we examine, electron spectra and pitch angle distributions and their evolution during ultra-relativistic flux enhancement events. The temporal evolution of spectra and pitch angle distributions can shed light on the underlying physical process of pitch angle scattering, and energization of these extremely high-energy electrons in the Earth's magnetosphere. We will also investigate the nature of the often observed extreme rapidity with which electrons are energized and lost at these very high energies.

Spence, University of New Hampshire Main Campus, Durham, NH

Published Material: Published in GRL in Dec 2014

Abstract Body: Electromagnetic ion cyclotron (EMIC) waves were observed at multiple observatory locations for several hours on 17 January 2013. During the wave activity period, a duskside relativistic electron precipitation (REP) event was observed by one of the BARREL balloons, and was magnetically mapped close to GOES-13. We simulate the relativistic electron pitch-angle diffusion caused by gyroresonant interactions with EMIC waves using wave and particle data measured by multiple instruments on board GOES-13 and the Van Allen Probes. We show that the count rate, the energy distribution and the time variation of the simulated precipitation all agree very well with the balloon observations, suggesting that EMIC wave scattering was likely the cause for the precipitation event. The event reported here is the first balloon REP event with closely conjugate EMIC wave observations, and our study employs the most detailed quantitative analysis on the link of EMIC waves with observed REP to date.

Title: New Multi-Spacecraft Observations of the Earth's Van Allen Radiation Belts

Presenter/First Author: Daniel N. Baker, University of Colorado at Boulder, Boulder, CO

Presenter/First Author Email: daniel.baker@lasp.colorado.edu

Co-authors: Shrikanth G Kanekal, NASA Goddard Space Flight Center, Greenbelt, MD

Published Material: Baker, D.N., et al., An inpenetrable barrier to ultrs-relativistic electrons in the Van Allen Radiation Belts, Nature, submitted, 2014.

Abstract Body: The first great scientific discovery of the Space Age was that the Earth is enshrouded in toroids, or "belts", of very high-energy magnetically trapped charged particles. Early observations of the radiation environment clearly indicated that the Van Allen belts could be delineated into an inner zone dominated by high-energy protons and an outer zone dominated by high-energy electrons. Subsequent studies showed that electrons in the energy range 100 keV < E< 1 MeV often populated both the inner and outer zones with a pronounced "slot" region relatively devoid of energetic electrons existing between them. This two-belt structure for the Van Allen moderate-energy electron component was explained as being due to strong interactions of electrons with electromagnetic waves just inside the cold plasma (plasmapause) boundary. The energy distribution, spatial extent and particle species makeup of the Van Allen belts has been subsequently explored by several space missions. However, recent observations by the NASA dual-spacecraft Van Allen Probes mission have revealed wholly unexpected properties of the radiation belts, especially at highly relativistic (E > 2 MeV) and ultra-relativistic (E > 5 MeV) kinetic energies. In this presentation we show using high spatial and temporal resolution data from the Relativistic Electron-Proton Telescope (REPT) experiment on board the Van Allen Probes that multiple belts can exist concurrently and that an exceedingly sharp inner boundary exists for ultra-relativistic electrons. Using additionally available Van Allen Probes data, we demonstrate that these remarkable features of energetic electrons are not due to a physical boundary within Earth's intrinsic magnetic field. Neither is it likely that human-generated electromagnetic transmitter wave fields might produce such effects. Rather, we conclude from these unique measurements that slow natural inward radial diffusion combined with weak, but persistent, wave-particle pitch angle scattering deep inside the Earth's magnetosphere can conspire to create an almost impenetrable barrier through which the most energetic Van Allen belt electrons cannot migrate.

Title: Identifying the Energization and Loss Processes of Relativistic Electrons with Multipoint Observations and Simulations

Presenter/First Author: Mei-Ching Hannah Fok, NASA Goddard Space Flight Center, Greenbelt, MD

Presenter/First Author Email: mei-ching.h.fok@nasa.gov

Co-authors: Kyoung-Joo Hwang, NASA Goddard Space Flight Center, Greenbelt, MD

Abstract Body: The relativistic electron populations in the Earth's radiation belts are highly dynamic during geomagnetically active periods. Their variations are controlled by the balance of energization and loss processes. It is a challenge to untangle the relative contributions from different mechanisms. With multipoint measurements and comprehensive radiation-belt models available recently, it becomes possible to identify the responsible processes for the observable changes. In this paper, we study a few relativistic-electron events using particle and field data from the Van Allen Probes, THEMIS and geostationary missions. We will also simulate the events with our Comprehensive Inner Magnetosphere-Ionosphere (CIMI) model. By combining data analysis and simulation methods, we seek to identify the major energization and loss mechanisms of relativistic electrons and determine how their roles change with different solar wind conditions.

Title: Recent Advancements of Understanding of Relativistic Electrons in the Inner Belt

Presenter/First Author: Xinlin Li, University of Colorado at Boulder, Boulder, CO

Presenter/First Author Email: lix@lasp.colorado.edu

Co-authors: Richard Selesnick, Air Force Research Laboratory Kirtland AFB, Kirtland AFB, NM; Hong Zhao, University of Colorado at Boulder, Boulder, CO; Daniel N. Baker, University of Colorado at Boulder, Boulder, CO; Allison N Jaynes, University of Colorado Boulder, Boulder, CO; Shri Kanekal, NASA Goddard Space Flight Center, Greenbelt, MD; Quintin Schiller, University of Colorado at Boulder, Boulder, CO; Lauren W Blum, University of California Berkeley, Berkeley, CA; Joseph Fennell, Aerospace Corporation, Los Angeles, CA; J. B. Blake, The Aerospace Corporation, Los Angeles, CA

Published Material: FALL AGU. Some of the results are to be published in JGR (just accepted)

Abstract Body: No instruments in the inner radiation belt are immune from the unforgiving penetration of the highly energetic protons (10s of MeV to GeV). The inner belt proton flux level, however, is relatively stable, thus for any given instrument, the proton contamination often leads to a certain background noise. Measurements from the Relativistic Electron and Proton Telescope integrated little experiment (REPTile) on board Colorado Student Space Weather Experiment (CSSWE) CubeSat, in a low Earth orbit, clearly demonstrate that there exist sub-MeV electrons in the inner belt because of their flux level is orders of magnitude higher than the background, while higher energy electron (>1.6 MeV) measurements cannot be distinguished from the background. Detailed analysis of high-quality measurements from the Relativistic Electron and Proton Telescope (REPT) and Magnetic Electron Ion Spectrometer (MagEIS) on board Van Allen Probes, in a geo-transfer-like orbit, provides, for the first time, detailed measurements of energetic electrons in both inner belt and outer belt, covering a wide energy range, from 10s of keV to multiple MeV. In this presentation, detailed pitch angle distribution of sub-MeV electrons from MagEIS measurements and quantified upper limits on multiple MeV electrons from REPT measurements will be discussed. These upper limits are rather different from flux levels in the AE8 and AE9 models, which were developed based on older data sources. For 1.7, 2.5, and 3.3 MeV electrons, the upper limits are about one order of magnitude lower than predicted model fluxes. The implication of this difference is profound in that unless there are extreme solar wind conditions, such as strong interplanetary shocks and coronal mass ejections, which have not happened yet since the launch of Van Allen Probes, enhancements of MeV electrons do not occur in the inner belt even though such enhancements are commonly seen in the outer belt.

Title: Measuring the Pitch-Angle Scattering of Radiation-Belt Electrons as They Drift Across the Plasmaspheric Drainage Plume

Presenter/First Author: Joseph Borovsky, Space Science Institute Los Alamos, Los Alamos, NM

Presenter/First Author Email: jborovsky@spacescience.org

Co-authors: Reiner H W Friedel, Los Alamos National Laboratory, Los Alamos, NM; Michael Denton, Space Science Institute Boulder, Boulder, CO

Published Material: Journal of Geophysical Research 2014

Abstract Body: Using the multisatellite SOPA data set of radiation-belt electrons at geosynchronous orbit, the pitch-angle scattering of radiation-belt electrons in plasmaspheric drainage plumes is investigated. When geomagnetic activity is high a plasmaspheric drainage plume flows in the dayside magnetosphere, crossing geosynchronous orbit post noon local time. Radiation-belt electrons drift from dawn to dusk across the dayside magnetosphere and during high geomagnetic activity they drift through the drainage plume. The locations of the drainage plumes are identified with the MPA plasma instrument onboard the geosynchronous satellites and the anisotropy of the radiation-belt electrons is measured upstream (dawnward) and downstream (duskward) of the drainage-plume crossings. Combining the measurements from 5 spacecraft from 126 drainage-plume crossings, statistical analysis of the reduction in anisotropy of the radiation-belt electrons across the drainage plumes yields estimates for the rate of pitch-angle scattering of the electrons within the plumes. The pitch-angle-diffusion coefficients estimated from the scattering measurements are of the magnitude as expected values for EMIC waves in the plume at high electron energies (1.5 MeV) and as expected values for whistler-mode hiss in the plume at lower electron energies (150 keV).

Title: Precipitation Loss and Nonlinear Acceleration of Broadband Energetic Electrons by Whistler Chorus Waves

Presenter/First Author: Shinji Saito, STEL, Nagoya University, Nagoya,

Presenter/First Author Email: saito@stelab.nagoya-u.ac.jp

Co-authors: Yoshizumi Miyoshi, Nagoya University, Nagoya, Japan

Abstract Body: The electron radiation belts, especially the outer radiation belt, have intense and rapid variation during geomagnetic storms. Whistler chorus wave is a plausible candidate to explain the flux variation in the heart of the outer belt through wave-particle interactions. While the quasi-linear model has been used to describe the wave-particle interactions so far, it has been proposed that nonlinear properties of whistler chorus elements can influence on the flux variation through the nonlinear scattering process, which cannot be described in the quasi-linear model. This study using test particle simulation code GEMSIS-RBW conducts electron precipitation loss and acceleration with the nonlinear scattering process by whistler chorus elements in the dipole magnetic field model. The simulations show that the broadband energetic electrons can be scattered by whistler chorus elements propagating from the magnetic equator to high magnetic latitudes. We will discuss precipitation flux of electrons in broadband energy range between keV and MeV, and influences of the nonlinear scattering process on the flux variation. The simulation studies would be applied to understand observation data from future mission such as ERG.

Published Material: The preliminary findings of this study were shown in a poster at Fall AGU 2014.

Abstract Body: Electromagnetic ion cyclotron (EMIC) waves have been hypothesized to be a primary source of precipitation loss of radiation belt electrons, contributing to the net response and dynamics of the outer radiation belt. Here we present simultaneous, conjugate measurements of EMIC wave activity, measured at GOES and on the ground, and energetic electron precipitation, seen by the 2013 BARREL balloon campaign, on two consecutive days in January 2013. The various overlapping, interacting plasma populations present are examined, as well as solar wind and geomagnetic conditions that contribute to the wave generation and wave-particle interactions. This study examines the temporal and spatial structure of EMIC waves and electron precipitation observed on Jan 18-19 2013 and provides direct evidence for this wave-particle interaction. This event is put in context through comparisons of global EMIC wave distributions to MeV electron precipitation events.

Published Material: Preliminary results were presented at the Fall 2014 AGU Meeting.

Abstract Body: Although most studies of the effect of EMIC waves on relativistic electrons have focused on wave events in the afternoon sector in the outer plasmasphere or plume region, strong magnetospheric compressions provide an additional stimulus for EMIC wave generation across a large range of local times and L shells. We present here observations of the effects of an intense, long-duration wave event on February 23, 2014. Waves extending 8 hours in UT and over 12 hours in MLT were stimulated by a gradual 4-hour rise and subsequent sharp increases in solar wind pressure. Large-amplitude linearly polarized hydrogen band EMIC waves (up to 25 nT p-p) appeared for over 4 hours at both Van Allen Probes as they moved near apogee from late morning through local noon, when these spacecraft were outside the plasmapause, in a region with densities ~5-20 cm^{-3}. Wave activity was also observed by ground-based induction magnetometers in Finland, Antarctica, Canada, Russia, and Japan, and briefly by GOES-13 and -15 in the midnight sector. Ten passes of NOAA-POES and METOP satellites near the northern hemisphere footpoint of the Van Allen Probes (over Siberia) showed the presence of 30-80 keV subauroral proton precipitation, often over extended L shell ranges; other passes identified a narrow L-shell region of precipitation over Canada. Observations of relativistic electrons by both Van Allen Probes showed that this wave event preferentially reduced the fluxes of more field-aligned and more energetic radiation belt electrons at both L* = 4.5 and 5.2, confirming the effectiveness of EMIC-induced loss processes, as predicted in recent theoretical studies, for this event.

Title: Comparison of POES and SAMPEX Observations of Radiation Belt Particles Precipitation

Presenter: Robyn M Millan, Dartmouth College, Hanover, NH

Presenter Email: Robyn.Millan@dartmouth.edu

First Author: Sapna Shekhar, Dartmouth College, Hanover, NH

First Author Email: sapna.shekhar.gr@dartmouth.edu

First Author Student?: No

Published Material: AGU fall meeting 2013. More progress has been made since then.

Abstract Body: The phenomenon of Duskside Releativistic Electron Precipitation (DREP) was first proposed by Thorne and Kennel [1971] as scattering of electrons by electromagnetic ion cyclotron (EMIC) waves at the plasmapause boundary on the duskside. Duskside precipitation is known to occur over a broad radial distribution (L = 3–8) and a wide range of magnetic activity levels, from small substorms (Lorentzen et al. 2000) to major Coronal Mass Ejections (CME) driven storms (Kokorowski et al. 2008). Furthermore, it does not strongly correlate with geomagnetic storms, and has slower temporal variations, from minutes to hours (Millan et al., 2002). Comess et al, JGR 2013 analyzed the energy spectrum for such precipitation events from 1992 to 2004 obtained from SAMPEX, a low Earth orbiting satellite, and found they follow an exponentially decreasing distribution. This study re-examines a selection of SAMPEX events with the NOAA-POES satellites, a low altitude, polar orbiting network of spacecraft measuring electrons and protons, which show good conjunctions with SAMPEX on 8th January 2004. Using the SAMPEX e-folding energy and POES Medium Energy Proton and Electron Detector (MEPED 0o) geometric factors obtained through GEANT simulations (Yando et. al., 2011), a model of the expected counts in each POES MEPED channel has been constructed for the events and compared with the observed counts. This work paves the way towards estimating the energy spectrum of precipitation from POES observations, which will allow for detailed observations of precipitation during the post- SAMPEX era.

Title: Van Allen Probes observations of oxygen cyclotron harmonic waves in the inner magnetosphere

Presenter/First Author: Maria Usanova, University of Colorado Boulder, Edmonton, AB

Presenter/First Author Email: maria.usanova@lasp.colorado.edu

Co-authors: Allison N Jaynes, University of Colorado Boulder, Boulder, CO; Ian Robert Mann, University of Alberta, Edmonton, AB, Canada; Benjamin Grison, Institute of Atmospheric Physics ACSR, Praha 4, Czech Republic; Robert Ergun, Univ Colorado, Boulder, CO

Published Material: Some of the results were presented at the Fall AGU 2014 mini-GEM

Abstract Body: Waves with frequencies in the vicinity of the oxygen cyclotron frequency and its harmonics are often observed on the Van Allen Probes spacecraft in the inner equatorial magnetosphere during geomagnetically active times. We will present observations of these waves during the main phase of a geomagnetic storm on November 1, 2012. Oxygen cyclotron harmonics were observed simultaneously by fluxgate magnetometers onboard two satellites, at L~3 in the early morning magnetic local time sector, just outside the plasmapause (as monitored by the spacecraft potential). Analysis of the magnetic field data in field aligned coordinate system showed that these harmonic waves are heft-hand polarized and propagating obliquely to the background magnetic field. Observations of associated energetic particle distributions by the HOPE instrument suggest that anisotropic (peaked at 90-degree pitch angles) oxygen distributions with energy ~1-2 keV might have provided the energy source for these waves, however further theoretical analysis is warranted to establish the nature of this wave instability. Since polarization and propagation angle of oxygen cyclotron harmonic waves are very similar to electromagnetic ion cyclotron (EMIC) waves, which are believed to influence ring current and radiation belt dynamics, they may be also important for energetic particle dynamics in the inner magnetosphere.

Title: A Web-Based HF Near Real Time Tool based on a Neural Network based Bottomside Profile Model for the Ionosphere

Presenter/First Author: Mohamed Osman Yousif, University of New South Wales, Sudan,

Presenter/First Author Email: moy_smart@hotmail.com

Co-authors: Sami Mohamed Sharif, University of Khartoum, Khartoum, Sudan

Abstract Body: A web-based HF near real time tool based on a neural network based bottomside profile model for the Ionosphere is developed. The model gives near real time calculations for the Maximum Usable Frequency (MUF) and the Optimum Working Frequency (FOT) for distances shorter than 2000 km. The tool is named UKIS and it relies on critical frequencies and virtual heights. In this paper we run UKIS over Sudan using monthly median critical frequencies and virtual heights data from IRI and also we run UKIS over Three Australian cities using both near real time and archived critical frequencies and virtual heights obtained from digisonde stations in order to train the neural networks based ionospheric model. For validation we use SAO-Explorer which is a software developed by University of Massachusetts Lowell Centre of Atmospheric Research (UMLCAR) to get near real time Ionograms from different cities and then we scale MUF from the oblique ionograms between Digisonde stations using SAO-Explorer. Finally a comparison between predicted MUF with measured MUF is presented.

Title: Plasmaspheric plume analysis during the 2013 Cluster close separation campaign

Presenter/First Author: Fabien Darrouzet, Belgian Institute for Space Aeronomy, Brussels,

Presenter/First Author Email: Fabien.Darrouzet@aeronomie.be

Co-authors: Johan De Keyser, Belgian Institute for Space Aeronomy, Brussels, Belgium; Pierrette Décréau, Laboratoire de Physique et Chimie de l'Environnement et de l'Espace (LPC2E) - CNRS - Université d'Orléans, Orléans, France; Jerry Goldstein, Southwest Research Institute San Antonio, San Antonio, TX; William S Kurth, University of Iowa, Iowa City, IA; Sebastian De Pascuale, University of Iowa, Iowa City, IA

Abstract Body: During the last Cluster close separation campaign (July-October 2013), two of the four Cluster satellites were only tens of kilometers apart, while the two others were located at a few hundreds of kilometers. This configuration offers an exceptional opportunity to analyze the plasmasphere with very high space and time resolution around the time of perigee at about 4 R_E. In particular, plasmaspheric plumes were crossed by the satellites on several occasions.
This poster presents such an event on 13 July 2013 with electron density data obtained from the WHISPER instrument onboard Cluster. A plasmapause test particle simulation is used to provide a global view of the plasmasphere and plasmapause. Also, the electron density is inferred inside the plume from EMFISIS/Waves observations taken onboard the two Van Allen Probes spacecraft, which crossed the same plume and provide another view.
The initial formation and global evolution of the plume are studied using the general context and data from the satellites at their respective locations. Density irregularities are observed inside the plume. Some are very stable at only a few kilometers scale, while others persist also at larger scales. Their spatial gradient is studied as well as their motion with the help of multi-spacecraft analysis.

Co-authors: Giuli Verbanac, , ,

Published Material: The paper associated to this study is in preparation

Abstract Body: Using Cluster satellite data and especially the observations of the instrument WHISPER from 2007 to 2011, we determined the electron number density along the orbit of the satellites to study the relationships between the plasmapause positions and different solar wind coupling functions and geomagnetic indices. A cross-correlation analysis was performed for three magnetic local time (MLT) sectors and for all MLT taken together. The plasmapause indicators suggest the faster plasmapause response in the post-midnight sector. The time lags are approximately 2-27 hours, always increasing with the MLT sector.
The obtained fits clearly resolve the MLT structures. All studies show that the plasmapause is more earthward during geomagnetically active periods with the plasmapause bulge displaced toward dusk. The variability of the plasmapause is the largest for low values of the indicators.
At low activity levels, the plasmapause position exhibits the largest values on the dayside and smallest in the post-midnight sector.
Displacements towards larger values on the evening side (between 16 and 01 MLT) and lower values on the dayside (between 7 and 16 MLT) are identified for enhanced magnetic activity. Based on the correlation coefficients, we conclude that all studied indicators are capable to well describe the observed plasmapause position. Our results are used to improve our understanding of the physical mechanisms involved in the plasmapause formation.

Title: Inter-hourly Variability of Total Electron Content during the quietest days over Akure, within the Equatorial Ionospheric Anomaly region

Presenter/First Author: Toyese Tunde Ayorinde, Organization Not Listed, Akure,

Presenter/First Author Email: thoscocolinus@yahoo.co.uk

Abstract Body: The Inter-hourly variability of the total electron content (TEC) was examined using a fixed GPS receiver installed at Akure (7.3^{o}N, 5.3^{o}E, dip latitude -2.62^0), based on two years data (Jan 2010-Dec 2011). Akure is a station within the equatorial ionospheric anomaly EIA region. The day to day variability was calculated by converting the observed slant TEC (*STEC*) value into the vertical TEC (*VTEC*) for every 1 hr and the differencing (ΔTEC) with its corresponding value from the previous day. The result showed the mean monthly TEC value varies from the minimum at 0200 hrs LT to a peak at about 1400 hrs LT and then decreases. There is a clear daily variation which depicts the expected temporal variability. The seasonal variation of the day to day variability of TEC over Akure in both years maximize (> 13 TECU) during Equinoctial months and minimizes (< 8 TECU) during the Solstice months. During equinoxes the study shows that the Inter-hourly variability of TEC in autumnal equinox period is high compared to the vernal equinox period. There is a significant relationship between solar activity and the Inter-hourly variability of TEC over Akure in the two years (2010&2011) with a higher level of dependence on solar activity in 2010.

Title: Science Highlights from the BARREL Antarctic Balloon Campaigns

Presenter/First Author: Robyn M Millan, Dartmouth College, Hanover, NH

Presenter/First Author Email: Robyn.Millan@dartmouth.edu

Co-authors: John Glen Sample, University of California Berkeley, Berkeley, CA; Michael McCarthy, University of Washington Seattle Campus, Seattle, WA; David Miles Smith, University of California Santa Cruz, Santa Cruz, CA

Published Material: A similar poster was presented at the Fall 2014 AGU meeting.

Abstract Body: The Balloon Array for Radiation belt Relativistic Electron Losses (BARREL) is an Antarctic balloon investigation designed to study electron loss from Earth's radiation belts. Two BARREL balloon campaigns were carried out from Antarctic Research Stations SANAE IV and Halley VI in January-February 2013 and 2014. During each campaign, 20 small (~20 kg) balloon payloads were launched to an altitude of 38 km to maintain an array of payloads distributed in L-value and magnetic local time. Each balloon carried a NaI scintillator to measure the bremsstrahlung X-rays produced by precipitating relativistic electrons as they collide with neutrals in Earth's atmosphere, and a DC magnetometer to explore the nature of Ultra Low Frequency temporal modulations of precipitation. We present several science highlights from BARREL. Precipitation was observed over a range of energies with temporal and spatial structure at a variety of scales. The combination of BARREL with in situ (e.g. Van Allen Probes, THEMIS) and ground-based (e.g. riometer, VLF) measurements provides a unique opportunity to study wave-particle interactions, and to quantify the spatial scale of energetic precipitation.

Title: Study of field aligned current (FAC) with D-component (east-west)and interplanetary electric field (Ey) during three different HILDCAA events

Presenter/First Author: Binod Adhikari, INPE National Institute for Space Research, Sao Jose dos Campos, SP

Presenter/First Author Email: binod.adhi@gmail.com

Co-authors: Odim Mendes, INPE National Institute for Space Research, Sao Jose Dos Campos, Brazil; Margarete Oliveira Domingues, INPE National Institute for Space Research, Sao Jose Dos Campos, Brazil; Ezequiel Echer, INPE National Institute for Space Research, Sao Jose dos Campos, Brazil

Abstract Body: Field Aligned Currents (FACs) play an important role for the coupling between ionosphere and magnetosphere. This coupling is directly influenced by solar wind and interplanetary magnetic field (IMF). In this work we observe characteristics of FACs during HILDCAAs (High-Intensity, Long duration, Continuous AE activity) by using high resolution OMNI data set consisting of 1-min averaged ACE, Wind, IMP 8 and Geo-tail magnetic field. We also observe the perturbations in the ΔD (east-west) component of the geomagnetic field from the low latitude station (Vassouras) to predicate the field aligned currents. For three different HILDCAA events, the characteristics of FACs and perturbations in the ΔD component observe are quite dissimilar. The wavelet techniques (CWT, DWT and wavelet modulus correlation) and cross-correlation also show different results for each event. The times and frequencies resolution of FAC and ΔD obtained from CWT are different in each event. The nature of square wavelet coefficients obtain from DWT for FAC and ΔD are totally different. Both FAC and ΔD show good wavelet modulus correlation with components of interplanetary magnetic field (By and Bz) at the time of HILDCAA. We also observe the cross-correlation between FAC and ΔD, FAC and Ey and Ey and ΔD. During the non-storm HILDCAA, FAC shows negative correlation with ΔD. But it shows positive correlation for CIR and ICME preceding HILDCCAs. Similary, Ey and FAC also show negative correlation during non-storm HILDCAA but other two events show positive correlation. Finally, Ey and ΔD show positive correlation for all events. Observing these results, it can be suggested that the ground magnetic datasets obtained from low latitude may serve as the proxy for interplanetary conditions in the solar wind.

Title: DIURNAL AND SEASONAL VARIATIONS OF THE Sq FOCI LATITUDES ALONG AFRICAN MERIDIAN

Presenter/First Author: Owolabi OLADEJO Charles, Federal University of Technology Akure, Iye,

Presenter/First Author Email: talk2ocleen@yahoo.com

Co-authors: Babatunde Rabiu, , , ; Olukayode S Oluyo, , ,

Published Material: These findings were reported at African Geophysical Society conference held in Abuja, Nigeria on the 7th of June 2014 and are under review by a scientific Journal-Advances in Space Physics Research-ELSEVIER

Abstract Body: The hourly data of the horizontal component (H) of the geomagnetic field monitored simultaneously at three stations of International Real-time Magnetic Network (INTERMAGNET) and twelve stations of Magnetic Data Acquisition System (MAGDAS) along African Meridian have been used to analyse the latitudinal variation of Sq current foci under the quiet condition in the year 2009 when the solar activity was extremely low (average sunspot number R_Z=3.1). Our results showed that the Sq current foci at both hemispheres exhibit a rise mostly during pre-noon hours and a decline during post-noon hours. The seasonal variation of latitudes of the Sq foci presented intermittent poleward and equatorward shift in both hemispheres. The Sq foci exhibited variability and maximised at local noon of the observatory stations' locality. The Sq foci latitudes on either side are mostly poleward in March equinox. Our correlation analysis results between the foci latitudes show high negative correlation in March and September equinoxes and negatively weak correlation in June solstice. The correlation in December solstice has been found to be positively weak.

Title: THE RESPONSE OF THE IONOSPHERE OVER ILORIN TO SOME GEOMAGNETIC STORMS

Presenter/First Author: Benjamin Wisdom Joshua, Kebbi State University of Science and Technology, Aliero,

Presenter/First Author Email: benjaminjoshua7@dlinksolutions.com

Co-authors: Jacob Olusegun Adeniyi, , , ; Bodo W Reinisch, Lowell Digisonde International, Lowell, MA; Isaac Adimula, , , ; Shola Adebiyi, , ,

Published Material: The paper has been published with the Journal of Advances in space research, but has not been presented in any Scientific meeting. the details are as follows: Joshua, B.W., J.O. Adeniyi, I.A. B.W. Reinisch Adimula, O.A. Oladipo, O.A. Olawepo, S.J. Adebiyi, The response of the ionosphere over Ilorin to some geomagnetic storms. Advances in Space Research, 2014 COSPAR. http://dx.doi.org/10.1016/j.asr.2014.08.027. Published by Elsevier Ltd.

Abstract Body: The effects of some geomagnetic storms on the F2 layer peak parameters over Ilorin, Nigeria (Lat. 8:53°N, Long. 4.5°E, dip angle, -2.96°) have been investigated. Our results showed that the highest intensity of the noon bite-out occurred during the March equinox and lowest during the June Solstice on quiet days. Quiet day NmF2 disturbances which appeared as a pre-storm enhancement, but not related to the magnetic storm event that followed were observed at this station. These enhancements were attributed to the modification of the equatorial electric field as a result of injection of the Auroral electric field to the low and equatorial Ionosphere. For disturbed conditions, the morphology of the NmF2 on quiet days is altered. Daytime and nighttime NmF2 and hmF2 enhancements were recorded at this station. Decreases in NmF2 were also observed during the recovery periods, most of which appeared during the post-noon period, except the storm event of May 28-29. On the average, enhancements in NmF2 (i.e. Positive phases) are the prominent features of this station. Observations from this study also indicate that Dst, Ap and Kp which have been the most widely used indices in academic research in describing the behavior of geomagnetic storms, are not sufficient for storm time analysis in the equatorial and low latitude Ionosphere.

Title: A COMPARATIVE STUDY OF TEC AT LOW AND MIDDLE LATITUDES OF AFRICA DURING DIFFERENT SOLAR ACTIVITY PHASES

Presenter/First Author: Kotoye Afolabi Adegboyega, University of Lagos, Yaba,

Presenter/First Author Email: afobuddy@gmail.com

Co-authors: Bolaji Oluwasegun, , , ; Oyeyemi O Elijah, , , ; Abe O E, , ,

Abstract Body: The total electron content (TEC) variability for three levels of solar activities; high solar active period (HSP; year 2000), moderate solar active period (MSP; year 2004) and low solar active period (LSP; year 2008) over middle and low latitudes of Africa were investigated. We have studied the day-to-day, monthly mean, seasonal relative standard deviation (SVR) and yearly mean changes. As expected, for the middle (Sutherland) and low (Libreville) latitudes, TEC variability was observed to be highest during HSP and higher in MSP compared to LSP. Comparing TEC variability between Sutherland and Libreville in each phase, the TEC magnitudes in each phase of the solar levels is always higher in Libreville compared to Sutherland during daytime hours. The range in magnitude of TEC during HSP at Libreville is ~ 50TECU-130 TECU and at Sutherland, it ranges between ~ 20 TECU and ~ 80 TECU. For MSP, the range was between ~ 35 TECU and ~ 80 TECU and between ~ 10 TECU and ~ 40 TECU at Libreville and Sutherland, respectively. In year 2008, the TEC magnitudes variability observed at Libreville is higher (~38 - ~59 TECU) compared to that of Sutherland (~20 - ~1TECU). Although, it is expected that SVR generally decreases when solar activity increases especially at nighttime. Interestingly, our results show that at different phases of solar activities on all seasons and hours, the SVR magnitudes at Sutherland were ~ halved of magnitudes observed at Libreville. Apart from photo-ionization that influences their magnitudes at different levels, their location played significant role regarding additional magnitudes of TEC. We therefore suggest stronger equatorial low latitude anomaly associated with the photo-ionization as the primary mechanism that initiated these higher magnitudes of TEC at Libreville. This is possible, since Libreville is situated along the highly variable equatorial anomaly crests of Africa and Sutherland is found where the anomaly is absent. The yearly mean changes on HSP, MSP and LSP at Libreville and Sutherland are also investigated and possible mechanisms responsible for their variability were discussed.

Title: Spatial Variations of GPS-Measured Total Electron Content over Nigeria

Presenter/First Author: Eyelade Victor Adetayo, Federal University of Technology Akure, Akure,

Presenter/First Author Email: adetayo.eyelade@yahoo.com

Co-authors: Babatunde Rabiu, National Space Research and Development Agency, Abuja, Nigeria; Adewale Adekola, University of Lagos, Lagos, Nigeria

Published Material: The presentation was reported during 2014 African Geophysical Society Conference held in Abuja, Nigeria between June 2nd to 6th. *It was Organized by National Space Research* and *Development Agency, Abuja*. The paper is currently under review.

Abstract Body: This paper examined the spatial variations of the ionospheric Total Electron Content (TEC) over Nigeria using the GPS data obtained from Nigeria Network Observation Stations (NIGNET) in the year 2012. GPS data for year 2012 recorded at various stations in Nigeria ranging from geographic latitude 4.80°N to 12.47°N and geographic longitude 3.40°E to 12.50°E was used for this study. Analysis of spatial variations of TEC, which features Sunrise, 12 noon, Sunset and daily maximum variations of TEC, were performed within the period under consideration and the result engaged to generate local TEC maps. At 07:00 LT, due to the relative position of the sun as the sun rises, TEC decreases westwards across all the latitudes and it is found to be weakest at this time because the intensity of solar radiation is quite low. Greater magnitude of TEC was observed at 12:00 LT while it decays gradually and smoothly at 17:00 LT through the midnight until pre-sunrise hours and it is evident that the magnitude of TEC post-sunset variation is always greater than its pre-sunrise variation. Also, TEC decreases eastward across all latitudes as a result of reduction in the ionization at the east due to the relative position of the Sun as it sets around 17:00 LT.

Title: Investigating Changes in Field Aligned Current Maps for Changing Solar Radiative Indices

Presenter/First Author: Thomas Edwards, Virginia Polytechnic Institute and State University, Blacksburg, VA

Presenter/First Author Email: hardsnow@vt.edu

Co-authors: Daniel R Weimer, Virginia Tech, Blacksburg, VA

Abstract Body: Further developments have been made in the understanding of the interaction between solar wind and the interplanetary magnetic fields in the polar regions of the Earth's magnetic field. Previously, measurements using the Oersted satellite were used to develop field-aligned current (FAC) distribution mappings, and measurements from the ACE satellite was used to provide IMF data to study the changes of the FAC mappings during different solar wind conditions.

Magnetometer measurements from the CHAMP satellite have been used to develop maps for field aligned currents (FAC) based on previously developed techniques. This additional data from the CHAMP satellite has been used to provide further detail to this procedure and to study the effects of solar radiation on the auroral regions of the Earth's magnetosphere and ionosphere. These maps are then compared with four solar indices, F_10.7, S_10, M_10, and Y_10, to study the effects of solar radiation on the FACs. Initial investigation suggest that during equinox conditions the FAC tends to increase with solar radiation as expected, however winter and summer conditions do not completely agree with expected results.

Title: Investigations on the Variations of Space Weather and Correlation Analysis with the GOCE Gradiometer Measurements

Presenter/First Author: E. Sinem Ince, York University, Toronto, ON

Presenter/First Author Email: seince@yorku.ca

Co-authors: Spiros D Pagiatakis, York University, Toronto, ON, Canada

Abstract Body: It is known that extreme variations in space weather and corresponding geomagnetic storms can affect satellite communication systems, disrupt electrical systems, damage hardware onboard the satellites and most importantly disturb the satellite measurements in an unusual way. In this study, we investigate the unexpected disturbances present in GOCE (Gravity Field and Steady-State Ocean Circulation Explorer) mission derived gravity gradients along the satellite track over the magnetic poles and its possible correlation with the magnetic storms occurred within the same time period. The interplanetary magnetic field and plasma flow velocity along with electric field data observed by the solar satellites ACE (Advanced Composition Explorer) and WIND are obtained from OMNI Website. Moreover, magnetic activity observations collected at CARISMA (Canadian Array for Real-time Investigations of Magnetic Activity) stations are included in our investigations for the comparison purposes. It is found that the CARISMA data are capable of monitoring the magnetic activity variations and agree well with the ACE and WIND observed datasets and can be useful for correcting GOCE mission gradiometer measurements due to their high resolution. By using these external and independent data we aim to understand the correlation between the disturbances observed in the GOCE gravity gradients and solar activity and eventually eliminate these effects from the gradiometer measurements.

Title: Partial melting, orogeny and crustal differentiation

Presenter/First Author: Olivier Vanderhaeghe, GET Géosciences Environnement Toulouse, Toulouse,

Presenter/First Author Email: olivier.vanderhaeghe@get.obs-mip.fr

Published Material: The presented research is a synthesis of previously published papers (Vanderhaeghe & Teyssier, Tectonophysics, 2001; Vanderhaeghe et al., Journal of Geodynamics, 2003; Vanderhaeghe, Tectonophysics, 2009; Vanderhaeghe, Journal of Geodynamics, 2012) augmented with ongoing work.

Abstract Body: Partial melting of the crust plays a key role during orogenic evolution and leads to crustal differentiation as it impacts rheology and allows for melt/solid segregation and thus for magma transfer. These processes are controlled by (i) the dynamic balance among forces arising from plate-tectonic, gravitational potential energy, and buoyancy, (ii) the thermal balance between deformation-induced and radioactive heat production and heat advection related to subduction, orogenic deformation, and magma transfer. The strength decrease associated with partial melting leads to strain partitioning expressed by channel flow driven either by forces related to plate tectonics and/or buoyancy (vertical extrusion) or by the gravity force associated with lateral variations of crustal thicknesses (horizontal channel flow). Structural characteristics of migmatites point to the role of deformation in melt migration, but the emplacement of laccoliths of leucogranites above migmatitic terranes attests to the efficiency of the buoyancy force. The transition from partially-molten rocks to magmas is marked by another strength decrease allowing for settling of floating/sinking solids and favoring the development of gravitational instabilities (domal flow) evidenced by domes cored by diatexites (former heterogeneous magmas) mantled by metatexites (former partially-molten rocks). Melt/solid segregation and magma mobility during orogeny leads to the development of a crustal-scale horizontal layering. The middle crust is dominated by migmatites with domes cored by diatexites and mantled by metatexites that correspond to a partially-molten and magmatic zone, respectively. The granitic dikes and sills and the associated laccoliths of leucogranites correspond to an intrusive zone overlying the partially-molten zone. The refractory lower crust comprises residual and non-fertile material segregated and from the overlying heterogeneous magmas and partly accumulated against the Moho.

Title: What controls the geometry of large collisional orogens: insights from numerical modelling

Presenter/First Author: Katharina Vogt, Utrecht University, Utrecht,

Presenter/First Author Email: k.j.vogt@uu.nl

Co-authors: Liviu-Ciprian Matenco, Utrecht University, Utrecht, 3584, Netherlands; Taras Gerya, ETH Swiss Federal Institute of Technology Zurich, Zurich, Switzerland; Sierd Cloetingh, Utrecht University, Utrecht, 3584, Netherlands

Published Material: These findings have been partly reported at the AGU 2014 Fall Meeting in San Francisco. These findings are not under review and have not been published by a scientific journal

Abstract Body: When continents collide mountain ranges with high topographies and complex geometries are formed. Compressional stresses during ongoing convergence result in crustal thickening, localized deformation, and material transport. Thus, crustal material is transported and redistributed within the orogen.

We use numerical thermo-mechanical models to investigate the physical processes of continent collision zones and its implications on crustal scale deformation and architecture. We demonstrate that compression of two continental blocks, separated by a rheologically weak suture zone can result in (i) double-vergent or (ii) single-vergent orogens, with distinct geometries, deformation and exhumation patterns. The transition between these different modes of collision is controlled by the rheology of the continental lithosphere and its temperature. Coupled crustal layers form double vergent orogens, while decoupled crustal layers result in single-vergent orogens.

Double vergent orogens are formed in response to the gradual accretion of crustal material along pro- and retro-shears (fore- and back-thrust). In these models, deformation is highly localized on the retro-side, where large off-sets are recorded. At Moho depth, the progressive decoupling of crustal material from the mantle lithosphere, leads to subduction of mantle lithosphere and accumulation of lower crust material at the plate interface. Typical examples include the collision recorded by the Swiss Alps and the Pyrenees.

In contrast, single-vergent orogens are characterized by large-scale lower plate deformation and are accompanied by the subduction of lower continental crust. In this situation, no significant retro-shear formation is observed, which is in agreement with recent physical modelling studies on deformation of the continental lithosphere. The resulting orogen is highly asymmetric and almost exclusively oriented towards the foreland. Natural examples of such single vergent orogens are common in the Mediterranean (Carpathians, Dinarides, Apennines, Betics) or the SE Asia subduction zones.

We conclude that deformation and exhumation in continent-continent collision zones may occur in foreland or hinterland settings, depending on the rheological structure of the continental lithosphere.

Published Material: Smit, M.A., Ratschbacher, L., Kooijman, E., and Stearns, M.A., 2014, Early evolution of the Pamir deep crust from Lu-Hf and U-Pb geochronology and garnet thermometry, Geology, v. 42(12), 1047-1050.

Abstract Body: The large hot orogen exposed in the Pamir-Karakorum-Himalaya is a focal point of research into the links between active plate dynamics, magmatism, and tectonics. Extensive research accomplishment during the past three decades has allowed detailed reconstruction of Miocene exhumation, uplift and magmatism. Earlier orogenic processes, however, are still largely obscured, owing to an apparent scarcity of well-preserved assemblages and the general difficulty in resolving prograde histories from these. Recent research efforts demonstrated the widespread occurrence of Cenozoic deep-crustal rocks in the Pamir plateau. In this study, we investigated the timing and cause of prograde metamorphism of these rocks using Lu-Hf geochronology, U-Pb rutile thermochronology, and garnet thermometry. Regional prograde metamorphism and heating to 750-830 °C, as constrained by Zr-in-rutile and diffusion thermometry, occurred between 37-27 Ma. Prograde growth of garnet first occurred in the South Pamir at c. 37 Ma and spread to the Central Pamir during the following 10 Myr. By c. 27 Ma, the deep crust had heated beyond c. 750 °C and was partially molten on a regional scale. We attribute this thermal evolution to enhanced mantle heat flow following the c. 45-Ma slab break-off of Indian lithosphere underneath the Pamir. The history uncovered here confirms a long-lived thermal history of the Pamir deep crust and advocates a causal link between break-off, enhanced mantle heat flow, and heating of the deep crust along margins of large hot orogens.

Title: Crustal Structure Variation Across the Western Himalayas and Tibet

Presenter/First Author: Amy Gilligan, University of Cambridge, Cambridge,

Presenter/First Author Email: a.gilligan@imperial.ac.uk

Co-authors: Keith F Priestley, University of Cambridge, Cambridge, United Kingdom; Steven W Roecker, Rensselaer Polytechnic Inst, Troy, NY; Vadim L Levin, Rutgers University, Piscataway, NJ; Shyam Sundar Rai, National Geophys Res Instt, Hyderabad, India

Published Material: Some of this work was presented at the AGU Fall meeting 2014 and a paper has just been submitted to JGR (awaiting reviewer asignment)

Abstract Body: We present new, high resolution, shear velocity models for the western Himalayas and West Tibet from the joint inversion of P receiver functions recorded using seismic stations from four arrays in this region and fundamental mode Rayleigh wave group velocity maps from 5-70s covering Central and Southern Asia. The Tibetan Plateau is a key locality in understanding large-scale continental dynamics. A large number of investigations has examined the structure and processes in eastern Tibet, however western Tibet remains relatively understudied. Previous studies in this region indicate that the western part of the Tibetan Plateau is not a simple extension of the eastern part. The areas covered by these arrays include the Karakoram and Altan-Tagh faults, and major terrane boundaries in West Tibet and the Himalayas.

We use the shear wave velocity models to obtain estimates of Moho depth. The Moho is deep (68-84km) throughout West Tibet. We do not observe significant steps within the Moho beneath West Tibet. A large step in Moho depth is observed at the Altyn-Tagh fault, where Moho depths are 20-30km shallower to the north of the fault compared to those to the south. Beneath the Lhasa Terrane and Tethyan Himalayas we observe a low velocity zone in the mid-crust. This feature is not interrupted by the Karakoram Fault, suggesting that the Karakoram Fault does not cut through the entire crust.

Title: Syn-Compression Normal-Sense Low-Angle Detachment in the Himalayan Foreland, Western Nepal: Implications for Orogenic Models

Presenter/First Author: Renaud Soucy La Roche, University of Quebec at Montreal, Montreal, QC

Presenter/First Author Email: renaudslr@hotmail.com

Co-authors: Laurent Godin, Queen's University, Kingston, ON, Canada; John M Cottle, University of California Santa Barbara, Santa Barbara, CA

Published Material: Results were partially presented in: Soucy La Roche, R., Godin, L., and Braden, Z., 2014, Recognition of the South Tibetan detachment in the Karnali klippe, western Nepal: Implications for emplacement of Himalayan external crystalline nappes, in Montomoli C. et al., eds., proceedings for the 29th Himalaya-Karakoram-Tibet Workshop, Lucca, Italy, p. 155.

Abstract Body: The Himalayan metamorphic core, exposed between two opposite sense shear zones, is locally preserved in a series of foreland klippen. The upper shear zone, the South Tibetan Detachment (STD), is a key element in many competing tectonic models. One of these, the tectonic wedging model, requires that the STD merges with the reverse-sense basal shear zone towards the foreland. The Karnali klippe in western Nepal is a doubly-plunging synform underlain by a ca. 2 km thick folded reverse-sense shear zone. It comprises amphibolite metamorphic facies rocks overlain by greenschist to subgreenschist facies sedimentary rocks. Based on quartz recrystallization textures and crystallographic preferred orientations, the metamorphic units record both coaxial and reverse-sense non-coaxial strain at temperature increasing structurally upward from 550-600°C just above the basal thrust to ca. 750 °C in the middle and upper levels. In contrast, a ca. 1 km thick low-angle normal-sense shear zone, correlated with the STD, separates the metamorphic rocks in the footwall from low grade sedimentary rocks in the hanging wall on both flanks of the klippe. Temperature of deformation decreases abruptly to 580 °C and to 475 °C in the lower and upper part of the STD, respectively. Calcite twin types suggest that sedimentary units of the hanging wall were deformed at temperatures of 150-200 °C. In situ U-Th/Pb geochronology on monazite, combined with chemical characterization, suggests that prograde metamorphism occurred between 36 and 30 Ma in the immediate footwall of STD, followed by tectonic exhumation from 28 to <24 Ma, possibly starting as early as 30 Ma. Transport-parallel exposure of the STD in this area implies a minimum slip of 145 km. The presence of the STD on both flanks of the Karnali klippe contradicts previous interpretations that it merges at depth with the basal shear zone, thus weakening the argument for tectonic wedging in western Nepal.

Title: Crustal evolution of ca. 1.9-1.85 Ga collisional orogen associated with the massif-type anorthosite in the Yeongnam Massif, Korea

Presenter/First Author: Moonsup Cho, Seoul National University, Seoul,

Presenter/First Author Email: moonsup@snu.ac.kr

Co-authors: Yuyoung Lee, , Seoul, South Korea; Wonseok Cheong, , , ; Keewook Yi, Korea Basic Science Institute, Ochang, Chungbuk, South Korea

Published Material: Results were partially presented in Lee et al. (2014, *Terra Nova*, 26, 408–416).

Abstract Body: The North China Craton (NCC) including the Korean Peninsula has experienced episodic amalgamation and intracrustal reworking since its formation in the Archean. The Yeongnam Massif, Korea, situated at the eastern margin of the NCC, records prolonged crustal evolution characterized by an arc-related magmatism at ca. 2.0-1.9 Ga and subsequent collisional event at ca. 1.9-1.87 Ga, followed by a massif-type anorthositic magmatism at 1.86 Ga. An extensive occurrence of migmatites is well documented throughout this massif, but their temporal relationship and tectonic setting are poorly constrained. Zircon and baddeleyite grains separated from the anorthositic rocks were dated using a sensitive high-resolution ion microprobe (SHRIMP)[1]. The weighted mean $^{207}Pb/^{206}Pb$ age of zircon from two anorthosites is 1862 ± 2 Ma, corroborated by the baddeleyite age of 1861 ± 14 Ma. On the other hand, the ages of hornblende gabbro and granitic gneiss are 1873 ± 4 Ma and 1875 ± 5 Ma, respectively. In contrast, zircon rims from mafic granulite and migmatitic gneiss yielded ages of 1860 ± 5 Ma and 1858 ± 4 Ma, respectively, implying that the granulite-facies metamorphism and anatexis are associated with the anorthosite emplacement. Our preliminary P–T–t analyses based on pseudosections and microstructures of garnet–sillimanite–cordierite–K-feldspar–plagioclase–ilmenite–melt-bearing aluminous migmatites suggest a peak metamorphic condition at 800–850 °C and 4–7 kbar, followed by a near-isobaric cooling with melt crystallization in the range of 700–750 °C and 4–6 kbar. These results together with available Re-Os data are compatible with ca. 1.9–1.85 Ga collisional orogeny prevalent in the NCC, and suggest that orogenesis was accompanied by the mantle delamination beneath the craton. Taken together, we suggest that the Yeongnam Massif has experienced a prolonged orogeny characterized by late-orogenic anorthositic magmatism.

Title: A 1 Ga Eclogite-bearing Hot Migmatitic Nappe in the Sveconorwegian Orogen – a Window into Depth beneath the Frontal Part of a Precambrian Himalayan-Tibetan-type Plateau

Presenter/First Author: Charlotte Möller, Lund University, Lund,

Presenter/First Author Email: charlotte.moller@geol.lu.se

Co-authors: Jenny Andersson, Geological Survey of Sweden, Uppsala, Sweden

Published Material: Möller, C., Andersson, J., Dyck, B., Antal Lundin, I. 2014: Exhumation of an eclogite terrane as a hot migmatitic nappe,Sveconorwegian orogen, in: Castelli, D., Godard, G., Hirajama, T., Medaris, G. (Eds.), High- and ultrahigh-pressure metamorphism, from microscopic to orogenic scale. Lithos (Special Issue). DOI 10.1016/j.lithos.2014.12.013

Abstract Body: The Eastern Segment of the Sveconorwegian orogen exposes a formerly deeply (35-40 km) buried section of continental crust, corresponding to a setting beneath an orogenic plateau. A 75 x 50 km large eclogite-bearing nappe proves deeper burial (>55 km) of parts of the same crustal block. The eclogite-bearing nappe was exhumed by tectonic extrusion, melt-weakening assisted and foreland-directed translation of eclogitized crust, and stalled at 35–40 km depth within the collisional belt.

The Eastern Segment is semi-continuous with the continental foreland in the east (Baltica) but tectonically bound by a major crustal shear zone, the “Mylonite Zone”, at the contact to the Idefjorden Terrane in the west. Different lines of evidence indicate that this boundary is a deep collisional suture, where the Eastern Segment was down-thrusted “India-style” beneath the frontal part of a Himalayan-Tibetan-type plateau: 1) the eclogite-bearing nappe is located at the boundary; 2) the Eastern Segment and the Idefjorden Terrane both experienced metamorphism ≤ 0.98 Ga, but share neither pre-Sveconorwegian 1.7-1.1 Ga nor Sveconorwegian 1.05-0.99 Ga igneous and tectonic evolutions.

The eclogite-bearing nappe in the Eastern Segment demonstrates that extrusion of melt-weakened crust is a viable exhumation mechanism within hot and deep collision zones. The eclogites are structurally restricted to a regional recumbent fold in which stromatic orthogneiss with pods of amphibolitized eclogite make up the core. High-temperature mylonitic gneiss with remnants of kyanite eclogite compose a basal shear zone, <4 km wide. Heterogeneously sheared and partly migmatized augen gneiss forms a tectonostratigraphic marker in front of and beneath the nappe, and is in turn structurally enveloped by a composite sequence of orthogneisses and metabasites. The entire tectonostratigraphic pile underwent near-pervasive deformation and recrystallization under high-pressure granulite and upper-amphibolite conditions.

Title: Orogenic wedge or channel flow for the tectonic evolution of Parautochthonous Belt? New evidence from the Central Grenville Province

Presenter/First Author: Sophie Jannin, Ecole Polytechnique de Montréal, Montréal, QC

Presenter/First Author Email: sophie.jannin@gmail.com

Co-authors: Felix Gervais, École Polytechnique, Montreal, QC, Canada; Abdelali Moukhsil, Ministère de l'Énergie et des Ressources naturelles du Québec, Val D'Or, QC, Canada; James L Crowley, Boise State University, Boise, ID; Lars Eivind Augland, , ,

Published Material: Some part of this presentation where reported in Québec Mines meeting in 2012 and 2013. And some are reported in a MERN report (Minsitère de l'Energie et de Ressources Naturelles) and are under review.

Abstract Body: The tectonic evolution of the Parautochthonous Belt is controversial. An orogenic wedge model was proposed based on detailed fieldwork conducted in the eastern Grenville Province, whereas synconvergent and postconvergent heterogeneous channel flow modes were based largely on geometrical similarities between observed crustal structures and prediction from numerical models. This study presents new field-based structural and geochronological data from the southwestern part of Manicouagan reservoir (Central Grenville Province) that provides important constraints on these hypotheses.

In the Parautochthonous Belt, three deformation phases have been mapped. D_2 structures were developed by oblique-reverse, top-to-the-NNE shearing. Pre- to syn- D_2 axial-planar leucosomes yielded a weighted mean average $^{206}Pb/^{207}Pb$ age of 992 ±22Ma (LA-ICPMS on zircons) and, one analysis gives a concordia $^{206}Pb/^{238}U$ age of 986 ±4Ma (TIMS). A cross-cutting D_2 gabbro, co-magmatic with a pegmatite, has a D_2 lineation defined by retrograde hornblendes. This late D_2 pegmatite gives a weighted average $^{206}Pb/^{207}Pb$ age of 961 ±22Ma (LA-ICPMS on zircons). D_3 structures have been found locally at upper structural levels of the belt and were formed by oblique-normal, down-to-the-SW shearing. Syn-D_3 leucosome yielded a concordia $^{206}Pb/^{238}U$ age of 993 ±3Ma (TIMS on zircons). In the Allochthonous Belt, two deformation phases have been mapped. The main transposition fabric was developed by reverse, top-to-the-NNW shearing associated with the 1080-1030 Ma granulite-facies metamorphism of this belt, whereas the second deformation is the newly-identified Thachic shear-zone (TSZ) developed by oblique-normal, down-to-the-SSE or E shearing. Pegmatitic dykes cross-cutting TSZ but having normal kinematic indicators and a TSZ lineation, yielded a Concordia $^{206}Pb/^{238}U$ age of 988 ±3Ma (TIMS on zircons).

Normal-sense shearing at the upper structural level of the Parautochthonous Belt and along the TSZ, was, therefore, synchronous within error with D_2 reverse deformation in the structurally underlying Parautochthonous Belt. These characteristics imply extrusive ductile flow and are thus compatible with a form of channel flow rather than an orogenic wedge.

Title: Syn-orogenic High Fe-Ti Tholeiitic Magmatism in the Hinterland of Central Grenville Province: Implications for the Evolution of Large Hot Long Duration Orogens.

Presenter/First Author: Barun Maity, Memorial University of Newfoundland, St. John's,

Presenter/First Author Email: barun.maity@mun.ca

Co-authors: Aphrodite Daphnee Indares, Memorial University of Newfoundland, St Johns, NL, Canada; Greg Dunning, Memorial University of Newfoundland, St John's, NF, Canada

Abstract Body: Late syn-orogenic (~1000 Ma) tholeiitic (high Fe-Ti) mafic rocks with granulite-facies assemblages and textures are documented for the first time in the hinterland of the central Grenville Province (Manicouagan area) where they form concordant or slightly discordant layers interleaved with felsic and mafic gneisses. Geochemically they are characterized by high FeO_t, TiO_2, P_2O_5 and HFSE ratios and low SiO_2, MgO, #Mg, Ni and Cr. Based on petrography, geochemistry and age they can be separated into two groups. The older group consists of granoblastic hornblende+ plagioclase+ clinopyroxene+ garnet+ ilmenite± orthopyroxene, and is characterized by $(La/Yb)_n$= 2.3-3.3, $(Nb/Th)_n$= 0.6-1.3, $eNd_{(1.0)}$= 1.5-2.8 and T_{DM1} = 1487-1523 Ma. One sample yielded a crystallization age of 1006±4 Ma and a metamorphic age of 1005.5±2.7 Ma (zircon U-Pb by CA-TIMS). The younger group consists of porphyroblastic garnet+ plagioclase+ orthopyroxene+ biotite+ ilmenite, large partially resorbed quartz grains, and minor K-feldspar, allanite, barite, thorite, monazite and apatite. A sample from this group has $(La/Yb)_n$= 5.3, $(Nb/Th)_n$= 2.4, $eNd_{(1.0)}$= 4.6 and T_{DM1} = 1131 Ma, and yielded a crystallization age of 997±2.6 Ma.

All samples plot in the within-plate or ocean floor basalt fields in tectonic discrimination diagrams, and the geochemical and isotopic characters of both groups indicate partial melting of a mantle source followed by fractional crystallization or assimilation-fractional crystallization along tholeiitic trend. The textural and age data suggest the rocks underwent medium-*P* granulite-facies metamorphism shortly after their emplacement. This record of late syn-orogenic magmatism and high-*T* metamorphism is compatible with delamination or convective thinning of the overthickened lithosphere beneath a large hot orogen (LHO) formed during the Ottawan phase of Grenvillian orogeny, followed by decompression melting of the rising asthenosphere and conductive heating of the thinned crust from below.

Title: Metamorphic Patterns of Aluminous Rocks from High and Mid-pressure Crustal Segments of the Central Grenville Province- a Review

Presenter/First Author: Aphrodite Daphnee Indares, Memorial University of Newfoundland, St Johns, NL

Presenter/First Author Email: aindares@mun.ca

Co-authors: Greg Dunning, Memorial University of Newfoundland, St John's, NF, Canada

Published Material: This is a review paper that summarizes work done ande published between 2005 and 1014

Abstract Body: Anatectic aluminous rocks in the Manicouagan area (central Grenville province) provide a record of partial melting, P–T evolution and the timing of metamorphism in granulite-facies crustal segments that were metamorphosed at different times and/or different depths during the Grenvillian orogeny: the southern part of the Parautochthonous belt (SPB), and the high-P and mid-P portions of the hinterland (HPH and MPH respectively).

In all segments the aluminous rocks consist of the assemblage garnet , ± biotite ± plagioclase, K-feldspar, and kyanite (in the HPH and in most of the SPB) or sillimanite (in the MPH), with textures suggestive of anatexis by breakdown of micas. The preservation of peak assemblages is consistent with melt migration, but widespread textural evidence of former melt at the sample scale suggests that a melt fraction was retained in most rocks at all levels. Textures and mineral chemistry, in conjunction with phase equilbria modeling, suggest that the rocks in the different segments followed contrasting P–T paths, with: (a) steep dP/dT gradients in the kyanite stability field, up to ~16 kbar and 850–900^{o}C in the HPH; (b) moderate dP/dT gradients limited between the ky-sil transition and the crd-in boundary with a peak at 9–11 kbar and 820–860^{o}C in the MPH; and (c) moderate dP/dT gradients in the kyanite field with a peak at 12–14 kbar and 800–850^{o}C in the SPB. In both the HPH and the SPB, the anatectic melt crystallized in the kyanite field. Monazite U-Pb data indicate that the granulite-facies metamorphism occurred during the Ottawan phase of the Grenvillian orogeny in the HPH (1.05–1.03 Ga) and the MPH (1.08–1.05 Ga; down to 1.02 Ga), and during the Rigolet phase (0.98–0.97 Ga) in the SPB. In addition, ages of 1.0–0. 98 Ga were also recorded by a texturally distinct generation of monazite rims in the SPB, and these ages are coeval with widespread ultrapotassic magmatism in the same crustal segment.

Title: The Supracrustal Rocks of the Escoumins Area: a Well-Preserved Pinwarian Arc-Backarc Sequence in the Central Grenville, Quebec.

Presenter/First Author: Pierre-Arthur Groulier, Memorial University of Newfoundland, St John's,

Presenter/First Author Email: pgroulier@mun.ca

Co-authors: Aphrodite Daphnee Indares, Memorial University of Newfoundland, St Johns, NL, Canada; Abdelali Moukhsil, Ministère de l'Énergie et des Ressources naturelles du Québec, Val D'Or, QC, Canada; Greg Dunning, Memorial University of Newfoundland, St John's, NF, Canada; Stephen J Piercey, Memorial University, St. John''S, Canada

Published Material: During the Quebec Mines congress in last november (2014).

Abstract Body: Well-preserved amphibolite-facies supracrustal rocks (Saint-Siméon Group) with primary textures is discontinuously exposed for over 100 km in the Escoumins-Petit Saguenay area of the central Grenville Province, and consists of metasedimentary (quartzite, meta-arkose, conglomerate, calc-silicate, greywacke, paragneiss and scarce marble) and metavolcanic rocks (mainly mafic to intermediate with few felsic). The latter are interpreted to represent flows and volcaniclastic deposits (hyaloclastite, breccia and different varieties of tuff) interbedded with sedimentary rocks, and suggests the Saint-Siméon Group is a volcano-sedimentary belt. The supracrustal rocks are located in synforms separated by antiforms of migmatite and orthogneiss with calc-alkaline continental arc signature (Tadoussac Group) in an overall domes and basins geometry. The geochemistry of the volcanic rocks from the Saint-Siméon Group range from those with E-type MORB-like REE patterns with negative Nb-Ta anomalies and enrichment in Th typical of back-arc basin basalts to those with more evolved arc signature and fractionation of LREE from HREE. A bomb-bearing dacitic tuff yielded a TIMS U-Pb zircon crystallisation age of 1493 ±3 Ma (Pinwarian) with a 1000 ±3 Ma metamorphic overgrowth. U-Pb analysis on titanite gave a similar age of 1000 Ma with a second cluster at 985 Ma. All metamorphic ages correspond to the Rigolet phase of the Grenvillian orogeny. These preliminary data add new insight on the makeup of the SE Laurentian margin and indicate the presence of a significant Pinwarian arc-back arc sequence in the southcentral Grenville Province.

Title: Muskoka Domain as a First-Order Detachment Zone during Exhumation and Orogenic Collapse: Support for a Core Complex Model for the Central Gneiss Belt, Western Grenville Province

Presenter/First Author: Toby Rivers, Memorial University of Newfoundland, St John's, NF

Presenter/First Author Email: trivers@mun.ca

Co-authors: Walfried Martin Schwerdtner, University of Toronto, Toronto, ON, Canada

Published Material: Paper is an overview. A small component of the information was reported by Schwerdtner et al (2014) in CJES. Other aspects were reported in a Field Trip Guide for Friends of the Grenville (FOG) in October 2014. This field trip guide has not been widely circulated. The overall message of the abstract has not been reported elsewhere.

Abstract Body: The Central Gneiss Belt (CGB) in the western Grenville Province of Ontario and Quebec is a large high-grade gneiss terrane with a surface area of >60,000 km^2. It consists of a crustal-scale stack of thrust sheets assembled during the Ottawan phase of the Grenvillian orogeny at ~1080 Ma, and is juxtaposed on its southeastern side against the lower grade Composite Arc Belt (CAB). Our work has focussed on the southern margin of the CGB (Ontario segment), where the granulite-facies rocks of the CGB (Algonquin domain) are separated from the CAB by a several km-thick, predominantly upper amphibolite-facies sheet known as the Muskoka domain.

On the basis of local, but widespread relict granulite-facies mineralogy and decompression textures, we infer that peak Ottawan metamorphic conditions in the Muskoka domain were comparable to those in the underlying Algonquin domain, and that the main amphibolite-facies mineralogy and high-strain planar gneissic fabrics characteristic of the Muskoka domain developed *after* the metamorphic peak during exhumation and retrogression. Post-peak exhumation and retrogression in the Muskoka domain began at ~1060 Ma while the rocks were still hot, and was associated with important ductile crustal thinning, orogen-perpendicular extension, transtensional folding and boudinage on all scales. Related fluid influx promoted widespread migmatization, which caused rheological weakening, with the result that the Muskoka domain became a mobile zone akin to a ductile glide horizon between two more competent units.

Collectively this evidence supports a core complex model for the exhumation of the CGB, in which the Muskoka domain formed a weak extensional detachment zone as the underlying hot granulite-facies mid crust rose into the thinned neck regions of the boudinaged overlying cooler amphibolite-facies upper crust during prolonged extensional collapse.

Title: Paleomagnetism: a Potential Avenue for Mapping the Allochthon Boundary Thrust and for Understanding the Development of the Grenville Orogen.

Presenter/First Author: Henry C Halls, University of Toronto, Toronto, ON

Presenter/First Author Email: henry.halls@utoronto.ca

Co-authors: Alan Lovette, University of Toronto, Toronto, ON, Canada

Abstract Body: Paleomagnetic data are presented for the ~2.47 Ga River Valley anorthosite (**RV**) and for 1.23 Ga Sudbury dykes **(SD)** which lie in the Grenville Province (GP) between the Grenville Front (GF) and the Allochthon Boundary Thrust (ABT). Both rock types yield high H_c/T_{ub} remanences with shallow down to the ESE directions. Their age is no more than ~ 980 Ma based on Ar-Ar plateaux on hornblende from the anorthosite. S of the ABT Dunlop & co-workers find multi-component remanences but one (**A**) with the highest H_c/T_{ub} has a steep up direction to the WNW. It may have an age close to the mean of U-Pb ages on titanite (T_b ~ 600-650°C) that range from ~1030±30 Ma, N=20 determinations in the Central Gneiss Belt (CGB) to 1100 ± 60 Ma, N=27, in the Central Metasedimentary Belt (CMB) (Tohver et al 2006). A large difference in magnetization direction across the ABT suggests that paleomagnetic data represent *a potential tool in mapping this thrust fault*. S of the ABT, Ar-Ar hornblende ages are similar to those closer to the GF; for the CGB the mean is 980±23 Ma (N=22); in the CMB, 970±40 Ma for N=23 (Tohver et al. 2006). They may date magnetic overprints, many of which are similar or antipolar to **SD** and **RV**. The **SD** and **RV** poles lie on, but the **A** pole lies to the west of, the Laurentian APWP. The **A** pole and the mean **SD** - **RV** pole lie on a great circle ~normal to the GF, and *could* suggest that the ABT is a thrust along which Grenville rocks, *already magnetized in response to an earlier collisional uplift and cooling*, have been transported to the NW. Further NW movement followed, utilizing deeper thrusts, one of which defines the GF, along which uplift and cooling produced the **RV** and **SD** poles. The collision causing **A** may have been the earliest (ca 1.2-1.3 Ga) of four which define the Grenville orogen. Collectively, they may have been responsible for transporting rocks of the allochthon 4000+/-1000 km to the NW, a distance based on that between the **A** and the mean **RV-SD** poles.

Title: Exhumation and cooling histories for high-pressure blocks above the western-most ABT: Potential insights from garnet zoning and rutile U-Pb depth profiling

Presenter/First Author: Jeff Marsh, CUNY Queens College, Flushing,

Presenter/First Author Email: jmarsh@qc.cuny.edu

Co-authors: Andrew Smye, University of Texas at Austin, Austin, TX

Published Material: The zircon ages that will be discussed we published in Marsh & Culshaw, 2014. Lithos.

Abstract Body: Geodynamic models applied to the western Grenville Province predict a protracted period of high-temperature conditions (e.g. T > 700 °C for >70 Myrs) across the orogenic infrastructure during and after the Ottawan collisional phase. This is supported by ~50 Myr range in zircon ages from mid-crustal migmatites and hornblende ^{40}Ar-^{39}Ar cooling ages that are younger by another ~65 Myrs across much of the western Grenville. This type of long-duration high-T thermal history should result in complete diffusional re-equilibration of growth zoning in all but the largest garnet crystals and young ages in U-Pb thermochronometers with amphibolite-facies closure temperatures (T_c). However, exploratory thermal-chronological studies of HP mafic blocks within the Shawanaga Shear Zone (SSZ), the expression of the ABT along the Georgian Bay transect, show that prograde growth zoning (i.e. decreasing Mn and increasing Mg from core to rim) is well-preserved in ~4 mm garnet crystals and moderately preserved in many ~1 mm crystals. Given that these samples yield peak T estimates from 750-850 °C, the preservation of growth zoning suggests relatively short high-T durations (<5-10 Myrs at T_{char} = 750 °C and <7-30 Ma at T_{char} = 700 °C). Similarly, depth-profiled rutile crystals commonly show $^{207}Pb/^{206}Pb$ age progressions from ~1080 Ma in the cores to ~980 Ma along the rims, indicating core-to-rim migration of the intracrystalline diffusional closure front (associated with cooling from ~650 °C to ~500 °C) over this timeframe. The older ages preserved in the rutile cores (commonly within ~10 Ma of U-Pb zircon ages for the same samples (1085-1097 Ma)) suggests relatively rapid cooling within the interval of >750 °C to <650 °C following HP metamorphism. The rapid cooling (~10 °C/Myr) during the early Ottawan suggests syn-convergent exhumation to relatively shallow crustal levels followed by much slower cooling (~1.5 °C/Myr) during post-convergent residence in the thermally-matured middle-crust.

Title: 3D Visualization of the Large-Scale Crustal Structure in the SW Grenville Province

Presenter: Alan P Dickin, McMaster University, Hamilton, ON

Presenter Email: dickin@mcmaster.ca

First Author: Jacob Walter, Douglas Strong, McMaster University, Hamilton,

First Author Email: stronj@mcmaster.ca

First Author Student?: No

Abstract Body: An accurate understanding of the three-dimensional structure of orogenic belts is a prerequisite to a correct understanding of their tectonic history. However, the complexity of crustal architecture in the SW Grenville province has obscured a correct understanding of its structure, and hence of its geological evolution. The recognised locus of Ottawan-age crustal stacking during the Grenville Orogeny is the Allochthon Boundary Thrust (ABT), which separates laterally translated terranes to the southeast from largely in-situ terranes to the northwest. In the central and eastern Grenville province, the ABT acts as a crustal-scale ramp, up which high grade gneisses were exhumed before further sub-horizontal transport to the northwest. In contrast, the 'standard' model for the Grenville Province in Ontario and western Quebec interprets the ABT as a very long ramp with gentle southeasterly dip, extending across much of the outcrop width of the Central Gneiss Belt. However, Nd isotope mapping suggests that parautochthonous crust extends much further south than previously recognized, such that salients and windows of

parautochthonous crust are recognised east of Whitney and south of Gravenhurst, between major allochthonous thrust sheets and erosional klippen. This implies a ramp-flat crustal structure in the SW Grenville Province, which can be understood with the aid of 3D visualization. This allows the complex three-dimensional shape of the ABT to be explored and compared with the attitude of other ramp surfaces of different ages, such as the Central Metasedimentary Belt Boundary Zone (CMBBZ) and the Grenville Front. The attached image shows a visualisation of the ABT surface (pale green) from a viewpoint in the mid crust, looking from Quebec towards the southwest, across the Central Gneiss Belt of Ontario. The yellow ground surface represents Paleoproterozoic crust.

Title: Chronology of the Torngat orogeny: duration and extent of crustal melting from combined U-Pb zircon and monazite geochronology and Lu-Hf and Sm-Nd garnet geochronology

Presenter/First Author: Benoit Charette, University of Waterloo, Quebec,

Presenter/First Author Email: b2charet@uwaterloo.ca

Co-authors: Carl Guilmette, Université Laval, Québec, QC, Canada; Daniel Bandyayera, Ministere de l'Energie et des Ressources Naturelles du Québec, Québec, QC, Canada

Abstract Body: The Torngat Orogen is a transpressional, hot, narrow, doubly-vergent orogenic belt part of the South-Eastern Churchill Province (SECP), located between the Superior and Nain cratons in north-eastern Canada. Exhibited as a tripartite structure, the SECP is composed of an Archean-Paleoproterozoic gneissic core, the Core Zone, surrounded by two NNW-trending orogens on its eastern and western margins, namely the Torngat (1.87-1.82 Ga) and the New-Quebec (1.82-1.77 Ga) orogens. Produced by the collision of the Core Zone and the Nain Province, the deeply eroded Torngat Orogen exposes granulitic roots dominated by ortho- and paragneisses and metaplutonic rocks, and lower-grade continental margin metasediments and orthogneisses. Although previous studies highlighted three tectonometamorphic phases associated with distinct regimes (i.e. crustal thickening, transpression, and exhumation-cooling), the understanding of the prograde to retrograde evolution of the Torngat orogeny in terms of dominant processes in the middle and lower crust – such as partial melting, melt extraction, crustal differentiation or crustal flow – is still embryonic. In this contribution, we present preliminary results from the application of multiple geochronology methods (i.e. U-Pb, Lu-Hf and Sm-Nd) to accessory and major metamorphic minerals (i.e. zircon, monazite and garnet) combined with microstructural analysis, mineral chemistry and multi-equilibria thermobarometry. Because of the different closure temperatures of the investigated isotopic systems and since metamorphic reactions producing these minerals occur at various phases through the orogeny, the new data provide insights in the evolution of the Torngat, from the onset of thickening to anatexis to the stabilisation and relaxation of the orogen. Preliminary results suggest that crustal thickening started as early as 1887 Ma, and that granulitic/anatectic conditions might have been sustained for tens of Ma.

Title: Is the Trans-Hudson Orogen a Large, Hot Orogen? Insights From Orogenesis and Cooling on Hall Peninsula, Baffin Island

Presenter/First Author: Diane Skipton, University of Ottawa, Ottawa, ON

Presenter/First Author Email: dskip037@uottawa.ca

Co-authors: David A Schneider, University of Ottawa, Ottawa, ON, Canada; Marc R St-Onge, , , ; Dawn Kellett, Geological Survey of Canada, Ottawa, ON, Canada

Published Material: Some of the U-Pb monazite ages were reported at the Geological Soc. of America meeting in Denver, 2013. Some of the Ar-Ar ages were reported at last year's GACMAC meeting in Fredericton, 2014.

Abstract Body: The Trans-Hudson Orogen extends with a northeasterly strike for over 4600 km from the United States to northern Canada, and has an across-strike width of about 400-800 km. It has a long-lived accretionary history, beginning with amalgamation of crustal blocks in the upper Churchill plate during ca. 1.92 to 1.84 Ga, and ending with its terminal collision with the lower Superior plate at ca. 1.83-1.80 Ga. The orogen likely possessed a high heat flow, as it includes voluminous charnockitic batholiths and extensive granulite terranes. As such, in many ways it conforms to the definition of a large, hot orogen, comparable to the modern-day Himalayan orogen. Granulite-facies metasedimentary rocks on Hall Peninsula, southeast Baffin Island can be used to further explore this notion since they contain significant partial melt and host charnockitic plutons. The dominant deformation mechanism in the granulite facies terrane is km-scale east-vergent folding. Monazite U-Pb ages coupled with mica Ar-Ar geochronology on Hall Peninsula indicates cooling rates of ~1-2°C/Ma from peak metamorphism in the mid-crust at ca. 1.85-1.83 Ga to cooling through muscovite closure temperatures at ca. 1.67-1.64 Ga. This slow cooling rate and the lack of extensional structures suggest that this segment of the Trans-Hudson Orogen did not experience orogenic collapse despite a flat Moho and average crustal thickness of 43 km. In fact, much of the Trans-Hudson Orogen exhibits slow cooling rates and is missing many of the hallmarks of collapse, such as core complexes or significant detachments. The absence of these features sets the Trans-Hudson Orogen apart from other large, hot orogens such as the Grenville, Variscan and Himalayan orogens.

Title: The Paleoproterozoic Trans-Hudson Orogen: Large, Hot, but Only Moderately Thick?

Presenter/First Author: David Corrigan, Geological Survey of Canada, Ottawa, ON

Presenter/First Author Email: david.corrigan@NRCan.gc.ca

Published Material: Part of these findings are reported in Corrigan et al. (2009) Journal of the Geological Society of London and in "Tectonic Styles in Canada: The Lithoprobe Perspective" (Chapter 4: Paleoproterozoic crustal evolution and tectonic processes: Insights from the Lithoprobe Program in the Trans-Hudson Orogen, Canada, by D. Corrigan)

Abstract Body: The composite Trans-Hudson Orogen (THO), which locally reaches up to 1,500 km in width, compares in size as well as duration of collision with the Grenville Orogen. That being said, in detail they are quite different entities. The most striking difference, notwithstanding local exceptions, is the lesser degree of crustal thickening, as well as the apparent absence of core complex structures and related syn- to post-collisional extensional shear zones observed in the THO in contrast to the Grenville Orogen. Assuming that the thermal gradient of the continental crust and convergence rates were similar at ca. 1.83 Ga and 1.10 Ga, other

factors need to be considered in order to explain the observed differences. The most apparent empirical observation is the contrasting pre-collisional tectonic and magmatic accretion histories of both orogens. In the THO, widespread terrane and magmatic accretion shortly preceded terminal collision, resulting in structural and thermal weakening of the crust prior to collision. By contrast, in the Grenville Orogen, terrane and magmatic accretion predated collision by tens or hundreds of million years, allowing sufficient time for crust to cool prior to terminal collision. These contrasting starting conditions likely dictated how both orogens evolved with time, placing constraints on thermal and rheological boundary conditions. Another important factor, well constrained in the THO and much less so in the Grenville, is the size and shape of colliding continents and the presence of indenters, re-entrants, and oceanic freeboard. Particularly, the Ungava indenter (NE Superior Craton) was responsible for the highest degree of exhumation (by thrusting), as well as producing lateral escape of crustal blocks in the western Churchill Province, and southerly-directed crustal extrusion in the Core Zone, perhaps by tectonic overpressure.

Title: Very-High Temperature Metamorphism and Deformation in the Footwall of an Eclogite-bearing nappe, Sveconorwegian Orogen: Meta-leuconoritic and Sapphirine-bearing Rocks of the Obbhult Complex, SW Sweden

Presenter/First Author: Charlotte Möller, Lund University, Lund,

Presenter/First Author Email: charlotte.moller@geol.lu.se

Co-authors: Jenny Andersson, Geological Survey of Sweden, Uppsala, Sweden; Gisella Rebay, University of Pavia, Pavia, Italy

Abstract Body: The Eastern Segment, Sveconorwegian orogen, exposes a formerly deep section beneath the frontal part of a Himalayan-Tibetan type plateau. It hosts a 50 x 75 km eclogite-bearing nappe, which proves deep burial of continental crust and subsequent exhumation by extrusion of partially molten crust. The P-T-t-d evolution of the footwall beneath the eclogite-bearing nappe is characterized using a composite meta-igneous sequence (Obbhult complex).

Polyphasal deformation of the Obbhult complex involved isoclinal folding, E-vergent shearing, and refolding. Coarse-grained leuconorite–andesine anorthosite was heterogeneously mylonitized at very high temperature. The igneous assemblage (andesine plagioclase + orthopyroxene + Fe-Ti oxide) was recrystallized to metamorphic garnet + orthopyroxene + plagioclase + sillimanite + biotite + cordierite + quartz + hemoilmenite. Thermodynamic modelling (THERMOCALC) suggests PT conditions at 10.5-11.0 kbar and 850 °C for this assemblage. Si-poor, Mg-, Al-rich host rocks formed symplectite of sapphirine + garnet + corundum + hemoilmenite + plagioclase.

U-Pb SIMS zircon analysis dates the intrusion of anorthosite–leuconorite at 1.39 Ga, and the primary crystallization of intermediate-basic host rocks at 1.41 Ga. Thin secondary 0.98 Ga zircon rims formed in sapphirine-bearing and other deformed rocks.

Meta-leuconorites host four types of monazite: large, euhedrally zoned grains with resorbed margins, thin recrystallized rims on, and healed fracture zones within, large grains, and neoblasts in mylonitic deformation trails. EMP “chemical dating” demonstrates a Sveconorwegian age for recrystallization and neoblast formation; a primary igneous origin is indicated for large monazite grains.

The 1.4 Ga Obbhult complex demonstrates a non-complex 0.98 Ga Sveconorwegian metamorphic evolution for this part of the footwall beneath the eclogite-bearing nappe, involving very-high temperature recrystallization (850 °C) under polyphasal deformation, at c. 40 km depth.

Title: Transpressional collision and post-orogenic deformation in the New Quebec Orogen.

Presenter/First Author: Deanne van Rooyen, Organization Not Listed, Sydney,

Presenter/First Author Email: deanne_vanrooyen@cbu.ca

Abstract Body: The New Québec orogen (NQO) is a Paleoproterozoic orogenic belt in the southeastern Churchill Province of the Canadian Shield. The NQO formed as a result of terrane accretion to the Superior margin at ca. 1.82 Ga, followed by terminal collision with the Core Zone in a SW-directed dextral transpressional regime at ca. 1.80 to 1.77 Ga. In the Kuujjuaq – Tasiujaq area on the SW margin of Ungava Bay, the NQO consists of three main zones. The foreland of the orogen, (the Knob Lake Group), contains autochthonous rocks deposited on the Archean Superior craton margin, shortened and imbricated in SW-verging thrust stacks. These domains are tectonically overlain by allochthonous metavolcanic and metasedimentary rocks of the Rachel-LaPorte Zone. These allochthonous rocks represent the hinterland of the orogen, and are juxtaposed against the Kuujjuaq Terrane, the northernmost part of the Core Zone. In the Kuujjuaq – Tasiujaq area there is evidence for multiple generations of structures, some of which are syn-orogenic. Greenschist to amphibolite facies rocks in the Rachel-LaPorte zone include metasedimentary rocks in which the main S_0-S_1 foliation dips moderately SE, overprinted by an F_2 crenulation with fold hinges plunging SW resulting in an S_2 cleavage dipping NW, in turn overprinted by an F_3 crenulation with fold hinges plunging N, resulting in an S_3 cleavage dipping W. In sheared metabasaltic units with strongly developed foliation dipping moderately NNE, there are overprinting folds with axial planes dipping steeply NW and fold hinges plunging NE. The fold vergence suggests a dextral, oblique, top-down-to-the-ESE shear sense. In both these examples the structural fabrics suggest at least one phase of deformation that post-dates the SW-directed transport that imbricated the rocks on the Superior margin. The Leaf Bay domain of the Kuujjuaq Terrane contains retrogressed garnet orthopyroxene granulite and tonalite with foliations dipping S that pre-date collisional deformation. The supracrustal assemblages include sheared mafic and semipelitic schists with foliations dipping shallowly E, overprinted by an S_2 cleavage dipping steeply SE. These fabrics could be a result of SE-directed transport post-dating orogenesis, suggesting that previously undocumented extensional deformation may be preserved in the NQO.

Title: Metamorphic record of anatetic aluminous gneisses from the mid-pressure belt of the Grenvillian hinterland

Presenter/First Author: Mackenzie Elizabeth Patrick, Memorial University of Newfoundland, St. John's, NL

Presenter/First Author Email: n99mep@mun.ca

Co-authors: Aphrodite Daphnee Indares, Memorial University of Newfoundland, St Johns, NL, Canada

Abstract Body: A large portion of the hinterland of the Central Grenville Province is characterized by mid-pressure granulite-facies metamorphism. In the Manicouagan region, aluminous gneisses derived from hydrothermally altered volcanic and sedimentary protoliths provide a record of anatectic processes and of the pressure-temperature (P-T) evolution during orogenesis. Samples from these gneisses, collected in areas separated by several tens of kilometers, contain the same mineral assemblage: garnet, biotite, plagioclase, K-feldspar, quartz, sillimanite and locally, retrograde cordierite. However, they have a wide range of bulk compositions and textures, and may be grouped in two types: quartz-rich fine-grained fairly homogenous rocks, and relatively coarse-grained rocks of broadly pelitic composition. The later type shows microtextural evidence of partial melting, including pseudomorphed former melt inclusions in garnet, relict quartz surrounded by thin feldspar rims, and inter-granular films in the matrix. In addition, the presence of biotite-quartz symplectites and local replacement of garnet by biotite-sillimanite, are consistent with a melt crystallization reaction. However, the general preservation of the peak assemblage suggests that some melt has escaped. Phase equilibrium modeling with Thermocalc constrained the P-T field of the dominant mineral assemblage at 800-900ºC and 6-11kbar, with melt solidification in the range of 800-865ºC and 6-9kbar. The presence of sillimanite inclusions in garnet, and of only scarce, retrograde cordierite, is consistent with moderate dP/dT gradient 'hairpin' P-T paths. The data suggest that large parts of the mid-P hinterland in the central Grenville experienced a uniform metamorphic evolution, with large temperature variations relative to pressure. The high metamorphic temperatures recorded by these rocks are likely linked to syn-orogenic magmatic activity, and are consistent with the idea that the Grenville is a large hot orogen.

Title: Insights into the Geology of the Central Metasedimentary Belt of the Grenville Orogen from Airborne Geophysical Data recently acquired by the Ontario Geological Survey

Presenter/First Author: Robert Michael Easton, Ontario Geological Survey, Sudbury, ON

Presenter/First Author Email: mike.easton@ontario.ca

Published Material: Approximately 20% was presented at meeting of the Eastern Section of the American Association of Petroleum Geologists Meeting in London, Ontario on September 30, 2014.

Abstract Body: Most of the Ontario Grenville is covered by low resolution (800m line-spacing) 1950s and 1960s aeromagnetic data. In fall 2013, the Ontario Geological Survey (OGS) collected new high-resolution aeromagnetic and/or radiometric data over the eastern Central Metasedimentary Belt. The data were published in June 2014 as OGS Geophysical Data Sets 1074 (Renfrew) and 1075 (E Ontario) and as a set of hard-copy maps.

The Renfrew survey collected aeromagnetic and radiometric data at 200m line-spacing over an area of ~6 000 km². Highlights from this survey include 1) delineation of numerous E-trending mafic dikes of the 590 Ma Grenville dike swarm, many of which are buried by Paleozoic cover; 2) Paleozoic outliers in the survey area are locally sufficiently thick (>>100 m) to subdue the magnetic character of the underlying Grenville strata; particularly in the 1VD field; 3) confirmation of the subdomain-bounding N-trending Ross fault; 4) delineation of a new subdomain (Rocher-Fendu) in the Cobden area consisting of high P-T deformed gneiss (~9 kb based on corundum-hercynite assemblages) that structurally overlie only moderately deformed middle amphibolite facies marbles. Rocks of Rocher-Fendu subdomain are more abundant on the Quebec side of the Ottawa River, and may link with gneisses in the Otter Lake area. 5) the OGS radiometric data defines the same eU and eTh spectrometric highs as shown by existing GSC data, but anthropogenic anomalies for K and eU limit its use in areas of active farming or Leda clay.

The Eastern Ontario survey, at 400m line-spacing, collected aeromagnetic data only over an area of ~12 350 km². Highlights (see figure) include 1) Paleozoic cover in the western 2/3 of the survey area is thin (<400 m) allowing for the subsurface delineation of major Grenville rock units; 2) the Maberly shear zone is not readily apparent in the magnetic data, but a 10 to 20 km zone in Frontenac terrane immediately to the south characterized by strong linear magnetic trends is likely a high strain zone in the hanging wall of the Maberly shear zone; 3) in the Carp Ridge area, the Maberly shear zone is at least 10 km SE of previous positions. Rocks of the Rocher-Fendu occur beneath the Paleozoic on the north side of the Carp Ridge; 4) surprisingly, few faults and lineaments identified in the basement propagate into the overlying Paleozoic strata.

Title: Tectono-Metamorphic History of the Eastern Taureau Shear Zone, Mauricie Area, Québec: Implications for the Exhumation of the Mid-Crust in the Grenville Province

Presenter/First Author: Renaud Soucy La Roche, University of Quebec at Montreal, Montreal, QC

Presenter/First Author Email: renaudslr@hotmail.com

Co-authors: Felix Gervais, École Polytechnique, Montreal, QC, Canada; Alain Tremblay, GEOTOP, Montréal, QC, Canada; James L Crowley, Boise State University, Boise, ID; Gilles Ruffet, Géosciences Rennes, UMR CNRS 6118, Université Rennes 1, Rennes, France

Published Material: Soucy La Roche, R., Gervais, F., Tremblay, A., Crowley, J. L., & Ruffet, G. (2015). Tectono-Metamorphic History of the Eastern Taureau Shear Zone, Mauricie Area, Québec: Implications for the Exhumation of the Mid-Crust in the Grenville Province. *Precambrian Research 257*, 22-46.

Abstract Body: This study investigates the tectono-metamorphic history and exhumation mechanisms of the mid-crustal Mékinac-Taureau domain of the Mauricie area, central Grenville Province. Macro- and micro-structural analyses reveal the top-down-to-the-ESE sense of shear on the eastern Taureau shear zone, a major extensional structure that exhumed the mid-crustal Mékinac-Taureau domain and juxtaposed it against the lower grade rocks of the Shawinigan domain. Peak metamorphism in the Mékinac-Taureau domain, inferred to be the result of northwestward thrusting and regional crustal thickening, took place under P–T conditions of 1000–1100 MPa and 820–880°C prior to 1082 ± 20 Ma. Retrograde conditions varying from 775 to 675°C and from 800 to 650 MPa were registered in its upper structural levels prior to and/or during shearing along the eastern Taureau shear zone that was active at 1064 ± 15 Ma. The Shawinigan domain records P–T conditions ranging from 850 to 625 MPa and from 775 to 700°C, P–T values that are similar to or slightly lower than those for retrogressed samples from the upper structural levels of the Mékinac-Taureau domain, but clearly lower than the peak metamorphism values of the latter domain. Finally, the area cooled below 550–600°C at ∼1000–1030 Ma and below 450°C at ∼900–970 Ma on the basis of $^{40}Ar/^{39}Ar$ geochronology on amphibole and biotite. Structural and metamorphic characteristics of the Mauricie area are similar to those expected from a metamorphic core complex formed during post-convergence orogenic collapse in a gravity-driven fixed-boundary mode. The Mékinac-Taureau and Shawinigan domains were thus probably exhumed by a similar process, which supports the orogenic collapse model recently proposed to explain the exhumation of mid-crustal metamorphic core complexes in the Grenville Province.

Title: Post-Peak Transtensional Buckling of High-grade Thrust Sheets in Western Central Gneiss Belt, Grenville Province of Ontario (Canada): A Signal of Orogenic Collapse

Presenter/First Author: Walfried Martin Schwerdtner, University of Toronto, Toronto, ON

Presenter/First Author Email: fried.schwerdtner@utoronto.ca

Co-authors: Toby Rivers, Memorial University of Newfoundland, St John's, NF, Canada; Jack F Yang, , , ; Jason Tsolas, , , ; Gianluca Barbieri, , ,

Abstract Body: The Central Gneiss Belt (CGB) hosts a system of upright to inclined, horizontal to gently-plunging, noncylindrical cross-folds making high angles with the orogenic front. The cross-folds are multi-order features, visible at a range of scales from the outcrop to regional maps. We present new evidence that the cross-folds postdate the metamorphic peak and formed during retrogression and exhumation of the early-Ottawan thrust-sheet stack, in a tectonic regime of regional transtension and multi-layer buckling. Three-dimensional numerical *kinematic* models predict that typical transtensional folds be pervaded by hinge-parallel elongation lineations and L>>S strain fabrics. In the km-scale cross-folds of the CGB, however, such fabrics are generally restricted to the hinge zones, where they are locally accompanied by horizontal to shallowly-plunging sheath-like mesoscopic folds, apparently coeval with the host structure. By contrast, the limbs of cross-folds in the CGB are characterized by L<<S strain fabrics, quasi-cylindrical parasitic folds and tight intrafolial structures formed by coaxial refolding of the gneissic layering. On the other hand, our measurements and field observations are consistent with (1) the recent results of two-dimensional numerical *dynamic* modeling of multi-layer buckle folds and (2) empirical data from other classical metamorphic terranes that demonstrate the style and efficacy of regional transtension in exhuming high-grade rocks. Thus we conclude that the contrasting types of L-S fabrics and mesoscopic buckle folds observed in the km-scale cross-folds of the CGB are to be expected during post-peak exhumation of polydeformed gneisses in a regional transtensional regime.

A transtensional origin of the multi-order cross-folds removes the need to appeal to orogen-parallel regional shortening, a common but implausible requirement of previously favoured tectonic scenarios, and is compatible with our present understanding that much of the visible fabric and structure of the CGB developed during post-peak exhumation, retrogression and gravitationally-driven collapse of the thrust-sheet stack.

Title: Nd Isotope Mapping of Large-scale Crustal Structure in the SW Grenville Province

Presenter/First Author: Alan P Dickin, McMaster University, Hamilton, ON

Presenter/First Author Email: dickin@mcmaster.ca

Abstract Body: The SW Grenville Province was an active continental margin for hundreds of millions of years before the 1 Ga Grenvillian terminal orogeny. This complex crustal evolution has for a long time obscured a correct understanding of crustal structure in the SW Grenville Province. However, crustal formation ages estimated from Nd isotope mapping can clarify the pre-collisional crustal history, and also characterize terranes that were displaced during crustal thickening, gravitational collapse, and exhumation associated with the Grenvillian collision. After the accretion of a Paleoproterozoic arc, an Andean-type ensialic arc was established on the composite Archean-Paleoproterozoic margin, causing extensive reworking, and also stepping ocean-ward to generate juvenile crust on the outboard edge of the continent. This complex crustal segment, displaying progressively younger Nd model ages southwards, was telescoped by Ottawan crustal stacking on the Allochthon Boundary Thrust (ABT). Basement exhumation occurred on a crustal-scale ramp, followed by sub-horizontal transport to the northwest, after which the allochthon was subjected to late buckle-folding. When this structure was denuded by erosion, it created a complex map pattern, consisting of large nappe lobes such as the Cabonga, Lac Dumoine and Parry Sound-Algonquin thrust sheets, interspersed with salients and windows of parautochthonous crust. In addition, at least six small allochthonous klippen have been recognised near North Bay, Mattawa, Lac Booth, Brent, Lac Perch and Lac Renzy. This ramp-flat crustal structure for the SW Grenville Province now places it in a consistent tectonic framework with the rest of the province.

Title: Early evolution of Earth-like planets

Presenter/First Author: Craig O'Neill, Macquarie University, Sydney,

Presenter/First Author Email: craig.oneill@mq.edu.au

Co-authors: Siqi Zhang, Macquarie University, Sydney, NSW, Australia; Simone Marchi, NASA Lunar Science Institute, Boulder, CO; Jonathon Wasiliev, , ,

Abstract Body: The tectonics of Earth-sized planets is both a function of its thermal state and heating mode, and also its history. Even for similar heating trajectories, planets with different initial conditions may evolve down substantially different evolutionary paths. The rate of change of thermal conditions was greater in the Hadean than at any other time – extremely high heat productions rates were rapidly decaying, the young fully-molten core was losing heat to the mantle, substantial vestigial heat from planetary formation was being lost, and large impact fluxes were both decimating the early crust, and adding substantial heat to the mantle.

In many ways, though, the geodynamics of the Hadean may be seen as a response by the planet its initial, post-accretion, conditions. Here we use parallel finite element models developed in the community code ASPECT to explore the evolution of Earth-like planets, from an initial post-magma ocean state, till the end of the Hadean. We incorporate i) a parameterized, evolving core-model to track the evolution of core-mantle conditions; ii) rapidly evolving heat-production rates, and iii) a parameterization of the thermal effects of impact flux. We find there is a large-lag between the onset of post-magma ocean subsolidus convection, and active tectonics on the surface. We also find that tectonics is generally episodic, with a number of discrete tectonic overturn events anticipated for the Hadean. While there is a sensitivity to the heating mode (variable basal, decaying radiogenic, and impact-induced), we find a large sensitivity to the initial conditions, and suggest that one of the fundamental problems in understanding terrestrial planet evolution is constraining the state of a planet immediately post-accretion.

Title: Temporal Stress Patterns in Episodic Plate Tectonics Models with Implications for the Initiation of Plate Tectonics on Terrestrial Planets

Presenter/First Author: Vlada Stamenkovic, Massachusetts Institute of Technology, Cambridge, MA

Presenter/First Author Email: rinsan@mit.edu

Co-authors: Tobias Hoeink, Rice University, Houston, TX; Adrian Lenardic, Rice University, Houston, TX

Abstract Body: Spherical shell mantle convection models are used to explore an episodic mode of plate tectonics. The time evolution of shear and normal stresses are tracked to determine how the stress levels vary coming into a global lithospheric failure event. The results indicate that an increase in convective mantle shear stress initiates lithosphere failure and an associated period were the lithosphere actively participates in convective mantle overturn (as is the case for the Earth's plate tectonics regime at present). The implication is that once the lithosphere is active, then normal stresses can exceed shear stress but it is not the normal stress itself that initiates the active lid mode of behavior. Based on our numerical results, we used 1D thermal evolution models to study the consequences of this shear-stress dominance for the initiation of plate tectonics. We find a reduced likelihood of initiating plate tectonics with increasing planet mass and interior heat. Moreover, our results indicate that for Earth an early (<500 Myr) or considerably later (0.5-3 Gyr after formation) start for plate tectonics are both possible. Once started, plate tectonics associated cooling of the interior can aid in its maintenance. In that situation, our thermal evolution models suggest the continuation for plate tectonics on Earth for the lifetime of the sun as a main sequence star.

Title: Evolving Lid-States, Bi-Stability, and the Evolution of Terrestrial Planets

Presenter/First Author: Matt B Weller, Rice University, Houston, TX

Presenter/First Author Email: mbweller@gmail.com

Co-authors: Adrian Lenardic, Rice University, Houston, TX

Published Material: Some early data has been presented, and further has been accepted to EPSL

Abstract Body: We use 3D mantle convection and planetary tectonics simulations to explore the links between tectonic regimes, lithospheric yield strength, the age of a planet, and thermal histories. At both high and low values of internal heating a single hot or cold stagnant-lid end state prevails. For lower initial and/or depleted radiogenics (e.g. thermal ageing) hot stagnant-lid states can yield through an episodic-lid, into a mobile-lid regime. Further reducing radiogenics leads the mobile-lid transitioning back into a (now) cold stagnant-lid. While high and low temperature tectonic end states may be fixed, the intermediate parameter range – a significant span of a planet's thermal evolution – may be governed by the thermal history of the system (e.g. initial conditions) allowing for regions of multiple stable tectonic states, or bi-stability. Within the bi-stability window, the tectonic regime becomes a function of a planet's specific geologic and climatic history. The timing of transitions in tectonic regimes is linked to internal temperature variations, which are a function of the lid-state evolution. Transitions from an initial stagnant-lid state are delayed (requiring a larger decrease in radiogenics) as a function of increasing yield strength and surface temperature, indicating that a system with a different thermal evolution has the potential to migrate through tectonic regimes at the same 'thermal time' (e.g. temperature), but very different 'temporal times'. Our results indicate that multiple modes of convection and surface tectonics can potentially operate on a single planetary body at different times in its evolution, as consequence of changing internal parameters, surface temperatures, and differing thermal histories, implying terrestrial worlds can alternate, and be offest between multiple tectonic states over giga-year timescales.

Published Material: This material was presented at the AGU Fall Meeting 2014 and was recently accepted to Earth and Planetary Science Letters (doi:10.1016/j.epsl.2014.08.019). Some of this material was also presented at the CIG meeting in Banff 2014.

Abstract Body: Planetary surface mobility depends on lithospheric stresses arising from the mantle's convective vigor. Using a model of thermochemical convection featuring force-balanced plates we examine the effect on surface mobility of different fractions of compositionally dense mantle material. Specifically, we introduce a uniform thickness compositionally enriched basal layer in a system with mobile-lid tectonics and monitor whether an active lid is subsequently maintained. We find that long-term surface mobility decreases when enriched material is present. High mobility is always maintained if the total material volume is no more than 1% of the mantle volume. For the inferred volume of the Large Low Shear Velocity Provinces (LLSVPs) in the present-day Earth, surface mobility is dependent on the buoyancy ratio of the enriched material. If the compositionally dense material self-organizes into provinces, both surface mobility and mantle upwelling vigor become more variable. Generally, upwellings that form at the edges of provinces are more buoyant relative to upwellings that form on the tops of provinces. If enriched material envelops the core, upwelling vigor is diminished so that plates are consumed more quickly than they can fragment, and surface mobility is eventually lost.

Title: Mantle Potential Temperature through time: Constraints from Greenstone Basalts and Komatiites

Presenter/First Author: Kent C Condie, New Mexico Institute of Mining and Technology, Albuquerque, NM

Presenter/First Author Email: kcondie@nmt.edu

Co-authors: Cin-Ty Lee, Rice University, Houston, TX; Richard C Aster, Colorado State University, Fort Collins, CO; Jeroen Van Hunen, University of Durham, Durham, United Kingdom

Abstract Body: Basalts can be divided into three groups using incompatible element distributions: undepleted/enriched (UE), depleted (D), and hydrated (H). We have calculated mantle potential temperatures (Tp) for each of these groups and for komatiites (K) based on major element contents filtered for alteration and extreme fractionation. Median Tp for the H and D groups decreases with time from 1500°C in the Archean to 1380°C today, whereas the UE and K groups maintain high and relatively constant Tp values through time (UE,1500°C; K, 1650°C). Decreasing Tp in ambient mantle may be expected with time, but the rather constant Tp in UE and K mantle sources requires an explanation. One possibility is that before 2.5 Ga, most of the mantle was well stirred and low-viscosity and only near the core-mantle thermal boundary layer (CMB) was the thermal gradient large enough to give rise to mantle plumes. Although plumes may have existed throughout Earth history, only some of them (those that gave rise to komatiites) made it to the base of the lithosphere before 2.5 Ga due to smaller plume sizes resulting in rapid diffusive heat loss. Archean UE basalts may thus reflect partial melting of compositional inhomogeneities embedded in the D-H upper mantle rather than thermal plumes. Widespread plume production in the late Archean may be related to the onset of plate tectonics, where the accumulation of cool slabs at the CMB increased the thermal gradient, thus enhancing plume generation. Plume heads may have been more robust in this cooler mantle and survived to the base of the lithosphere, producing most of the post-2.5 Ga UE basalts. Supporting this interpretation are increases in Ti and Nb in UE basalts after 2.5 Ga. After 2.5 Ga, a maintained high Tp for UE and K mantle plume sources may reflect sustained high CMB temperatures, perhaps due to growth of the inner core.

Title: Origin and Evolution of Silicate Reservoirs in the Early Earth: an Archean Komatiite Story

Presenter/First Author: Igor S Puchtel, University of Maryland College Park, College Park, MD

Presenter/First Author Email: ipuchtel@umd.edu

Co-authors: Richard J Walker, Univ Maryland, College Park, MD; Mathieu Touboul, University of Maryland College Park, College Park, MD; Janne Blichert-Toft, Ecole Normale Supérieure Lyon, Lyon, France

Abstract Body: Isotopic signatures created in early terrestrial silicate reservoirs *via* radioactive decay of short- and long-lived nuclides have been sampled by early magmas and preserved in crustal rocks. These isotopic signatures can be used to constrain the timing of formation and the nature of these, now likely vanished, reservoirs. Using the combination of $^{142,143}Nd/^{144}Nd$, $^{176}Hf/^{177}Hf$, $^{186,187}Os/^{188}Os$, and $^{182}W/^{184}W$ isotope systematics and highly siderophile element (HSE) abundances in Archean komatiite systems from around the globe ranging in age between 3.6 and 2.4 Ga, we attempt to place new constraints on specific processes that may have controlled mantle differentiation, on the timing of late terrestrial accretion, and the mixing times of the terrestrial mantle.

Our isotopic and HSE abundance data for the early to late Archean komatiite systems from around the globe are most consistent with formation and long-term isolation of deep-seated mantle domains, with fractionated time-integrated Sm/Nd, Lu/Hf, Hf/W, and Pt/Os ratios, within the first 100 Ma of Earth's history. These domains may have been generated as a result of crystallization of a primordial magma ocean, with Mg- and Ca-perovskite and Pt alloy acting as the fractionating phases. The inferred mantle domains remained isolated from the convecting mantle for more than a billion years, and, in some cases, may have never been completely re-homogenized, indicating very slow mixing times of the terrestrial mantle.

The absolute HSE abundances in the sources of early and late Archean komatiite systems studied are calculated to be generally similar and are within the range of those present in estimates for the modern primitive mantle, although at least some early Archean komatiite systems (e.g., 3.6 Ga Schapenburg, South Africa) were derived from mantle sources strongly depleted in HSE. Our combined isotopic and HSE abundance data indicate that late accretion of HSE to Earth may have been largely complete by the time the final terrestrial magma ocean had crystallized. Large HSE fractionations observed in some, mostly early Archean, komatiite systems may reflect rather sluggish mixing of diverse post-magma ocean domains characterized by variably fractionated HSE abundances.

Title: Zircon Evidence Reveals that Iceland is Not a Modern Analogue for Earliest Crustal Construction (Hadean, >4 Ga)

Presenter/First Author: Tamara L Carley, Lafayette College, Easton, PA

Presenter/First Author Email: carleyt@lafayette.edu

Co-authors: Calvin F Miller, Vanderbilt Univ, Nashville, TN; Joseph Wooden, Stanford University, Los Altos Hills, CA; Abraham J Padilla, Vanderbilt University, Nashville, TN; Axel K Schmitt, University of California Los Angeles, Los Angeles, CA; Rita C Economos, Southern Methodist University, Dallas, TX; Ilya N Bindeman, Univ of Oregon, Eugene, OR;

Brennan T Jordan, South Dakota School of Mines and Technology, Rapid City, SD

Published Material: This conference submission is based on work published earlier this year: Carley, T.L., Miller, C.F., Wooden, J.L., Padilla, A.J., Schmitt, A.K., Economos, R.C., Bindeman, I.N., and Jordan, B.T. (2014) Iceland is not a magmatic analog for the Hadean: Evidence from the zircon record. Earth and Planetary Science Letters Vol. 405, pp. 85–97.

Abstract Body: Tangible evidence of Earth's earliest (Hadean; >4.0 Ga) crust, and the processes and materials that led to its formation, exists almost entirely in detrital zircon. Iceland's crust (hot, thick, juvenile, dominantly mafic, substantial silicic component) resembles what is often intuitively visualized for Hadean crust. Because zircon crystals provide a unique view of the >4.0 Ga world, a zircon-based comparison of Icelandic and Hadean zircon data is a first-order test of this model. We present the first extensive dataset for Icelandic zircon, with O isotopes and trace elements for samples spanning the island's history and tectonic settings. Comparison of isotopic and trace elemental data suggest fundamental differences in magmatic environments. Deviations from juvenile $\delta^{18}O$ reveal that surface waters interacted with magmatic source materials for many Hadean and most Icelandic zircons, but under very different circumstances. Preserved Hadean zircons have dominantly normal to high $\delta^{18}O$ (median value 6‰; 85% have $\delta^{18}O \geq 5.3$‰). Protolith material for host magmas may have been altered at low T by subaerial meteoric water or submarine seawater with $\delta^{18}O \geq 0$‰. Abundant low- $\delta^{18}O$ Icelandic zircons (98% ≤ 5.3‰; median 3‰) imply high T alteration of protolith by meteoric water. Titanium abundances in zircon are also distinct (Iceland median 12 ppm, Hadean 5 ppm), suggesting that Hadean zircons crystallized in cooler magmas (median difference ≥75°C). Other trace elements, e.g. MREE and HREE (Iceland >> Hadean zircons), are also consistent with distinct origins of zircon-bearing magmas. Perhaps Iceland-like settings and magmas existed in the early Earth, but evidence for this is very rare in >4 Ga zircons. Iceland is thus not representative of Hadean crust. Based on zircon, mid-ocean ridges, evolving continental rifts and continental hotspots are equally poor matches. Arc zircons provide a closer fit, although >4 Ga zircons appear to be from even cooler, wetter, magmas.

Title: An Iceland-like Setting for Generation of a ~4.02 Ga tonalite, Acasta Gneiss Complex, Canada

Presenter/First Author: Jesse Ray Reimink, University of Alberta, Edmonton, AB

Presenter/First Author Email: reiminkjesse@gmail.com

Co-authors: Tom Chacko, University of Alberta, Edmonton, AB, Canada; Richard A Stern, University of Alberta, Edmonton, AB, Canada; Larry Heaman, University of Alberta, Edmonton, AB, Canada; Joshua Davies, University of Geneva, Geneva, Switzerland; Graham D Pearson, University of Alberta, Edmonton, AB, Canada; Robert A Creaser, University of Alberta, Edmonton, AB, Canada

Published Material: A portion of the data and conclusions in this talk were presented in poster form at the Goldschmidt Geochemistry conference (2013) and in talk format at the Northwest Territories Geoscience Forum (2013) as well as published in Nature Geoscience (2014).

Abstract Body: The Acasta Gneiss Complex (AGC) contains the oldest known continental rocks on Earth with U-Pb zircon ages indicating crust formation between 3.6-4.03 Ga [Stern and Bleeker, 1997; Bowring and Williams, 1999; Iizuka *et al.,* 2007]. Here we discuss whole-rock elemental and isotope geochemistry along with SIMS U-Pb, trace element, Hafnium and O-isotope compositions of zircon from a >4.0 Ga tonalitic gneiss unit identified by Reimink *et al.,* [2014]. Unlike typical Archean TTG magmatism [Moyen and Martin, 2012], this unit is characterized by moderate silica contents (58-62 wt % SiO_2), strong Fe-enrichment (12-15 wt% FeO), and low Mg numbers (13-18). REE patterns are relatively flat with a significant negative Eu anomaly. These features strongly suggest that, unlike deep-seated Archean TTG magmas [Moyen and Martin, 2012], the evolution of this AGC tonalite was dominated by shallow-level fractionation processes involving plagioclase.

Zircons from this well-preserved unit document primary crystallization at ~4.02 Ga. Oxygen isotope compositions from zircon centers and mantles document a marked decrease in $d^{18}O$ from a mean of +5.6 ‰ to a mean of +4.7 ‰ that can be explained by processes occurring within a shallow magma chamber involving late-stage assimilation of hydrothermally altered crust.

The whole-rock and zircon data for the >4.0 Ga AGC tonalitic gneiss are similar to those of intermediate rocks from Iceland (e.g., icelandites), thought to be formed by shallow-level basaltic magma fractionation and assimilation of surface-water altered crust. Comparisons of zircon trace element data also compare favorably with Icelandic zircons [Carley et al., 2014]. We will present recently collected radiogenic isotope data and discuss these new findings in relation to the issue of crust formation on the Hadean Earth.

Title: Structure and dynamics of the North American lithosphere imaged using waveform inversion of global and USArray data

Presenter/First Author: Andrew J Schaeffer, Dublin Institute for Advanced Studies, Dublin,

Presenter/First Author Email: aschaeff@cp.dias.ie

Co-authors: Sergei Lebedev, Dublin Institute for Advanced Studies, Dublin, Ireland

Published Material: Some results recently published in EPSL; some new results will be presented.

Abstract Body: The North American continent has had a long, eventful tectonic history. The assembly of the stable cratonic core has undergone numerous collisions and accretion at its boundaries, major rifting episodes within it, as well as the loss of ancient lithosphere beneath parts of it, all of which are examples of cratonic dynamics and evolution. Seismic tomography offers rich evidence on the structure and evolution of the cratonic lithosphere. With the continued deployment of the USArray during the last decade, the North American continent has now been densely sampled with broadband seismic data from west to east coast. We present a new high-resolution model of the upper mantle beneath North

America constrained by waveform fits of over 700,000 vertical-component broadband seismograms. Automated multimode waveform inversion was used to extract structural information from surface and *S* waveforms, yielding resolving power from the crust down to the transition zone, and improved resolution for a variety of features in North America.

We focus on central and eastern North America; in particular, the internal structure of the central cratonic core is resolved in detail, with clear delineation from the deformed continental margins. The northern and northeastern boundaries of the cratonic lithosphere closely follow the coastlines, with North America's and Greenland's lithospheric roots clearly separated. On the eastern margin of the continent, where multiple episodes of continental rifting are superimposed, the craton boundary coincides with the western extent of the Appalachian orogenic front, with significantly lower lateral velocity gradients than in the west.

Within the cratonic interior, the lithosphere surrounding the 1 Ga failed Mid-Continental Rift shows a reduction in wavespeeds compared to the surrounding craton, likely indicating thermo-chemical alteration of the sub-continental lithospheric mantle, in agreement with results from geochemical and petrological analyses of diamondiferous kimberlites and peridotites. We examine the spatial extent of the lithospheric mantle root and LAB variations across the continent, and compare them with respect to the spatial location of diamondiferous kimberlites. Finally, we discuss potential lithospheric control on the distribution crustal seismicity.

Title: On the Thermal Evolution of Archean Cratons : High-Grade Metamorphism, Granite Formation and Long-Term Cooling

Presenter/First Author: Claude P Jaupart, Institut de Physique du Globe de Paris, Paris,

Presenter/First Author Email: jaupart@ipgp.fr

Co-authors: Jean-Claude Mareschal, University of Quebec at Montreal UQAM, Montreal, QC, Canada

Abstract Body: High-precision geochronological and thermodynamic studies provide records of unprecedented detail on the thermal evolution of continents following major episodes of continental assembly and orogenesis in the Archean. Similar characteristics have been observed in all the major cratons worldwide. Metamorphic events affect very large areas quasi-simultaneously, indicating that the driving mechanism operates on a large-scale, but peak temperatures vary between terranes. The timing of high-grade metamorphism lags magmatism and tectonic amalgamation by several tens of million years. Final stage metamorphic events are associated with granite formation and emplacement. These events are followed by slow and long lasting isobaric cooling that persists for up to 1 Gy at rates of less than 1K/My. The source of the heat that is required to account for these phenomena remains controversial. The most common explanations are the underplating of basaltic melts due to a mantle plume or the instability of thickened lithosphere, which is also expected to generate basaltic melts, but they are not consistent with the significant time-lag that separates voluminous mafic magmatism and high-grade metamorphism.

We show that all these features are consistent with the thermal evolution of a new continental assemblage that adjusts to heat released by radioactive decay in crustal rocks. Quantitative results depend on the total amount of radioactive elements in the newborn crust, which can be determined by heat flow studies. Using heat flow and heat production data from the Archean Superior Province of the Canadian Shield, we show that peak temperatures of ≈ 800-900°C were reached a few tens of millions years after the final amalgamation event that occurred at ≈2.7 Ga. Lateral variations of peak metamorphic temperatures are accounted for by lateral changes of crustal heat production. We also show that peak temperatures are sensitive to the width of the newly accreted terranes. It is only after the final docking event that saw the width of the accreted belts exceed ≈400 km that the necessary conditions for high-grade metamorphism were met. The slow and long-term cooling that followed peak metamorphism is a straightforward consequence of the decay of heat producing elements in the crust.

Title: Investigating Precambrian Tectonics in Northernmost Hudson Bay: Insights from Joint Inversion of Receiver Functions and Surface Waves

Presenter/First Author: Amy Gilligan, University of Cambridge, Cambridge,

Presenter/First Author Email: a.gilligan@imperial.ac.uk

Co-authors: Ian D Bastow, Imperial College London, London, United Kingdom; Fiona Ann Darbyshire, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Laura Petrescu, Imperial College London, London, SW7, United Kingdom

Abstract Body: How tectonic processes operated and changed through the Precambrian still remains a matter of debate: when did plate tectonics as we observe on Earth today begin, and did different processes occur on the younger, hotter Earth? The Canadian Shield contains one of the largest exposures of Precambrian rocks on Earth, and the rocks of the northernmost Hudson Bay region span more than 2 billion years of Earth's history, from 3.9-1.8 Ga. This is thus an important locality for trying to understand the processes that may have occurred on the early Earth.

Previous geophysical work in northernmost Hudson Bay has shown interesting variations in crustal properties within this region. These variations appear to relate to differences in tectonic processes operating when distinct parts of the crust in northernmost Hudson Bay formed. In this study we use data from broadband seismic stations in northernmost Hudson Bay including from the POLARIS network to obtain new shear velocity models for the crust and upper mantle in northernmost Hudson Bay by jointly inverting P receiver functions and ambient noise surface wave dispersion measurements. A joint inversion for shear velocity reduces the inherent ambiguities in each individual method, while constructing a model that is consistent with both. These models are used to estimate crustal thicknesses within this region. Variations in crustal thickness and shear velocity are interpreted with respect to changes in tectonic processes over time.

Title: Precambrian Processes, the Trans-Hudson Orogen, and Cratonic Keels: Insights From Teleseismic Tomography in Northern Hudson Bay, Canada

Presenter/First Author: Mitch Vagn Liddell, Imperial College London, London,

Presenter/First Author Email: m.liddell14@imperial.ac.uk

Co-authors: Ian D Bastow, Imperial College London, London, United Kingdom; Nicholas Rawlinson, Australian National University, Canberra, Australia; Fiona Ann Darbyshire, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Amy Gilligan, Imperial College London, London, United Kingdom; Michael Kendall, University of Bristol, Bristol, United Kingdom

Abstract Body: Earth conditions in the Precambrian, and their effect upon the formation of cratons and orogenies from that era, are not fully understood. For example, the precise onset of modern plate tectonics remains ambiguous; it has been hypothesised to have begun anywhere from ~4.1Ga (Hopkins, 2008) to ~1Ga (Stern, 2005). Also, some cratons are associated with large geoid signatures and exceptionally deep fast wave-speed anomalies, pointing to the existence of thick "cratonic keels", the origin of which remains unexplained. To improve our understanding of the early Earth processes, geological evidence preserved within ancient plates that have remained largely unchanged since the Precambrian can be used. The rocks of northern Hudson Bay include Archean domains, the Paleoproterozoic Trans-Hudson Orogen (THO), and lie atop one of the largest cratonic keels on Earth (Bastow et al., 2013), making this region an ideal laboratory for study of Precambrian processes.

Here, we use seismological data recorded at Canadian POLARIS and Hudson Bay Lithospheric Experiment (HuBLE) stations to perform a relative arrival-time study of northern Hudson Bay region and the THO. Waveforms are aligned using the adaptive stacking routine of Rawlinson et al. (2004), and inversions are produced using the Fast Marching Tomography (FMTOMO) inversion code of Rawlinson et al. (2006). Our inversions provide an improved velocity model of the lithosphere and upper mantle of northern Canada and constitute new body-wave constraints on their structure. The results are used to address a number of outstanding questions regarding the processes that formed the THO and the Laurentian Keel of North America.

Title: New Results of Earthquake Relocation in Charlevoix Seismic Zone, Eastern Canada and Implications for Regional Geological Structure

Presenter/First Author: Hongyu Yu, ITAG Institute of Theoretical and Applied Geophysics, Peking University, Beijing,

Presenter/First Author Email: 1101110441@pku.edu.cn

Co-authors: Yajing Liu, McGill University, Montreal, QC, Canada; Meng Pang, McGill University, Montreal, QC, Canada

Abstract Body: The Charlevoix Seismic Zone (CSZ), located on the St Lawrence River about 100 km downstream from Quebec City, has the most active seismicity in eastern Canada. Historically there have been five magnitude 6 to 7 earthquakes in the CSZ, and about 200 events recorded by the Canadian National Seismograph Network (CNSN) every year. The high seismic hazard in this area is a result of its complex tectonic history, including the opening of Iapetus Ocean formed the St. Lawrence paleorift system (700 Ma), and a Devonian meteorite impact (350Ma) that shattered the plateau and created a highly fractured circular zone (56 km in diameter; Rondot, 1989) on the north shore of St Lawrence River (SLR).

In this study, we studied 1442 earthquakes that occurred in the CSZ area during January 1988 and October 2010, using the Double-Difference Hypocenter Locations (HYPODD, Waldhauser & Ellsworth (2000)) method. Broadband waveforms from 7 permanent CNSN stations are used in the relocation. We manually picked 11,525 P wave arrivals out of 29,737 recordings, with the reference of automatically picked P phases using the maximum kurtosis and κ-statistics criteria (C. D. Saragiotis et al., 2004). We used a layered CSZ velocity model from Lamontagne (1999). In total 1035 (71.8%) events have been relocated, by setting the cross-correlation coefficient (CC) to be greater than 0.8 at 4 or more stations.

The relocated earthquake hypocenters depicts the impact crater. Cross-section profiles also show a "bowl" shape envelope at the bottom of the seismicity. Events are more aggregated under SLR than under the north shore area, indicating that rifting faults beneath the SLR are probably weaker structures. The relocated earthquakes also define a series of SE steeply dipping faults, which are consistent with the surface traces of the Gouffre NW fault, the St-Laurent fault, Charlevoix fault and South shore fault. Finally, a series of SW low-angle dipping faults under SLR also agree with local compressive stress orientation implied by previous CSZ focal mechanism solutions (Zoback & Zoback, 1991).

Charlevoix relocation with CC > 0.8 & Nsta ≥ 4 & north shore velocity model

Title: Superior Layer-Cake: Gradual Lower Boundary and Textured Interior of the Lithosphere

Presenter/First Author: Vadim L Levin, Rutgers University, Piscataway, NJ

Presenter/First Author Email: vlevin@eps.rutgers.edu

Co-authors: Benjamin Dunham, Rutgers University, Piscataway, NJ; Michael Klaser, Rutgers University New Brunswick, Highland Park, NJ; Andrea Servali, Rutgers University, Piscataway, NJ

Abstract Body: The lithosphere of Archean cratons reaches deeper than 200 km, and may be delineated by the distribution of elevated seismic wave speed in the mantle. The precise location of the decrease in speed that marks the lower boundary of the lithosphere has been difficult to define, leading to the inclusion of the Lithosphere-Asthenosphere Boundary (LAB) among the main challenges in modern seismological studies.

We investigate the properties of the mantle lithosphere beneath the Superior province of Quebec using teleseismic receiver function analysis. We rely on a data set spanning over 5 years from a number of long-running observatories in Quebec. Long duration of observations ensures excellent directional coverage at all sites we examine.

The appearance of a converted phase in a receiver function documents the presence of a vertical gradient in properties that takes place over a distance that is "short" relative to the wavelength of the phase. Our examination of the receiver functions from the Superior province fails to identify consistent P-to-SV converted phases with delay times ~20 s that would be consistent with the likely depth to the LAB. This is true for all frequencies down to 0.125 Hz, and implies that changes in isotropic seismic properties associated with the LAB take place over vertical distances similar to, or larger than the corresponding shear-wave wavelength (~36 km).

Interestingly, numerous converted phases are detected between 10 and 20 s at most sites we have examined. This range of delays corresponds to depths in excess of 100 km. On the transverse component of receiver functions these phases display directional polarity changes characteristic for conversions from boundaries that have significant dip, or else have anisotropic seismic velocity adjacent to them. On the Radial component the interval between 10 and 20 s delays is overprinted by crustal multiples that are excited well by the sharp Moho of the Superior province crust. Directional patterns of SH-polarized (transverse) phases are distinct from those of the crustal multiples. As we do not find corresponding SV-polarized phases, we favor an interpretation in terms of the abrupt changes in mantle rock texture, as might result from episodes of shearing, delamination or underplating, all likely to have affected the long-lived lithosphere of the craton.

Title: Lithospheric Structure of Greenland and the Northwest Atlantic from Rayleigh Wave Group Velocities

Presenter/First Author: Fiona Ann Darbyshire, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: darbyshire.fiona_ann@uqam.ca

Co-authors: Trine Dahl-Jensen, Geological Survey of Denmark and Greenland, Copenhagen, Denmark; Tine Larsen, Geological Survey of Denmark and Greenland, Copenhagen, Denmark; Peter Voss, Geological Survey of Denmark and Greenland, Copenhagen, Denmark

Published Material: Approximately 30-40% of material was presented at the 2013 AGU Fall Meeting.

Abstract Body: Greenland is largely thought to be underlain by Precambrian lithosphere, including Archean cratons and Proterozoic mobile belts. The margins of the continent are characterised by extensive orogenic belts, and by magmatic extrusives and intrusives related to breakup of the North Atlantic region.

Most detailed studies of crustal structure have been carried out at the edges of the continent and its margins, using controlled-source experiments. However, the establishment of broadband seismographs across Greenland, principally from the GLATIS and GLISN initiatives, has permitted an increasing number of passive-source studies such as receiver function analysis.

We investigate the crust and uppermost mantle structure of Greenland and the Northwest Atlantic, using Rayleigh wave group velocities from regional earthquakes recorded at the GLATIS and GLISN seismograph stations on Greenland, as well as permanent stations in the eastern Canadian Arctic. Dispersion data for periods from 10 to 80 seconds are combined in a tomographic inversion that solves simultaneously for group-velocity heterogeneity and azimuthal anisotropy. For each grid-point in the group-velocity maps, we extract a 1D dispersion curve, which is inverted for 1D shear-wave velocity structure using a probabilistic modelling scheme. The results are combined to create a pseudo-3D model of the crust and uppermost mantle across the region.

The resulting models indicate crustal thicknesses ranging from ~30 km to almost 50 km beneath mainland Greenland. At shallow depths, the extensive and deep sedimentary basins on the northwest and northeast margins are clearly imaged. Beneath the continental margins and the ocean basin, crustal thickness decreases significantly. In the uppermost mantle, the Greenland mainland region is characterised by high seismic wavespeeds, consistent with a cratonic structure, whereas the Northwest Atlantic shows wavespeeds lower than the global average, likely related to processes at and around the Mid-Atlantic ridge and Iceland hotspot.

Title: Variations in Seismic Anisotropy Across the Canadian High Arctic

Presenter/First Author: Jean-Michel Dubé, GEOTOP-UQAM, Mont-Saint-Hilaire, QC

Presenter/First Author Email: dube.jmichel@gmail.com

Co-authors: Fiona Ann Darbyshire, University of Quebec at Montreal UQAM, Montreal, QC, Canada

Abstract Body: The Canadian High Arctic is a complex and little-studied area made up of the northern edge of the Canadian Shield plus several orogenic belts and basins. Each geological province has its own characteristics, from the NW-SE thrust fault and fold structures of Ellesmere Island to the NE-SW structures and diapirism of the Sverdrup basin. This great variation in surface geological structure likely reflects tectonic complexity at the scale of the entire lithosphere, but the role of past and present mantle processes in the development of the region is still poorly understood. One of the signatures of mantle tectonic processes is seismic anisotropy, the directional dependence of seismic wave propagation speed. This seismic anisotropy can arise from 'fossil' fabric in the lithosphere, related to past tectonic processes, and from present-day mineral alignments due to sub-lithospheric mantle flow. We use measurements of shear-wave splitting to investigate the anisotropy beneath the Canadian High Arctic. Our seismic data come from permanent seismograph stations (the Global Seismograph Network and the Canadian National Network) across the region, and a temporary installation on Ellesmere Island (the 'ELLITE' project). Data timespans range from 2 years for the temporary installations to 24 years for the longest-running permanent stations. Both SKS and SKKS waveforms are used in the analysis. Preliminary shear-wave splitting measurements, showing the dominant directions of seismic anisotropy across the High Arctic, are presented and interpreted in the context of tectonic structure and present-day mantle flow. The results show significant variability in splitting parameters across the region, including variations in fast-polarisation orientation at short spatial wavelengths. This and the correspondence between large-scale tectonic structure and fast orientation (e.g. E-W at

station ALE and WNW-ESE at station RES) suggests that lithospheric anisotropy plays a significant role.

Title: What is the Driving Mechanism of Earthquakes in the New Madrid Seismic Zone? – A Study of Shear Wave Splitting and Tomography.

Presenter/First Author: Cecilia Anyango Nyamwandha, Center for Earthquake Research and Information, Memphis, TN

Presenter/First Author Email: cnymwndh@memphis.edu

Co-authors: Christine Ann Powell, Center for Earthquake Research and Information, Memphis, TN

Published Material: Preliminary results of part 1 (tomography) of this work was presented at the annual AGU 2014 meeting in San Francisco California. The results are still being improved with addition of more data from the Flex Array Deployment and in preparation to be submitted to a journal in the near future. The second part (Shear wave splitting study) has not been presented anywhere else.

Abstract Body: Seismicity in the New Madrid Seismic Zone (NMSZ) remains an enigma with no agreed upon driving mechanism hypothesis. In order to address this issue we present detailed P and S wave velocity models for the crust and upper mantle structure of the NMSZ. We also use the SplitLab processing environment to measure shear wave splitting of teleseismic SKS phases recorded at seismic stations in the NMSZ to map the orientation and strength of the mantle fabrics beneath this region.

We use data from January 2011 to date recorded by the broadband USArray Transportable Array (TA), Northern Embayment Lithospheric Experiment (NELE) project stations and Cooperative New Madrid Seismic Network broadband stations. NELE is a lithospheric-scale passive array experiment. Fifty stations of the TA form the basic grid. 51 Flex Array (FA) broadband stations are used to form three profiles over a two-year deployment (July 2013 to June 2015) and an additional 6 FA broadband stations are moved to fill in the TA grid in six month intervals in order to increase the background spatial resolution in velocity structure from 70km to about 35km.

For the tomographic study, we use arrival times from local earthquakes and travel time residuals from teleseismic earthquakes recorded by the three networks. We perform a joint local and teleseismic inversion using the TOMOG3D inversion code of Zhao et al., (1994) to determine the velocity structure. Our results indicate a consistent low velocity anomaly in both the Vp and Vs solutions at about 200-300 km depth. Checkerboard tests show that the spatial resolution is high in the upper mantle especially for the Vp model and fairly high in the crust for most of the study area.

For the SKS splitting study we select events (Mw ≥ 6.5) from the global centroid moment tensor catalog recorded by the three networks. We compare three inversion techniques simultaneously: the rotation-correlation method, minimum energy on the transverse component and the eigenvalue criteria. Preliminary results indicate a complex pattern of anisotropy beneath the study region. We combine the splitting results with the new, detailed P-wave and S-wave velocity models for the upper mantle to further our understanding of the driving mechanism of the NMSZ intraplate earthquakes and allow us to better assess the associated seismic hazard.

Title: Superior Layer-cake: An Investigation of the Mid-Lithospheric Discontinuity in the Superior Craton in Quebec, Canada

Presenter/First Author: Michael Klaser, Rutgers University New Brunswick, Highland Park, NJ

Presenter/First Author Email: michaelklaser@gmail.com

Co-authors: Vadim L Levin, Rutgers University, Piscataway, NJ; Fiona Ann Darbyshire, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Huaiyu Yuan, Macquarie University, Kensington, WA, Australia

Published Material: Most of the data was presented at the AGU Fall 2014 meeting, though an investigative focus of the MLD (and geologic interpretation) is new.

Abstract Body: The Superior craton has some of the thickest lithosphere on the planet, extending as deep as ~250 km, as suggested by elevated shear wave speed, considerations of heat flow, petrology of xenoliths, electrical resistivity etc. However, in the Superior the most significant decrease in shear wave speed with depth (over 10 m/s per 1 km of depth) does not correspond to the expected lower limit of the lithosphere. Rather, the continent-scale shear-wave velocity model of Yuan et al (2014) puts it at depths of ~125 km within the Superior. In the velocity model, the vertical extent of this region of large negative shear wave speed gradient is approximately 50 km.

P-to-S converted waves from teleseismic earthquakes offer a way to detect abrupt changes in seismic properties in the upper mantle, and may be used to determine the depth and the vertical extent of such abrupt changes.

We produced P-to-S receiver function (RF) gathers for 5 long-term seismograph stations, utilizing 5.0 and greater magnitude teleseismic earthquakes from the period 2000-2013. For each station, we constructed RF gathers arranged by back-azimuth and epicentral distance, to identify phases that can be associated with horizontal discontinuities within the crust and upper mantle. We also use newly collected data from a portable seismic array between Lake Mistassini and James Bay to augment the data from the permanent stations.

We detect clear negative P-S conversions consistent with an abrupt decrease in shear wave speed. Their delays range from 6 to 9 s, corresponding to the depths between 60 and 90 km. Similar observations are found in most cratons, and give rise to the concept of a Mid-Lithospheric Discontinuity (MLD). Conversions from the MLD in the Superior craton appear clearly in RFs with frequencies up to 0.5 Hz, suggesting a relatively abrupt boundary with a vertical extent of ~2 km or less.

We use seismic velocities from the model of Yuan et al (2014) and the timing of pulses in our receiver function time series to develop more precise estimates of the depth to the MLD in the Superior. Also, we use synthetic seismogram computations in simple layered models to evaluate vertical profiles of seismic properties within it.

Title: Seismic constraints of the crustal structure of the Appalachian Front: An investigation of the St. Lawrence River Valley

Presenter/First Author: Benjamin Dunham, Rutgers University, Piscataway, NJ

Presenter/First Author Email: bldunham@scarletmail.rutgers.edu

Co-authors: Vadim L Levin, Rutgers University, Piscataway, NJ; Andrea Servali, Rutgers University, Piscataway, NJ; Michael Klaser, Rutgers University New Brunswick, Highland Park, NJ

Abstract Body: Lithosphere beneath the present day Appalachian Front (AF) experienced three major tectonic events over the last 1.5 Ga. First, the crust to the west of the AF was formed and consolidated by the Grenville Orogeny. At ~620 Ma the Iapetus Ocean began to open, leading to rifting and possible thinning of Grenville crust. Subsequently, the closure of Iapetus and the Taconic, Acadian, and Allegenhian orogens sutured the Applachian crust onto pre-existing Grenville crust.

Most reconstructions of the Appalachian orogeny envision a thin-skin tectonic regime, where thrust sheets of relatively small thickness are emplaced onto the pre-existing continental margin of the thick-skinned Grenville tectonic regime. In this view, the crustal structure on the opposite sides of the modern AF should be very similar, specifically in the deep crust. Alternatively, if the Iapetan rifting event broke up and separated blocks of Grenville basement, then the deep crustal structure of the Appalachians, Iapetan rift and Grenville terrain should have features that reflect their individual geologic setting. The underlying basement of the Appalchians and Iapetan rift does not have to be similar to the Grenville's, and we would expect a major difference in deep crustal structure on the opposing sides of the AF.

We use seismic data from a group of long-operating seismometers on the banks of the St Lawrence River, and also data from recently installed portable observatories in the region. We employ teleseismic receiver function analysis methodology to construct detailed descriptions of seismic properties in the crust on opposite sides of the AF.

Our preliminary results show that while the thickness of the crust is similar (~50 km), on both sides of the AF, the internal structure of the crust is highly variable on lateral scales of ~20 km. Our density of observations in the St. Lawrence region helps us relate this complexity to the tectonic events that shaped the lithosphere.

Title: Detailed study of the Moho boundary in the Superior province of Quebec.

Presenter/First Author: Andrea Servali, Rutgers University, Piscataway, NJ

Presenter/First Author Email: servihunter@gmail.com

Co-authors: Michael Klaser, Rutgers University New Brunswick, Highland Park, NJ; Benjamin Dunham, Rutgers University, Piscataway, NJ; Vadim L Levin, Rutgers University, Piscataway, NJ

Abstract Body: Our project focuses on the description of the Moho discontinuity beneath the Superior Province in Quebec. We determine the depth to the Moho, its sharpness, and investigate such attributes as inclination, and relationships with the other discontinuities within the crust.

Our highly descriptive observations are facilitated by a large amount of clear data collected over a decade from long-operating seismic stations in Quebec. Also, we include data gathered by a temporary seismic array placed between Charlevoix and James Bay. We use teleseismic P wave data and carry out receiver function analysis to identify P to S converted waves.

To investigate the sharpness of the Moho we examine the shape of the P-to-S converted phase associated with it at different frequencies, from 0.25Hz to 2-3 Hz. To determine whether there is a systematic dip in the Moho we use directional changes in the timing of this pulse.

In the northern part of the Superior Province the Moho is very sharp. Converted waves with frequencies up to 2Hz are observed, suggesting a vertical change in seismic properties over a few hundred meters. This is not the case close to the Grenville Front, where a complex signature at high frequencies suggests a more diffuse crust-mantle boundary.

A very clear signature of the regional dip in the Moho is found at a site close to James Bay, while sites further south show a relatively flat Moho boundary. The finding of a dipping Moho in the oldest part of the Canadian Shield is surprising, and documents long preservation of the signature of past tectonic events.

Title: Appalachian Front is a Shallow Feature: Insight From Studies of Seismic Wave Speed in the Mantle

Presenter/First Author: William H Menke, Lamont-Doherty Earth Obs, Palisades, NY

Presenter/First Author Email: menke@ldeo.columbia.edu

Co-authors: Vadim L Levin, Rutgers University, Piscataway, NJ; Trevor Neitz, University of Maine at Farmington, Farmington, ME; Brandon Schow, Stanford University, Monument, CO; Fiona Ann Darbyshire, University of Quebec at Montreal UQAM, Montreal, QC, Canada

Published Material: 20% at 2014 Fall AGU Meeting

Abstract Body: The Appalachian Front (AF) is a major feature in the surface geology of eastern North America, separating 0.4 Ga old Appalachian terranes from the 1.2 Ga Grenville Province. North of Quebec City, it strikes northeast-southwest, and is approximately collocated with the St. Lawrence River. We use a group of long-operating seismic observatories that straddle the AF in Charlevoix region of Quebec, and a new portable array of observatories extending northwest and southeast from it, to investigate the seismic wave speed in the upper mantle beneath a region extending from the Archean craton near James Bay, across the AF, to the Appalachian terranes of coastal Maine.

Travel time delays of teleseismic P waves indicate that although the mantle tends to be faster in the craton 100-200 km northwest of the AF and slower in the Appalachian terranes 100-200 km southeast of the AF, there is no significant vertical boundary in the uppermost mantle (100-150 km) directly beneath the AF. Furthermore, the cross-strike variability (relative to the AF) is not in a form of a uniform decrease of mantle P velocity from James Bay to coastal Maine, but instead has two en echelon gradients (neither of which aligns with the AF). The Appalachian upper mantle is very heterogeneous (much faster in New Brunswick and northern Maine than in southern New England), and these heterogeneities are not aligned with the strike of the AF.

Stations on both sides of the AF in the Charlevoix region detect strong birefringence in SV-polarized teleseismic shear waves. The nature of birefringence is complex, with considerable scatter in individual observations. There is, however, no systematic difference in birefringence observed by sites on the "Grenville" and "Appalachian" sides of the AF, confirming that this tectonic boundary does not extend into the upper mantle. We detect a distinct pattern of birefringence in shear waves arriving from a narrow range of north-western back-azimuths (330-360NNW). Directional limits of this anomalous birefringence pattern, and the strength of the teleseismic P wave travel-time delay offset suggest a presence of a distinct upper-mantle feature to the NW that is faster, and has distinct rock fabric. A good candidate for such a feature would be an underplated oceanic slab preserved within the body of the craton since the time of its formation.

Title: Glacial erosion during orogenesis: A study of the intraplate Eurekan Orogeny of Ellesmere Island.

Presenter/First Author: Joseph Michael Housam, University of Toronto, Newmarket,

Presenter/First Author Email: joseph.housam@mail.utoronto.ca

Co-authors: Russell N Pysklywec, University of Toronto, Toronto, ON, Canada; Philip J Heron, University of Toronto, Toronto, ON, Canada; Randell Stephenson, University of Aberdeen, Aberdeen, United Kingdom

Abstract Body: The Eurekan Orogeny of northeastern Ellesmere Island in the Canadian arctic was formed as a result of mountain-building processes in the Paleogene. The orogen developed relatively distant from any active convergent plate boundaries making it a representation of a class of intraplate mountain-building. In this work we investigate the geodynamics of the Eurekan and in particular focus on the potential role of glacial erosion in modifying the orogenesis. The study is motivated by important recent research that has demonstrated a significant interaction between (climate-controlled) surface processes and solid Earth tectonics at collision. Glacial erosion is thought to have the capability of eroding at a rate which matches with that of rock uplift in active orogens, referred to as the “buzz saw” effect of glaciers. Using the geodynamic modelling code of SOPALE we developed forward 2D models of the idealized Ellesmerian lithospheric structure and imposed shortening to explore Eurekan-style orogenic deformation. In the numerical experiments, we modified the erosional algorithm in the model such to investigate various implementations of the glacial buzz saw. The model results show how the surface topography and internal lithospheric structure of the orogeny are modified by variable glacial erosion. In addition to illustrating how the Eurekan orogeny may have evolved, the results provide insight into how the generic orogenic zones may develop in a glacial environment.

Title: Computational Modelling of the Continental Collision near South Island, New Zealand

Presenter/First Author: Lev Karatun, University of Toronto, Toronto,

Presenter/First Author Email: lev.karatun@gmail.com

Co-authors: Russell N Pysklywec, University of Toronto, Toronto, ON, Canada; Cedric Thieulot, Utrecht University, Utrecht, Netherlands

Abstract Body: Among tectonic plate boundary types, the process of continental collision is poorly resolved, especially compared to the evolution of subduction, spreading, and transform plate boundary systems. There is still debate about the first-order response of the mantle lithosphere (sub-crustal lithosphere), such as whether there is distributed pure shear-type thickening, subduction-like consumption of the sub-crustal portions of the plate, or a combination of these two. This work explores in more detail a number of questions regarding the dynamics of the coupled crust and mantle lithosphere at continental collision. It focuses on the active continental convergence occurring at the South Island of New Zealand as a natural prototype for collision. The modest amount of shortening in this collision and relative abundance of observational constraints make this an ideal locale for studying the geodynamic processes of early orogenesis — a key step in understanding continental collisions generically. An important feature of the South Island tectonics is the highly oblique nature of the plate collision meaning high rate of along-strike material transfer. The oppositely verging subduction zones bounding the collision likely have their own influence on the deformation. However, previous studies on modelling the dynamics of the South Island collision have not included these important factors in the direction parallel to the plate boundary; instead considering this as a two-dimensional problem. In the scope of the research, we are conducting 3D geodynamical modelling to explore these tectonic questions for the collision. Here, we present the first results of forward computational modelling of the transpressional lithospheric system demonstrating the influence of rheology and varied rates of strike-slip versus convergent plate motion on the structures formed.

Title: Sharp Mantle Tansition from Cratons to Cordillera in Southwestern Canada

Presenter/First Author: Yu Jeffrey Gu, University of Alberta, Edmonton, AB

Presenter/First Author Email: ygu@ualberta.ca

Co-authors: Yuanyin Zhang, , , ; Mauricio D Sacchi, University of Alberta, Edmonton, AB, Canada; Yunfeng Chen, University of Alberta, Edmonton, AB, Canada

Abstract Body: The Western Canada Sedimentary Basin (WCSB) marks the transition from the old North American continental lithosphere to young accreted terranes and Cordillera. Earlier studies in this region have suggested a large number of intricate basement domains as well as major seismic velocity gradients in the mantle. To investigate the effect of the accretion and subduction on the mantle structure beneath the western margin of the North American craton, we analyze P-to-S converted waves from upper mantle discontinuities from Canadian Rockies and Alberta Network (CRANE). The depths of the 410 and 660 km seismic discontinuities are correlated and are, on average, 9 km and 7 km greater than the respective global estimates. The largest depression is observed beneath the Rocky Mountain foreland belt in southern Alberta, which highlights a steep south/westward structural gradient from cratons to Cordillera at lithospheric mantle depths. The severity of the depressions, especially in the southernmost Alberta, may be triggered by diffuse partial melt or increased water content above the mantle transition zone. This result is jointly corroborated by locally increased impedance contrast across the 410-km discontinuity and a strongly depressed 660-km discontinuity. The existence of, and the mantle processes associated with, a Mesozoic slab fragment may be responsible. Overall, the availability of local arrays, particularly the CRANE network, offers a new window into the history of the lithosphere and upper mantle beneath the southern WCSB.

Title: The Gravity and Magnetic Field Characteristics of North China Area and Its Tectonic Significance.

Presenter: Xiaohong Meng, China University of Geocsience, Beijing,

Presenter Email: mxh@cugb.edu.cn

First Author: Zhaoxi Chen, China University of Geosicences(Beijing), Beijing,

First Author Email: zxchen2010@126.com

First Author Student?: No

Co-authors: Changli Yao, China University of Geoscience, Beijing, China

Abstract Body: The Bouguer gravity and aeromagnetic anomaly data sets of North China Craton are finely processed and the method such as anomaly separation, reduction to equation pole by varying declination angles, tectonic feature extraction are used to obtain enhancing and comparative results. With comprehensive understanding of MT and other geological results, the identification of tectonic units and faults by gravity and magnetic field are preformed and the 3D distribution of density contrast and equivalent susceptibility in the scale of lithosphere are obtained.

The framework of regional gravity field in North China can be summarized as “East high and west low for regional gravity field, three vertical and two horizontal for gradient gravity zone”. The magnetic field has high amplitude, complex for negative and positive characteristics and also has different kinds of trends.

From the northeast to southwest four orogneic belts and eight tectonic units can be identified according to the corresponding gravity and magnetic field. Four orogneic belts include central Asian orogneic belt, Yinshan orogenic belt, central orognic belt and Qinling orogenic belt. Eight tectonic units consist of Alashan block, Qinlian block, East Kulun block, Songpan block, Eastern block， Western block, Yangtze Block and Sulu block. In addition, eleven main faults can be recognized by gravity and magnetic lineament.

The 0-40km and 0-15km 3D subsurface distributions of density contrast equivalent susceptibility in North China Craton are obtained by 3D gravity inversion and 3D correlation for gravity and magnetic data respectively. The analysis shows that the central orogenci belts region has an overall low density contrast. With increasing depth, density contrast changes by a larger range. The south, north, middle abnormal variations are not identical. This discrepancy may be illustrated by the south, north and central orogneic belt experienced different geological process, and also implies that the lithosphere destruction in North China may have extended from the eastern block to the area. Similarly, the magnetic distribution of North China Craton is not uniform for shallow to deep region in each block units. The boundaries of most tectonic belts are approximately located at the transitional belts of high and low magnetic distribution.

Title: Experimental Characterisation of Slip Properties in Similar and Dissimilar Volcanic and Sedimentary Rocks during Flank Motion at Mount Etna (Italy)

Presenter/First Author: Jackie Evan Kendrick, University of Liverpool, Liverpool,

Presenter/First Author Email: jackieek@liv.ac.uk

Co-authors: Yan Lavallée, University of Liverpool, Liverpool, United Kingdom; Wojciech Rozanski, , , ; Angela Castagna, , , ; Michael John Heap, Université de Strasbourg, Strasbourg, France; Sergio Vinciguerra, University of Leicester, Leicester, United Kingdom; Takehiro Hirose, JAMSTEC Japan Agency for Marine-Earth Science and Technology, Kanagawa, Japan; Donald B Dingwell, Ludwig Maximilian University of Munich, Munich, Germany

Published Material: They will be presented in-part at EGU2015

Abstract Body: The edifice of Mount Etna (Italy) is structurally unstable, exhibiting near-continuous ESE sliding along a set of faults that results from interplay between regional tectonics, gravity instability and magma intrusion. Ground deformation and seismic monitoring reveal large-scale flank motion at variable rates. However, the mechanisms controlling this faulting remain poorly constrained. Examination of the fault zones reveals a range of rock types along the different fault segments: fresh and altered basalt, sandstone, clay and limestone. Here, we experimentally investigate the frictional properties of these rocks using rotary shear tests on similar and dissimilar rocks, to better understand episodes of slow flank motion as well as potential rapid and catastrophic sector collapse events.

Experiments were performed at velocities up to 1.2 m/s and at normal stresses up to 1.5 MPa, commensurate with depths of the contacts in the Etna edifice. Friction experiments on solid rocks show a wide range of mechanical behaviour. At high velocity (>0.6 m/s) volcanic rocks tend to melt whereas the clay and limestone do not; rather they decarbonate, which prevents the rock from achieving the temperature required for melting. Experiments on dissimilar rocks clearly show that shear resistance on the slip zone is intermediate between the shear resistances of each component rock individually. Host rock composition affects the composition and viscosity of the resultant frictional melt, which causes fault weakening or strengthening depending on the combination of host rock samples. Friction experiments on clay gouge show the strong rate-weakening dependence of slip in this material as well as the release of carbon dioxide. The range of lithologies encountered by the fault system at Etna serve to complicate the model for flank instability, but these results provide important insights to realistic slip behaviour.

Co-authors: Tariq Mohammed, University of Alberta, Edmonton, AB, Canada; Douglas R Schmitt, University of Alberta, Edmonton, AB, Canada

Abstract Body: The aim of this research is to investigate the cross-property relationships between electrical and elastic properties of sandstone to improve the joint inversion of seismic and electromagnetic monitoring surveys in a CO_2 sequestration context. We conducted a laboratory study of the impact of pressure change on the P and S wave velocity, attenuation and electrical conductivity of Berea sandstone. Measurements were obtained varying both the confining and the pore pressure in the 0-40 MPa range. Similar measurements were performed on a porous alumina rod with different petrophysical properties as a comparison. The four properties mentioned above are found to follow the exponential equation Z(P)=A+BP+Cexp(-DP) where the parameter D is universal for the properties under consideration.

Title: Seismic Properties from EBSD Data and Receiver Function Analyses: Results from a Crustal-Scale Detachment System, Aegean Region

Presenter/First Author: Élise Cossette, University of Ottawa, Montréal,

Presenter/First Author Email: elise.cossette@gmail.com

Co-authors: Pascal Audet, University of Ottawa, Ottawa, ON, Canada; David A Schneider, University of Ottawa, Ottawa, ON, Canada; Bernhard Grasemann, University of Vienna, Vienna, Austria; Gerlinde Habler, University of Vienna, Vienna, Iceland

Published Material: Only part of the results were previously reported, at the Geological Society of America Annual Meeting (Denver, CO) in 2013. These findings are not yet submitted to any journal.

Abstract Body: The crystallographic preferred orientations were measured on a suite of samples representative of different structural depths along the West Cycladic Detachment System of Greece. Electron backscatter diffraction (EBSD) analyses were conducted on calcitic and mica schists, impure quartzites, and a blueschist, and average seismic properties of the rocks were calculated with the Voigt-Reuss-Hill average of the single minerals' elastic stiffness tensor. The calcitic and quartzitic rocks have P- and S-wave velocity anisotropies (AVp, AVs) averaging 8.1% and 7.1%, respectively. The anisotropy increases with depth as represented by the blueschist, with AVp averaging 20.3% and AVs averaging 14.5%, due to the content of aligned glaucophane and mica, which strongly control the rock seismic properties. Localised anisotropies of high magnitudes are caused by the presence of mica schists as they possess the strongest anisotropies, with values of 26.6% for AVp and 23.9% for AVs. The direction of the fast and slow P-wave velocities occurs parallel and perpendicular to foliation, respectively, for most samples. The fast propagation has the same NE-SW orientation as the lithospheric stretching direction experienced by the Cyclades since the Late Oligocene. The maximum shear wave anisotropy is subhorizontal, similarly concordant with mineral alignment that developed during extension in the Aegean. Our results strongly favour radial anisotropy in the Aegean mid-crust over azimuthal anisotropy. Receiver functions (RF) for several stations in the Cyclades have been calculated to characterize the underlying crustal structures, such as anisotropy. We present preliminary results of RF post-processing, which will be used in conjunction with velocities and anisotropies from our EBSD data to build a seismic velocity model. This model, based on rock textures and seismic observations, will be helpful for understanding the crustal structure of an extensional province.

Title: Experimental Determination of the Elastic Anisotropy of Shales: Comparison of Static and Dynamic Measurements

Presenter/First Author: Douglas R Schmitt, University of Alberta, Edmonton, AB

Presenter/First Author Email: dschmitt@ualberta.ca

Co-authors: Nam (Oliver) Ong, , , ; Jaime Melendez Martinez, UNIVERSITY OF ALBERTA, Edmonton, AB, Canada

Published Material: Similar material presented at the Geoconvention in Calgary that is running at the same time as this meeting.

Abstract Body: Interest in the physical properties of unconventional reservoir rocks, which are often all characterized as 'shales', has accelerated due to the rapid growth in the use of hydraulic stimulation for the recovery of hydrocarbons. Similarly, it has long been known that such rocks are anisotropic and this has significant implications for proper seismic imaging. We are currently making measurements of the elastic anisotropy of such materials under the assumption they are transversely isotropic. An array of strategically oriented P- and S-wave PTZ ceramics are mounted directly to a specially machined prism of the core material in order to capture the wave speeds in a number of different directions. The measurements are conducted under hydrostatic confining pressures. Strain measurements are simultaneously obtained to allow for comparison of static to dynamic moduli. We observe high levels of anisotropy of up to 25% or more in both P- and S-wave speeds. More interestingly, we see that the physical properties parallel to layering are nearly independent of pressure while those perpendicular to layering show significant nonlinearity with pressure. Heuristically, this is likely a result of the preferential layering of both minerals and pore shapes.

Title: Seismic Properties and CPO Relationships of a Crustal Scale Shear Zone in Granodiorite, Serifos, Greece

Presenter/First Author: Élyse Gaudreau, University of Ottawa, Ottawa,

Presenter/First Author Email: egaud052@uottawa.ca

Co-authors: Élise Cossette, University of Ottawa, Montréal, Canada; David A Schneider, University of Ottawa, Ottawa, ON, Canada; Bernhard Grasemann, University of Vienna, Vienna, Austria

Abstract Body: Serifos island is the southern-eastern terminus of the West Cyclades Detachment System, where a late-tectonic granodiorite pluton exhibits ductile to brittle structures due to ongoing extension accommodated by the shear zone. The crystallographic preferred orientations (CPO) of samples collected across a strain gradient were measured using electron backscatter diffraction and seismic properties were calculated using Voigt-Reuss-Hill averaging. All samples show bulging quartz grains with brittle fractures and the weakly deformed granodiorite exhibits feldspars with straight, sharp boundaries. Quartz in the moderately deformed samples is recrystallized, feldspar grains have serrated boundaries and mica crystals are bent. In the mylonite, the magmatic quartz grains recrystallize by a combination of dislocation glide and bulging resulting in a smaller grain size, suggesting a significant component of shear strain. Quartz CPO is very strong in the weakly deformed sample recording prism <a> slip and is very weak in the mylonite. Orthoclase and anorthite possess a weak CPO in all samples suggesting that temperatures were too low for feldspar to deform by dynamic recrystallization (450-500°C for Fsp, compared to 250°C for Qz). All but the less deformed samples have similar directions for fast P-wave velocity and slow P-wave velocity for anorthite. Orthoclase P-wave and S-wave velocities are similar for only the highly deformed samples. Also in highly deformed samples, there appears to be a relation between the maximum P-wave velocity and the CPO of anorthite. The S-wave anisotropy of the weakly deformed granodiorite is the highest of all samples (maximum anisotropy: 8%), and the anisotropy of the mylonite is the weakest of all samples (maximum: <3%). Texture analysis provides

information on the seismic anisotropy of variably deformed granodiorite, which can be considered as a good approximation of bulk crustal material.

Title: Magnitude and symmetry of seismic anisotropy in schists and geophysical implications

Presenter/First Author: Shaocheng Ji, Ecole Polytechnique de Montreal, Montreal, QC

Presenter/First Author Email: sji@polymtl.ca

Co-authors: Tongbin Shao, , , ; Katsuyoshi Michibayashi, Shizuoka University, Shizuoka, Japan; Matthew H Salisbury, , Dartmouth, NS, Canada

Abstract Body: We have calibrated the magnitude and symmetry of seismic anisotropy in various schists by laboratory measurements at pressures up to 600 MPa and analyses of EBSD fabrics in order to evaluate whether seismic properties of the schists can be reasonably well approximated by a transverse isotropic (TI) symmetry. The average bulk anisotropy values for chlorite schists, mica schists, phyllites and sillimanite-mica schists at 600 MPa are 12.0±4.1%, 12.8±5.6%, 12.8±9.0% and 18.4±4.4%, respectively. These schists show much higher V_p anisotropy (13.1±6.1%) than other categories of metamorphic rocks such as granitic gneisses, felsic mylonites, granulites and peridotites. V_p anisotropic pattern of the schists depends mainly on the interference effects between mica and quartz. Basal slip of mica causes $V_p(X) \approx V_p(Y) >> V_p(Z)$ while prism <a> slip of quartz increases $V_p(Y)$ but decreases $V_p(X)$. Accordingly the quartz-mica schists display $V_p(Y)>V_p(X)>V_p(Z)$. However, schists containing considerable volume fractions of quartz deformed by prism <c> slip show $V_p(X)>V_p(Y)>V_p(Z)$. Mica schists containing amphibole, kyanite and sillimanite are of orthorhombic symmetry due to the needle minerals whose fast c-axes are aligned preferentially parallel to the lineation. The average polarization direction of fast split SKS and SKKS waves (ϕ) between the Ailao Shan-Red River fault zone and the Nabang Fault zone in west Yunnan is 110±19°, which is approximately parallel to the absolute plate motion (APM) of the region but at high angles with the strikes of the crustal fault zones. The average delay time is 1.58±0.44 s. However, Pms phases, which are generated at the Moho and their wave path are confined within the crust only, display their fast polarization directions parallel essentially to the strikes of the fault zones and splitting times of up to 0.45 s with typical values of 0.30 s. Hence, S-wave anisotropy in the west Yunnan is consistent with a model of two anisotropic layers: the upper layer related to frozen fabrics of mica-rich and amphibole-bearing rocks within the crust, which deformed during folding and strike-slip shear, whereas the lower layer related to present-day APM-driven flow in the lithospheric mantle and asthenosphere. The data indicate that mechanical decoupling occurs between the crust and mantle of the region.

Abstract Body: The Grabens, Canyonlands National Park, Utah is an area of arcuate horsts and grabens formed by extending and gliding Pennsylvanian and Permian brittle rocks down dip towards the Colorado River over the Pennsylvanian Paradox salt. Dissolution and deformation of salt enhanced the extensional fracture system, widening individual fractures. Slumped blocks that constrict river flow and create rapids are evidence that gravity gliding is still active.

Scaled analogue models were constructed with sand and silicon to recreate brittle layer extension as the underlying salt deforms on a slightly inclined sliding plane. During the early stages, deformations within the ductile layer resulted in unequal thickness, exhibiting areas of spreading and compression where deep-seated, normal or reverse faults bounding the horsts and grabens form. During spreading, shallow-penetrating faults developed within existing horsts and grabens in the distal and medial areas and propagated towards the source area. Extensional features in the analogue slide translation and source zones are similar to the Grabens area and its vicinity east of Shay Mountain.

We suggest that a large, multi-stage and slow-moving gravity driven slide affects the Canyonlands area west of the Shay Mountain up to the Colorado River. It is caused by a deforming salt layer underneath. Deformation factors including basement faults; sinking basin; and sediment overburden were present by the end of Middle Pennsylvanian. The slide was triggered by Shay Mountain intrusion during the Cretaceous as evidenced by uniform thicknesses of Late Triassic overburden in the Bridger Jack and Boundary Butte. The sliding translated the upper brittle layer initially towards the northwest and eventually to the west due to thicker and stronger sedimentary confinement to the north. When the Colorado River in the west started eroding the toe of the translating mass during the Middle Miocene, retrogressive failure started, forming The Grabens.

Title: Two earthquake sequences along the Selaha and Zheduotang branches of the Xianshuihe fault, southwest China, and implication for aseismic transient slip on continental transform faults

Presenter/First Author: Guoyan Jiang, Institute of Geology, CEA, ,

Presenter/First Author Email: guoyanjiang@gmail.com

Abstract Body: During one week since 22 November 2014, over 900 earthquakes of $M<6$ struck the northwest of Kangding within a distance of ~30 km on the Xianshuihe fault in southwest China. This intense seismicity are two earthquake sequences initiated by two large events: November 22 (UTC 08:55:25) Mw 5.9 and November 25 (UTC 15:19:07) Mw 5.6, along the Selaha branch and the Zheduotang branch respectively. The inversion results of slip distribution from InSAR images taken between September 26 and December 5, 2014, show the optimal dip angle of the seismogenic fault is ~84°, and the maximum slip of the first earthquake sequence is 0.5 m. Using a rigidity of 30 GPa, the geodetic moment is 2.45×10^{18} N m, which is about two-fold the total seismic moment (equivalently Mw 6.0) accumulated during the same time period. This implies that there was probably aseismic slip between these two earthquake sequences. The along-strike migration velocities of seismicity in the first ~5 hours after two large events are both ~ 5 km/hr, which is on the order of the propagating speed (km hr^{-1}) of seismicity driven by aseismic slip on tectonic transform faults [Roland and McGuire, 2009]. However, the occurrence of two

earthquake sequences does not completely decrease the seismic risk of a big earthquake on this Kangding segment of Xianshuihe fault, which has accumulated seismic moment up to 7.15×10^{18} N m since the 1955 M7(1/2) event [Jiang et al., JGR, 2015; under review].

Title: AMS Investigation in the Pingluoba and Qiongxi Anticlines, Sichuan, China: Implications for Deformation Mechanism of the Qiongxi Structure

Presenter/First Author: Liang Luo, China University of Petroleum, Beijing,

Presenter/First Author Email: luoliang1225@gmail.com

Co-authors: Jiafu Qi, College of Geosciences， China University of Petroleum,, Beijing, China; Mingzheng Zhang, College of Geosciences， China University of Petroleum,, Beijing, China

Published Material: This research has been recently published in Tectonophysics.

Abstract Body: Stratigraphic attitude is one of the most important field data for structural geology research. However, it is difficult to measure directly sometimes, especially in weak deformed sediments with low dip angle. Pingluoba anticline, mainly consisting of medium-high dip angle strata, is located on the Longmen Shan fold-and-thrust belt front. Qiongxi anticline is located in the southwestern Sichuan Basin, and it is mainly composed of sub-horizontal to low dip angle strata. An investigation of the anisotropy of magnetic susceptibility (AMS) in 78 sites has been carried out in these two folds. Stepwise demagnetization of three orthogonal isothermal remanent magnetization suggests that hematite is the main magnetic carrier mineral in the Qiongxi anticline, meanwhile, hematite and magnetite are both existing in the Pingluoba anticline. It reveals three types of magnetic fabrics: sedimentary magnetic fabic, initial deformation magnetic fabric and pencil structure magnetic fabric, which indicate weak deformation. Throughout AMS theoretical analysis and example test in the Pingluoba anticline, magnetic fabric is a suitable technique to confirm the stratigraphic attitude in weak compressional deformed sediments. For the sedimentary magnetic fabric, initial deformation magnetic fabric and one atypical initial deformation magnetic fabric developed in the weak deformed tectonic superposition region, dip direction of bedding plane = pitch direction of K_3＋(or－) 180°, and dip angle of bedding plane = 90°－pitch angle of K_3. 38 stratigraphic attitudes with low dip angle in the Qiongxi anticline have been rectified by magnetic fabric results. Qiongxi structure is a weak tectonic superposition deformation anticline. The deformation mechanism of Qiongxi structure may contain two stages: NW-SE compression stage started from the latest Cretaceous-early Cenozoic and nearly E-W shortening stage in the Late Cenozoic.

Title: 3-D seismic velocity structure of Kumaon-Garhwal Himalaya: Insight in to Main Himalayan Thrust and earthquake occurrence

Presenter/First Author: Perugu Mahesh, National Geophysical Research Institute, Hyderabad,

Presenter/First Author Email: mahesh_jan22@yahoo.co.in

Co-authors: Sandeep Gupta, , , ; Shyam Sundar Rai, National Geophys Res Instt, Hyderabad, India; Ajay Paul, , ,

Abstract Body: We present a detailed three-dimensional *P*- wave velocity (V_p) and *Vp/Vs* structure for the Kumaon-Garhwal Himalaya generated by inverting arrival times of 1180 local earthquakes recorded by 50 broadband stations operated during April 2005 - June 2008. The upper crust (< 20 km) show heterogeneous structure in this region. In the near surface (upper 5 km), south of Main Frontal Thrust (MFT) is characterised by low V_P (~5.2 - 5.4 km/s) and low V_P/V_S (~1.67 - 1.72) that could be impression of unconsolidated sediments. We observe that the earthquakes are localized in the regions of low V_P (~ 5.3 - 5.7 km/s) and low V_P/V_S (~1.6 - 1.72) in the upper crust (< 20 km) possibly due to the presence of quartz-rich rocks. To the north of Main Boundary Thrust (MBT) a low velocity (V_P ~5.7 km/s) layer is observed at 10-15 km depth. This could be signature of the Main Himalayan Thrust (MHT) in this region. At the depth of 18 - 25 km beneath the Main Central Thrust (MCT) zone an isolated zone of anomalous V_P ~5.7-6.0 km/s and V_P/V_S ~1.75.1.85 is observed. This is just below the maximum concentration of seismicity and coincides with the low resistivity zone reported by magneto telluric studies. This could be interpreted as possible presence of fluids due to metamorphic dehydration reaction during underthrusting of the Indian crust. The presence of fluids around and below the seismogenic zone can influence the activity of the fault system; it can affect the long-term structural and compositional evolution of the fault zone, and can alter the fault-zone strength and local stress regime. As fluids enter the active faults in the crust (such as the MCT zone), fault zone friction decrease facilitating the stress concentration in the seismogenic layer leading to mechanical failure. We, speculate that the earthquake occurrence in the Kumaon-Garhwal Himalaya is not only due to stress caused by collision tectonics, but also associated with the lithology of the region.

Abstract Body: NW-SE trending of the Zagros Foreland Folded Belt (ZFFB) developed during Mio-Pliocene Arabia-Eurasia convergence. Tectonic convergence is still ongoing and intense seismicity in the ZFFB. Our study area covers the Eastern Zagros (Fars area) with significant set of nearly N-S trending right-lateral strike-slip and several NW-SE trending thrust faults. These lateral fault zones play a major kinematic role by matching the change in shortening state through the study area. Multiple detachment levels (e.g. Hormuz Salt) allow decoupling of deformation between the basement and the cover. Such decoupling of deformation controls the stress conditions between different units within the cover sequence and the brittle crust. In order to reconstruct the paleo and recent stress conditions, we analyzed fault slip and focal mechanism data sets using stress inversion method. Our results show the compressional regimes from Miocene to recent with an anticlockwise change in the direction of main compression stress through time, consistent with variation in Arabia–Eurasia convergent path. Based upon the evidence of pre-syn-folding stage of faulting, it suggests a general NE-SW trending of σ1 axis with no significant change in long term seismicity through the study area. On the other side, the inversion of earthquake focal mechanism shows NNE to N-S compression with a low ratio between differential stresses. It suggest that not only the shortening within the thick sedimentary cover of the Zagros

(~12 km) completely decouples from the brittle crust deformation, but our results also mention to a possible non-completely-aligned decoupling due to the obliquity of the shortening directions in the sedimentary cover with respect to the basement.

Title: Evolutionary model of oblique rift basins-Study of Central African Rifts

Presenter/First Author: I-Wen Cheng, NCKU National Cheng Kung University, Tainan,

Presenter/First Author Email: cgw0814@gmail.com

Co-authors: Kenn-Ming Yang, National Cheng Kung University, Tainan, Taiwan; Jong-Chang Wu, Chinese Petroleum Corporation-Taiwan, Miaoli, Taiwan; Ta-Heng Hsiuan, Chinese Petroleum Corporation-Taiwan, Miaoli, Taiwan

Abstract Body: The geometry of oblique-rifting basin has relationship with the acute angle – α-between the rift trend and trend of tensile stress. In this study, we simulated the formation of oblique-rifting basin by Particle Flow Code 3-Dimensions-(PFC 3D) and drew a comparison between the simulation results and the evolutional models of Doba basin, Doseo basin and Salamat basin in Central African Rifts. The main theory of PFC 3D is based on the Discrete Element Method (DEM) which a whole model framework is established by applying different parameters to the every particles in the model.

There are two big-model sets in this study, Model-set1 and Model-set2. Model-set1: The model is divided into two blocks according to the rift trend. Both blocks are applied two tensile stresses parallel to the y-axis. Model-set2: Set the plate below the model. The plate is divided into two plates according to the rift trend. A fixed -tensile velocity parallel to the y-axis is applied to the both plates. The α is set at 90°, 75°, 60° and 45° in both model-sets. The study results indicated that 1. The en echelon faults in the rifting basins are sub-vertical to the trend of tensile stress. 2. The density of en echelon faults in rift basins decrease gradually when α is close to 45°. 3. By comparison with the α value of the Central African Rifts, we reckon that the α of the Doba Basin, Doseo Basin and Salamat Basin are 60°, 60° and 75°, respectively. 4. The Doba basin- wide and shallow- is a mesoscale rift basin, while the Doseo basin and the Salamat basin- narrow and deep- are megascale rift basins. We proposed that the petroleum systems of Doba basin and Doseo-Salamat basin are different.

Title: Structural, geochronological, and geochemical analysis of a Cycladic detachment system II: Results from the Lavrion Unit, Greece

Presenter/First Author: Renelle Dubosq, University of Ottawa, Ottawa,

Presenter/First Author Email: rdubo026@uottawa.ca

Co-authors: Jennifer Spalding, University of Ottawa, Ottawa, Canada; David A Schneider, University of Ottawa, Ottawa, ON, Canada; Bernhard Grasemann, University of Vienna, Vienna, Austria; Konstantinos I Soukis, university of Athens, Athens, Greece

Abstract Body: The West Cycladic islands comprise the footwall of the West Cycladic Detachment System (WCDS), characterized by a system of high and low angle normal faults that cuts different structural levels of the Cycladic Blueschist Unit (CBU). Whereas the hanging wall has mostly been eroded on the islands, the Lavrion peninsula preserves the Lavrion Unit, interpreted to be the upper structural levels of the WCDS. The main foliation is a compressional crenulation cleavage with ENE-WSW to NE-SW stretching and intersection lineations. Kinematic indicators reveal top-to-SSW sense of shear, and along the detachment both units are overprinted by cataclastic deformation and high-temperature metallic ore mineralization. Glaucophane and chlorite pseudomorphs of glacophane are preserved. New single-crystal Ar-Ar geochronology on muscovite from the Lavrion Unit yields ages between 35-28 Ma, and together with published zircon (U-Th)/He dates of 16-12 Ma and preservation of glaucophane suggests these rocks did not witness the dominant Miocene greenschist facies deformation that characterizes the WCDS. One muscovite sample along the west coast at Thimari yielded an Ar-Ar age of c. 175 Ma and maybe part of the Sub-Pelagonian Berzekos Unit. Moreover, the geology of Lavrion peninsula is strikingly similar to Serifos island on the southeast termination of the WCDS. Pinning the ends of the detachment system, the geology of Lavrion and Serifos both include late-tectonic granodiorite plutons intruded at c. 10 Ma into the low-angle normal fault that cuts different structural levels of the CBU, which preserves an Eocene-Oligocene cooling signature and ENE-WSW trending lineations. The western Cyclades including the Lavrion peninsula can be resolved into a coherent and uniform tectonic progression commencing in the Eocene involving ENE-WSW to NNE-SSW ductile to brittle extension through the Miocene, localized plutonism at the tips of the detachment system, and relatively rapid cooling of the footwall.

Title: Structural, geochronological, and geochemical analysis of a Cycladic detachment system I: Results from the Kamariza Unit, Greece

Presenter/First Author: Jennifer Spalding, University of Ottawa, Ottawa,

Presenter/First Author Email: jennifer.spalding93@gmail.com

Co-authors: Renelle Dubosq, University of Ottawa, Ottawa, Canada; David A Schneider, University of Ottawa, Ottawa, ON, Canada; Bernhard Grasemann, University of Vienna, Vienna, Austria; Konstantinos I Soukis, university of Athens, Athens, Greece

Abstract Body: The Lavrion peninsula of Greece marks the northern terminus of the West Cycladic Detachment System (WCDS), a low-angle normal fault system accommodating extension under ductile-brittle condition. The Kamariza unit comprises the lowest structural levels, and is composed mainly of greenschist facies marble and schist recording SSW-directed kinematics. We have collected samples to conduct Ar-Ar geochronology on white mica in an attempt to better understand the thermal history of this extensional terrane. In the schists, white mica is abundant, defining the main foliation and locally forming a secondary SC foliation with mica fish structures; in the marble samples, white mica is rare. In all samples, the quartz and calcite crystals are recrystallized and quartz often has bulging grain boundaries. Chemical maps show that the white mica has a dominant muscovite composition and is strongly zoned within samples yielding younger cooling ages. Mica from the Kamariza unit yields Early to Middle Miocene Ar-Ar ages, and coupled with Late Miocene zircon (U-Th)/He ages and top-to-SSW shear sense, suggests these rocks experienced the same extensional tectonism as the other WCDS footwall exposures on Makronisos, Kea, and Kythnos. Relatively rapid exhumation initiated decompressional melting in the Late Miocene generating the Plaka pluton as well as attendant hydrothermal fluids. Fluid infiltration along the brittle detachment metasomatized the host marbles resulting in high-temperature Mississippi Valley Type deposits. Some of our mica ages may reflect reheating associated with mineralization. Similar to the tectonic history on Serifos, the final extensional movements along the low-angle normal faults took place at rather shallow depths, postdating the intrusion and illustrating the >10 m.y. evolution of the detachment system.

Title: Magma production rate along the Ninetyeast Ridge and its relationship to the Indian plate motion and the Kerguelen hot spot activity

Presenter/First Author: K M Sreejith, Space Applications center, Ahmedabad Gujarat,

Presenter/First Author Email: sreejith81@gmail.com

Co-authors: Kolluru Sree Krishna, National Institute of Oceanography, Panjim, India

Abstract Body: The Ninetyeast Ridge (NER), a linear trace of the Kerguelen hot spot in the Indian Ocean, was emplaced on a rapidly drifting Indian plate. Magma production rates along the ridge track are computed using gravity-derived excess crustal thickness data. The production rates change between 2 and 15 m3/s over timescales of 3-16 Myr. Major variations in magma production rates are primarily associated with significant changes in the Indian plate velocity with low production phases linked to high plate velocity periods. The lowest magma production rate (2m3/s) at 62 Ma is associated with the rapid northward drift of Indian plate under the influence of the Reunion mantle plume. The contemporaneous slowing of the African plate coincides with increase in magma production rate along the Walvis Ridge in the Atlantic Ocean. The present study suggests that variations in the Indian plate motion and frequent ridge jumps have a major role in controlling the magma production, particularly on long period cycles (~16 Myr). Short-period variations (~5 Myr) in magma productions may be associated with intrinsic changes in the plume, possibly due to the presence of solitary waves in the plume conduit.

Title: Thick sediments in the central Ganga basin: evidence from magnetotelluric investigations

Presenter/First Author: Adilakshmi Lolabhattu, NATIONAL GEOPHYSICAL RESEARCH INSTITUTE, Hyderabad,

Presenter/First Author Email: lakshmi@ngri.res.in

Abstract Body: The collision of the Indian and the Eurasian plates around 55 million years ago and flexing of the Indian plate created a foreland basin south of the Himalaya, named as the Indo-Gangetic basin. The sedimentation in the basin by the giant Himalayan Rivers and their tributaries has led to the deposition of a thick sequence of sediments masking the underlying rocks and tectonic features of the Indian plate. Mapping of the thickness of these sediments is of immense importance for the assessment of earthquake hazard potential due to amplification of seismic waves. Since a large population lives in this basin, it is necessary to quantify the thickness of sediments in the basin and use this information in site amplification studies. We have carried out a magnetotelluric (MT) investigation along a 285 km long profile across the central Ganga basin to delineate the sedimentary thickness in this part of the basin. MT time series processing and transfer function analysis of the data of 39 sites in the frequency range of 0.001-1000s has been carried out for this purpose. The subsurface electrical resistivity section obtained after the inversion of MT data reveals a significant contrast in the geoelectric structure along the profile. The sedimentary thickness at the northern end of the profile, close to the Himalayan foothills, is estimated to be more than 9 km, which is considerably thicker than the average thickness of 4 to 5 km used in flexural modeling studies. The high conductivity of sediments together with the high Vp/Vs ratio obtained by a seismological study in the Ganga basin implies poorly consolidated nature of the sediments and, thus, high seismic hazard potential.

Title: Geometrical and Kinematic Setting of L-tectonites in the Tongbai Orogenic Belt, Central China

Presenter/First Author: Huan Liu, University of Waterloo, Waterloo,

Presenter/First Author Email: liuhuanwaterloo@gmail.com

Co-authors: Shoufa Lin, University of Waterloo, Waterloo, ON, Canada; Chuanzhong Song, , ,

Abstract Body: L-tectonites are well developed and widely distributed in the Tongbai orogenic belt in central China. The orogenic belt as a whole has an antiformal geometry and the hinge of the antiform is subhorizontal and trends west-east. The L-tectonites occur in the core of the antiform, in a zone that is ~20-40 km wide and over 100 km long. Lineations in the L-tectonites are subhorizontal, parallel to the hinge of the antiform. Sheath folds are also well developed associated with the L-tectonites, with the hinges parallel to the lineations.

The L-tectonite zone is bounded by two ductile shear zones, on the north and south side, respectively. Well-developed shear sense indicators indicate that the southern and northern shear zones have a dextral and sinistral sense of shear, respectively. The L-tectonite zone is capped by a sub-horizontal shear zone with the hanging wall moving west relative to the footwall. These geometrical and kinematic data indicate that the three shear zones are likely part of a single shear zone that wraps around the L-tectonite zone. The L-tectonite zone in the core moves east relative to the hanging wall. The development of the tectonites is interpreted to be a result of this special geometry and kinematics. Available geological and geochronological data indicate that this took place in Early Cretaceous. Magmatism in late Cretaceous affected but did not significantly change the overall geometry.

Title: Transpression vs. simple shear superimposed on inherited pure shear – methodology for a more refined kinematic analysis

Presenter/First Author: Amol Dayanand Sawant, Indian Institute of Technology Kharagpur, Kharagpur,

Presenter/First Author Email: amoldayanand@gmail.com

Co-authors: Saibal Gupta, Indian Institute of Technology Kharagpur, Kharagpur, India; Surajit Misra, , ,

Abstract Body: Determination of the extent of shortening that accompanies simple shearing in transpressional shear zones is of great importance to regional deformation studies. A kinematic method is developed here to discriminate between combined pure and simple shear deformation (i.e. general shear - transpression/transtension), and cases where the simple and pure shear occurred at distinct times in a specific lithology within the shear zone. The following assumptions should be valid for the selected lithology: (i) the non-coaxial shearing is the last deformation event; (ii) the strain field prior to this last shearing event was homogeneous; (iii) no strain recovery has occurred during or after the last deformation event; and (iv) the last shearing event operated at constant

strain rate. The method involves determination of the states of finite strain at different locations within the selected sheared lithology as input parameters. The finite incremental strain is then calculated from the finite strain using any standard methodology, e.g. Horsman & Tikoff (2006). Thereafter, assuming constant strain rate, more precise estimates of the *infinitesimal incremental* strain can be obtained by taking roots of the *finite incremental* strain. Restriction of finite strain determination to a specific lithology eliminates errors arising from the presence of pre-shearing finite strain inhomogeneities in lithologies of varying competencies. Thus, this method can be used to distinguish whether the last shearing event within a lithology of a particular shear zone was one of general shear, or a case of simple shearing superimposed on earlier, inherited pure shear deformation. This method has been applied to a quartzite unit in a major, crustal-scale shear zone in the eastern Indian shield, to demonstrate that shortening features in the unit are temporally unrelated to the later, dominantly simple shear strike-slip event.

Title: Earth evolution as a thermal system

Presenter/First Author: Chunan Tang, Organization Not Listed, Dalian,

Presenter/First Author Email: tca@mail.neu.edu.cn

Abstract Body: After fifty years of plate-tectonic theory, the reasons why the Earth sometimes froze as a snowball or sometimes became lethally hot resulting in mass extinction remain enigmatic. Here we propose a new model on the Earth evolution as a thermal system. The unbalance of heat between input and output is considered as the driving force for the Earth evolution, the lithospheric expansion and associated uplift are the triggers, the self-organized progressive failures following certain scale law in terms of fracture spacing leading to the crust collapse of the Earth (CCE) are the amplifier, and the global scale response in terms of volcanism and magmatism is the globalizer. These shallow processes of lithosphere may reach a critical state with a positive feedback loop, and result in the formation of Large Igneous Provinces (LIP) in a top-down pattern. Endothermic phase changes during de-compressive melting remove heat from the inner Earth and cool their surroundings, including the upper parts of the lithosphere. The huge loss of the Earth's heat during eruption of LIPs, together with the endothermic cooling, may put the thermal cycle to an end and a new start of the thermal cycle initiates. In summary, Earth drives itself to evolve in terms of thermal cycles. Global cooling and warming are the two stages of many cycles during the Earth evolution. The LIPs are the extreme results of global warming, whereas glaciations are the extreme results of global cooling, with a long recovering age, the interglacial stage, between them. They come and go as thermal cycle evolves, with climate warming, being caused by the Earth itself rather than by external forces or human activities, as the most attractive prediction.

Title: Nuclear Planetology

Presenter/First Author: Goetz Roller, Kompassbau, Munich,

Presenter/First Author Email: info@kompassbau.de

Abstract Body: Earth-like planets, like free-floating planets of few Jupiter masses or ultra-cool Y dwarfs, may be regarded as the low-mass extension of the stellar population. Nuclear planetology is a new research field, which aims at constraining the evolution of such ultra-substellar objects in the light of nuclear astrophysics and particle physics. For example, based upon findings from ^{187}Re-^{187}Os nuclear geochronometry [1-2], it is argued that the Earth's core contains Re-Os isotopic signatures of at least two rapid (r) neutron-capture process events: The 13.78 Ga old component, represented by the signature of a komatiitic basalt [5085 BasKom] [3] from the BGB, South Africa, is assigned to the Earth's inner core. The other signatures identified so far within pyroxenites/komatiites [2] are assigned to its outer core, due to the gravitational collapse of the old component ≈ 3.48 Ga [1]. Supporting evidence comes from recent SCP measurements showing increasing paleointensities of the Earth's magnetic field from 3.55 Ga to 3.45 Ga [4]. Hence, the following conceptual model is suggested: A gravitational core collapse ≈ 3.48 Ga would compress matter and pre-existing magnetic field lines, thus increasing field strength and magnetic pressure. The latter, together with nuclear repulsive forces, centrifugal forces and thermal expansion prevents the core from collapsing further; the bounce fractures the Achaean crust, thus initiating the transformation from stagnant lid to plate tectonics. If this conceptual model can be further constrained, it may be concluded that those planets within the habitable zone going through a gravitational core collapse with subsequent nuclear element synthesis and increasing magnetic field strength are suitable candidates for carrying life.

Title: Secular cooling and crystallization over 1Ga of partially molten Archaean felsic crust

Presenter/First Author: Olivier Vanderhaeghe, GET Géosciences Environnement Toulouse, Toulouse,

Presenter/First Author Email: olivier.vanderhaeghe@get.obs-mip.fr

Co-authors: Célia Guergouz, , , ; Cecile Fabre, University of Lorraine Nancy, Nancy Cedex, France; Stéphanie Duchene, , ,

Abstract Body: Archaean cratonic nuclei, with an average thickness of about 40 km, are dominated by gneisses exposed in the core of crustal-scale domes delineated by greenstone belts. The emplacement of komatiites implies partial melting in a mantle with a temperature 200-300°C higher than the present-day one. Similarly, the widespread occurrence of high-temperature metamorphic mineral assemblages, and of former partially molten rocks (migmatites) attest for a high geothermal gradient within the crust. The geochronological record of the oldest cratonic nuclei typically span over a billion years which is classically interpreted as reflecting a succession of continental growth/reworking events associated to lithospheric scale dynamics. In contrast, geophysical data combined with the petrological analysis of xenoliths from the subcontinental mantle suggest that the formation of a depleted relatively buoyant lithospheric mantle root allowing for the stabilization of these cratons, occurred at the early stage of the Archaean crust accretion. In this contribution, we use present-day thermal and lithologic structure of Archaean cratons to calculate its thermal evolution considering solely the effect of secular exponential decrease of HPE (^{238}U, ^{235}U, ^{232}Th, and ^{40}K) with time, and discuss the implications in terms of Archean dynamics and crustal differentiation. This modelling shows that Archaean cratonic nuclei, characterized by an initially high geothermal gradient at 4.0 Ga with a Moho temperature close to 1000°C and a thickness for the thermal lithosphere limited to 130km, remained partially molten for about a billion years after their formation, despite a potential rapid stabilization at the lithospheric scale. This result provides a new key for the understanding of the peculiar tectonic evolution of Archaean cratons marked by (i) widespread deformation characterized by crustal-scale structural domes, and (ii) protracted (polyphased?) high-temperature metamorphism and magmatism.

Title: Implications of Surface Boundary Conditions on Evolution of Mantle Thermal Structure

Presenter/First Author: Petar Glisovic, Université du Québec à Montréal, Montreal, QC

Presenter/First Author Email: pglisovic@gmail.com

Co-authors: Alessandro M Forte, University of Quebec at Montreal UQAM, Montreal, QC, Canada

Published Material: Glišović, P., and Forte, A. M., 2014. Importance of initial buoyancy field on evolution of mantle thermal structure: implications of surface boundary conditions, Geoscience Frontiers, DOI: 10.1016/j.gsf.2014.05.004

Abstract Body: It is now understood that the dynamic impact of plates plays a crucial role in the evolution of the Earth's mantle flow - organizing and modulating cold downwellings and hot upwellings. The use of a plate-like boundary condition over very long geological time intervals, however, requires consideration of which geological era were likely characterized by modern plate-tectonic activity dominated by motions of a few large plates. Differing interpretations of the geological record suggest that modern-style plate tectonics began to operate either at around 2.7 Ga or at around 1 Ga. Some evidence also suggests the possible presence of a stagnant or sluggish lid at the top of the mantle during pre-plate tectonic period. This leads us to explore the use of a rigid surface to model surface mechanical conditions during the Archean (or in terrestrial planets without plate tectonics: Mercury, Venus, Mars). To carry out this modelling we use a dissipative and compressible 3-D pseudo-spectral method for calculating mantle convection with Earth-like vigour. We find the rigid-surface boundary condition yields remarkably stable and long-lived convection patterns that are therefore dependent on the starting configuration (i.e., a long-term "mantle memory") and that the dominant wavelength of mantle flow is also sensitive to the depth variation in rheology. Models with a plate-like boundary condition demonstrate that the most stable (i.e., steady-state) pattern of downwellings is dominantly hemispherical. However, the evolution of subduction zones may be influenced by the mantle-wide flow driven by deeply-rooted and long-lived superplumes since Archean time.

Title: Mapping the Transition to the Stagnant-lid Regime in Variable Core Size Spherical Shell Convection with a Temperature-dependent Viscosity

Presenter/First Author: Joshua Martin Guerrero, University of Toronto, Toronto,

Presenter/First Author Email: joshua.guerrero@mail.utoronto.ca

Co-authors: Julian Philip Lowman, University of Toronto, Toronto, ON, Canada; Frederic Deschamps, Academia Sinica, Taipei, Taiwan; Paul J Tackley, ETH Zurich, Zurich, Switzerland

Abstract Body: Many features of the behaviour of mantle convection in the terrestrial planets are dependent on the relative sizes of the core and planet surface areas. In previous studies implementing Cartesian geometry models, convection in strongly temperature-dependent viscosity fluids was investigated for a range of viscosity contrasts and Rayleigh numbers. The viscosity contrasts give rise to convective regimes widely described as mobile-lid, transitional (or sluggish)-lid, and stagnant-lid. For systems with small core-to-planet radii ratios, f, the combinations of Rayleigh number and viscosity contrast required for stagnant-lid convection differ substantially from what is found for f values greater than 0.5. Accordingly the first challenge in modelling stagnant-lid convection with small cores is to find parameter combinations that will yield surface stagnation. In the present study, a series of isoviscous convection calculations with rigid top boundary conditions were performed, to model the steady state characteristics of stagnant-lid convection in a spherical annulus. Utilizing existing parameterizations, the mean temperatures of these calculations are then used to predict surface Rayleigh number and viscosity contrast parameters for the stagnant-lid regime as a starting point for a search for finding the parameters (surface Rayleigh number and viscosity contrast) associated with the delineation of mobile surface and stagnant-lid convection in small core planets ($f < 0.5$). Geotherms are used to distinguish between convective regimes characterized by a stagnant-lid versus mobile systems. Findings from several full 3D spherical shell calculations are compared to the 2D model results to test whether our method of determining the appropriate viscosity contrast and Rayleigh number is accurate.

Title: Ophiolite obduction in the Precambrian

Presenter/First Author: Katharina Vogt, Utrecht University, Utrecht,

Presenter/First Author Email: k.j.vogt@uu.nl

Co-authors: Kent C Condie, New Mexico Institute of Mining and Technology, Albuquerque, NM; Jonas B Ruh, Geological institute, ETHZ, Zurich, Switzerland; Taras Gerya, ETH Swiss Federal Institute of Technology Zurich, Zurich, Switzerland

Abstract Body: Ophiolites are and not recognized in the geological record before 1 Ga and only become abundant after 800 Ma. Hence, different hypothesis have been proposed to explain this major shift in plate tectonics.

In a recent study on modern subduction zones, Vogt and Gerya (2014) have proposed that serpentinized mantle may provide a mechanically weak horizon along which basal detachment of oceanic crust is feasible. It has been suggested that deformation of this serpentinized layer may lead to decoupling and separation of oceanic crust from the downgoing slab. Subsequently, the oceanic crust is broken and obducted onto continental crust.

However, conditions for subduction were different in the past. The oceanic crust has been thicker and mantle temperatures have been higher. The resulting oceanic lithosphere was, therefore, more likely to resist subduction. Thus, bending-related fractures may have been less common for water to be transmitted downwards.

In a series of experiments using a 2D petrological–thermomechanical numerical model of oceanic subduction (Gerya and Yuen, 2003) we have systematically investigated the dependence of ophiolite obduction along serpentinized fracture zones in relation to upper-mantle temperatures and oceanic-crust thickness. First results indicate that detachment of oceanic crust from the downgoing slab becomes less likely with increasing temperatures and increasing crustal thickness. The transition from a hot to a cool subduction zone after 1Ga could therefore be a major factor controlling ophiolite obduction along partially serpentinized fracture zones.

Title: Lithosphere Temperature Constraints and the Thermal Control of Lithosphere Thickness

Presenter/First Author: Roy D Hyndman, Geological Survey of Canada Sidney, Sidney, BC

Presenter/First Author Email: rhyndman@nrcan.gc.ca

Abstract Body: The lithosphere thickness, as defined by the boundary between conductive and underlying convective asthenosphere heat transport, is directly related to the thermal regime. Although local variations, thermal regimes and thicknesses are strongly bimodal; cold strong cratons (Can. Shield) with thicknesses of 200-250 km and hot weak backarcs (Cordillera) with thicknesses of about 60 km. Intermediate thicknesses appear to be transient. I first summarize the temperature constraints, and then discuss time variations in lithosphere thickness and their possible origins. Good temperature-depths require more than one estimator; the three principal are: (1) Heat flow-heat generation; upper crust radioactive heat is important; increasing temperature uncertainty with depth. (2) Mantle seismic velocity; temperature is the primary control of mantle velocity; some composition effects. (3) Upper mantle xenoliths; rocks torn off the conduit walls by kimberlites in cratons and volcanics in bacarcs that preserve insitu P-T. Continents divided into: (1) Hot backarcs like Cordillera (<50 Ma); (2) Cold cratons like Canadian Shield (thermotectonic age >500 Ma); asymptotically approach adiabatic below 200-250 km. (3) Transient conditions: Intermediate (50-500 Ma) cooling and thickening from hot backarcs following subduction termination (e.g., Appalachia); and second, rapid lithosphere thinning from cold-thick to thin-hot backarc regimes (e.g., Colorado Plateau). Some questions: Lithosphere thickness and the thermal regime are directly related, but which is the primary control? Why are craton lithospheres thick and backarcs thin? Craton upper mantles may be refractory so convection is limited to below ~200 km, but how was a special mantle formed if the lithosphere thickens with age from a formerly hot backarc? Vigorous backarc convection may result from viscosity reduction by subducted water, but how does it start? i.e., abrupt thinning of the lithosphere?

Title: Thermochemical Structure of the Hudson Bay Lithosphere, Northern Canada: Evidence from Multi-Observable Probabilistic Inversions

Presenter/First Author: Fiona Ann Darbyshire, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: darbyshire.fiona_ann@uqam.ca

Co-authors: Juan Carlos Afonso, Macquarie University, Sydney, NSW, Australia

Published Material: About 30-40% of material was presented in an article: Darbyshire et al., 2013 (EPSL). About 80% was presented as an Invited talk at Fall AGU 2014.

Abstract Body: The Paleoproterozoic Trans-Hudson Orogeny (THO) was a Himalayan-style collision at ~1.8 Ga that brought together two of the largest North American cratonic blocks. The geometry of the collision is difficult to ascertain from surface geology, as much of the structure is concealed beneath the Paleozoic Hudson Bay intracratonic basin. However, seismographs placed around the periphery of the Bay have provided a wealth of data in recent years, allowing for regional-scale studies of lithospheric structure.

We use multi-observable probabilistic inversions to investigate the thermal and compositional structure of the Hudson Bay lithosphere. A joint inversion of Rayleigh wave phase velocities, geoid anomalies, elevation and surface heatflow is performed, giving a pseudo-3D model of the upper mantle.

Broadly, the Hudson Bay lithosphere is characterised by pervasive low temperatures and a high degree of chemical depletion. The thermal lithosphere is at least 250 km thick across the entire region, and may extend to 300 km depth in the centre of the Bay. The phase-velocity data are best explained by a stratified lithosphere, in which the upper layer is highly-depleted and the lower layer shows a slightly more fertile character (though still depleted compared to the average non-cratonic lithosphere). Within the upper layer, a relatively narrow zone of lower depletion is visible across the Bay and the Hudson Strait, coinciding with the inferred location of the THO collision zone. This zone likely preserves the signature of juvenile material trapped between the cratonic cores at the end of the THO collision.

Some outstanding issues remain; in some areas beneath the cratons, there is evidence from intermediate-period phase-velocities for anomalous mid-lithospheric structure. Variations in long-period phase velocities also suggest the presence of localised thermal heterogeneities in the sublithospheric mantle and transition zone beneath the region.

Title: Lithosphere Structure of Canada: Constraints From Ambient Seismic Noise Tomography

Presenter/First Author: Claire A Currie, University of Alberta, Edmonton, AB

Presenter/First Author Email: claire.currie@ualberta.ca

Co-authors: Honn Kao, Geological Survey Canada, North Saanich, BC, Canada; Roy D Hyndman, Geological Survey of Canada Sidney, Sidney, BC, Canada

Abstract Body: The continental lithosphere of Canada contains a record of the events that have shaped its formation and evolution over the last 4 Gyr. In this study, we provide an updated assessment of the crust and uppermost mantle structure of Canada using shear wave velocities (Vs) from a recent continental-scale ambient noise tomography model (Kao et al., J. Geophys. Res., v. 118, p. 5865-5887, 2013). The model is derived from Rayleigh waves recorded from 2003 to 2009 at 788 seismic stations throughout Canada and adjacent regions. The more uniform data coverage and higher frequency content of ambient noise provides better resolution of crustal structure than images based on earthquake waveforms. The ambient noise tomography model shows both regional and local spatial variations in Vs, with generally high crustal and mantle velocities in the Canadian Shield and lower velocities in surrounding areas, especially in the Cordillera. In many areas, the Moho is characterized by a velocity increase over ~2 km depth, but in some places (e.g., the southern Western Canada Sedimentary Basin, WCSB), a 6-8 km thick velocity gradation is observed, suggesting that this may be a zone of mixing between crustal and mantle

rocks or an area where the lowermost crust is partially eclogitized. Moho depth varies between 30 and 55 km, with the thinnest crust below the Cordillera and thickest crust below the southern WCSB. Within the Canadian Shield and Cordillera, the Moho depth exhibits significant relief over 100-500 km spatial scales, which is not reflected in the surface topography. Such Moho relief may be compensated by lateral variations in crust/mantle density structure. We are currently inverting the Vs model for lithosphere thermal and density structure to examine the implications for lithosphere composition, strength and surface topography.

Title: Temporal Evolution of the Lithosphere-Asthenosphere Boundary and its Effect on the “Diamond-Window” in the Western Superior Craton

Presenter/First Author: Karen Smit, Gemological Institute of America, New York, NY

Presenter/First Author Email: ksmit@gia.edu

Co-authors: Graham D Pearson, University of Alberta, Edmonton, AB, Canada; Thomas Stachel, University of Alberta, Edmonton, AB, Canada; Michael Seller, , ,

Published Material: Findings in the abstract have been accepted as part of two scientific papers: in Journal of Petrology (2014: 55, 9, 1829-1863) and Contributions to Mineralogy and Petrology (2014: 167, 962).

Abstract Body: The Attawapiskat area of the Superior craton provides the ideal opportunity to evaluate the thermal and compositional effects of a rifting event on the cratonic lithospheric mantle. Rather than being a stable entity since Archaean craton amalgamation (2.7 Ga), the lithospheric keel records evidence for significant thinning, melt impingement and diamond destruction, all related to the impact of the Midcontinent Rift.

Kimberlites in the Attawapiskat area of the western Superior sample the lithospheric mantle at two time periods, i) during the Mesoproterozoic, concurrent to the 1.1 Ga Midcontinent Rift and ii) during the Jurassic.

Thermobarometry studies of peridotite xenoliths and xenocrysts from the two kimberlitic age groups reveal a temporal evolution of the lithospheric mantle beneath Attawapiskat. The Palaeoarchaean lithospheric keel was thinned to less than 180 km at the time of Midcontinent rifting. The rifting resulted in higher heat flow into the base of the lithosphere and appears to have caused diamonds residing in the deep lithosphere to be destroyed.

Small-degree rift-related melts infiltrated and refertilised the lithospheric mantle as evidenced by (1.) enrichment of incompatible trace elements in clinopyroxene, (2.) the generation of Mesoproterozoic Re depletion (T_{RD}) ages, and (3.) decreased Mg# in olivine (89 – 91).

After the thermal and igneous effects of the Midcontinent Rift subsided, the lithospheric root cooled and thickened, such that xenoliths erupted in Jurassic kimberlites define P-T arrays close to ‘typical’ cratonic geotherms - that correspond to crustal heat flow of ~ 40 mW/m^2. This thermal thickening of the lithospheric mantle led to the lithosphere-asthenosphere boundary being extended to depths of 200 km. This new stable, cooler and thickened cratonic root provided the optimum conditions for post-Midcontinent Rift diamond formation at Attawapiskat.

Title: Electrical Resistivity Structure of the Proterozoic Grenville Province Lithosphere

Presenter: Ian J Ferguson, University of Manitoba, Winnipeg, MB

Presenter Email: ij_ferguson@umanitoba.ca

First Author: Ademola Quadri Adetunji, University of Manitoba, Winnipeg,

First Author Email: Ademola.Adetunji@umanitoba.ca

First Author Student?: No

Co-authors: Alan G. Jones, Dublin Institute for Advanced Studies, Dublin, Ireland

Published Material: This work forms part of a PhD thesis and a manuscript based on this presentation is still under review with Geophysical Journal International.

Abstract Body: The large-scale lithospheric resistivity images structure of the Proterozoic Grenville Province and its margin with the Archean Superior Province in southern Ontario is investigated with 84 MT sites, distributed across southern Ontario. Dimensionality analysis indicates dominantly 2-D resistivity structure below the Grenville Front and northwestern Grenville Province, with more significant 3-D responses to the southeast. It allows the division of the lithosphere into upper (45-150 km) and deeper (>200 km) mantle layers with regional strike azimuths of N85^{o}E (±5^o) and N65^{o}E (±5^o) respectively. The entire Grenville Province in southern Ontario is characterized by large-scale, laterally extensive, resistive lithosphere. The top of this feature is at about 45 km depth and the geometry of its base shows that the true thickness of the lithosphere in this region is about 280 km. This resistivity anomaly extends for about 300 km southeast of the GF from the exposed Superior Province and along strike for at least 800 km. This feature is interpreted to be Superior Province lithosphere and the corresponding N85^{o}E geoelectric strike to be associated with the fabric of the Superior Province. This Archean lithospheric root provided the stable basement for the Grenville orogen. A large region of enhanced conductivity in the lower lithosphere is attributed to the refertilization of the mantle lithosphere by fluids associated with the Cretaceous kimberlite magmatism. The results provide evidence for refertilization of a large volume of the lower mantle lithosphere by the passage of fluids. The enhanced conductivity is interpreted to be associated with the presence of water in nominally anhydrous minerals. A water content of 50 wt ppm was estimated based on average crustal heat flow, average resistivity at 180 km depth and temperature of 1220^{o}C. It is hypothesized that the strike direction measured in the deeper mantle of the study area was established in the Cretaceous and potentially records the plate motion at that time.

Title: The role of the temperature and stress fields for evolution of asthenospheric layers

Presenter/First Author: Leszek Czechowski, University of Warsaw, Warszawa,

Presenter/First Author Email: lczech@op.pl

Co-authors: Marek Grad, University of Warsaw, Warsaw, Poland

Published Material: Parts of results were presented in EGU 2014. No part is presently under review. Na part was recently accepted by a scientific journal

Abstract Body: The boundary between the lithosphere and the asthenosphere (LAB) is usually defined by a difference in response to stress. The reology of rocks depends on many factors but the basic differences of lithosphere and asthenosphere properties could be explained as a result of the temperature and pressure. The effective viscosity is proportional to C exp(A *q*), where *q* is the ratio (melting temperature/temperature), C and A are positive constants. The mantle is not molten, so *q*>1. In asthenosphere *q* is close to 1 and effective viscosity is low (e.g. 10^{18} Pa s).

In upper part of lithosphere *q* is high, but the temperature gradient in the lithosphere is high. Below the lithosphere, the gradient is low and the melting temperature is increasing with depth faster than true temperature. Hence, *q* and the viscosity reach minimum value below LAB and are increasing with depth. It is a typical situation..

Another important factor determining rheological properties is a stress tensor T. Generally viscosity is proportional to the power of the invariant of the stress tensor: I(T)^(1-n) where n is probably in the range from 3 to 5.

We investigate the processes of formation and evolution of low viscosity layers ("asthenospheric layers") in the upper mantle. The time scale of the temperature changes is of the order of 10 Myr. The characteristic time of stress changes could be much shorter depending on tectonic processes. Eventually processes of formation and vanishing of low viscosity layers is very dynamical. In a relatively short time (below 1 Myr) the pattern the viscosity distribution and velocity gradient could change substantially.

Using results from deep seismic sounding and surface wave tomography we have found that below some regions there are structures in the mantle that could be a forming/vanishing low viscosity layers. Reflectors in the lower lithosphere are observed beneath Trans-European Suture Zone between Precambrian and Palaeozoic platforms. In a thick Baltic shield lithosphere (200 km or more) low velocity zones and seismic reflectors are observed in the depth range 60-100 km, which could be interpreted as mechanical low Vp velocity zones, in contrast to thermal velocity zone in deeper asthenosphere.

Title: On the History and Integrity of the Cratonic Lithosphere in Western Canada

Presenter/First Author: Yu Jeffrey Gu, University of Alberta, Edmonton, AB

Presenter/First Author Email: ygu@ualberta.ca

Co-authors: Yunfeng Chen, University of Alberta, Edmonton, AB, Canada; Shu-Huei Hung, NTU National Taiwan University, Taipei, Taiwan

Abstract Body: The crystalline basement beneath the Western Canada Sedimentary Basin (WCSB) exemplifies a complex tectonic assembly of welded lithospheric fragments during the Paleoproterozoic era. Earlier studies have suggested extensive subduction, magmatism and accretion, especially along the boundaries of major tectonic blocks such as the Hearne and Rae provinces, Wabamun domain, Medicine Hat Block (MHB) and Trans-Hudson orogen. The existence and the state of the lithosphere beneath southern WCSB remain largely speculative, however, due to the thick Phanerozoic sedimentary cover and relatively few regional broadband seismic stations prior to 2006. In this study we combine teleseismic travel time data from the USArray, the Canadian National Seismographic Network (CNSN) and a recently established Canadian Rockies and Alberta Network (CRANE) to invert for a new P-wave velocity model of the mantle lithosphere beneath the craton-Cordillera transition region. We adopt finite-frequency kernels during the inversions to account for 3D finite-volume sensitivity to model and improve data coverage surrounding the geometrical ray paths. The P wave velocity decreases by more than 1 percent from Alberta Basin to the foothills of the Rocky Mountains at lithospheric depths, which suggests a sharp mantle gradient along the Cordillera deformation front. The stable cratonic lithosphere appears to extend down to a maximum depth of ~180 km beneath the Archean Loverna Block ---- the core of the Hearne craton. High mantle velocities are further observed beneath the controversial Medicine Hat Block (MHB) in southern Alberta. The complex shape of the lithospheric root beneath the MHB could be an indication of considerable erosion. Distinct high velocity anomalies beneath the Loverna Block and MHB, which are separated by lower crustal and average mantle velocities beneath the Vulcan structure (VS), suggest different Archean formation and collision histories between these two tectonic regimes. Overall, the mantle lithosphere beneath the craton-Cordillera transition region in southwestern Canada appears to be relatively intact down to 120-150 km depths.

Title: Pockets, conduits, channels, and plumes: structures beneath and within the continental lithosphere beneath western Mediterranean

Presenter/First Author: Meghan Samantha Miller, University of Southern California, Los Angeles, CA

Presenter/First Author Email: msmiller@usc.edu

Co-authors: Daoyuan Sun, University of Science and Technology of China, Hefei, China; Leland O'Driscoll, University of Southern California, Los Angeles, CA; Thorsten W Becker, University of Southern California, Los Angeles, CA; Adam Holt, University of Southern California, Los Angeles, CA; Jordi Diaz Cusi, ICTJA-CSIC, Barcelona, Spain; Christine Thomas, University of Münster, Münster, Germany

Abstract Body: Detailed upper mantle and lithospheric structure from the Canary Islands to Iberia have been imaged with data from recent temporary deployments and select permanent stations from over 300 broadband seismometers. The stations extended across Morocco and Spain as part of the PICASSO, IberArray, and Morocco-Münster experiments. We present results from S receiver functions (SRF), shear wave splitting, waveform modeling, and geodynamic models that help constrain the tectonic evolution of the westernmost Mediterranean, including orogenesis of the Atlas Mountains and occurrence of localized alkaline volcanism. Our receiver function images, in agreement with previous geophysical modeling, show that the lithosphere is thin (~65 km) beneath the Atlas, but thickens (~100 km) over a very short length scale at the flanks of the mountains. We find that these dramatic changes in lithospheric thickness also correspond to dramatic decreases in delay times inferred from S and SKS splitting observations of seismic anisotropy. Pockets and conduits of low seismic velocity material below the lithosphere extend along much of the Atlas to Southern Spain and correlate with the locations of Pliocene-Quaternary magmatism. Waveform analysis from the USC linear seismic array across the Atlas Mountains constrains the position, shape, and physical characteristics of one localized, low velocity conduit that extends from the uppermost mantle (~200 km depth) through the lithosphere up to the volcanoes in the Middle Atlas. The shape, position and temperature of these seismically imaged low velocity anomalies, topography of the base of the lithosphere, morphology of the subducted slab beneath the Alboran Sea, position of the West African Craton and correlation with mantle flow inferred from shear wave splitting suggest that the unusually high topography of the Atlas Mountains and isolated recent volcanics are due to active mantle

support that may be from material channeled from the Canary Island plume.

Title: Deformation within continental plates: Surface deflection and magmatism induced by lithosphere removal

Presenter/First Author: Huilin Wang, University of Alberta, Edmonton, AB

Presenter/First Author Email: huilin1@ualberta.ca

Co-authors: Claire A Currie, University of Alberta, Edmonton, AB, Canada

Abstract Body: Many localized pulses of deformation have been found in the interior of continental plates, and in some cases, these can not be readily linked to regional tectonics. Further, beneath many regions, the lithosphere is found to be abnormally thin, and there is evidence for detached lithosphere material located at 100-200 km depth. One hypothesis is that the lower lithosphere has been gravitationally removed and been replaced by upwelling asthenosphere. This sudden removal abruptly changes the stress and temperature field in crust and mantle, which may generate localized transient basins/orogens and pulses of volcanism. Thus, studying this surficial evidence provides a window to investigate the deep mantle dynamics. 2D thermal-mechanical numerical models are used to explore the surface deflection and magmatism induced by gravitational lithosphere removal. We find that topography and magmatism are primarily controlled by lithosphere structure. In hot lithosphere (e.g., a back arc), the lithosphere is removed through small wavelength (<50 km) instabilities. Magmas can be generated through conductive heated of sinking lithosphere and through decompression melting of upwelling asthenosphere. Lithosphere destabilitization causes thickening of warm and weak crust, producing in isostatic uplift. The resulting surface topography either has small subsidence (<0.5 km) or generate a topographic high during the removal. In warm lithosphere (e.g., average Phanerozoic lithosphere), lithosphere foundering occurs on longer wavelengths (50-100 km). In this case, the only melts are from asthenosphere. The surface subsides, followed by a partial uplift as the instability detaches. In cold lithosphere (e.g., craton), the lithosphere removal has the longest wavelength (>100 km), and the surface can subside >1 km; however, no magmas are generated. In most models, lithosphere removal and the associated surface deflection and magmatism occur on time scales of a few Myr. After this, stress relaxation and surface cooling erase these expressions. Observational data from a number of regions (e.g., Sierra Nevada in California, Tibet in China, Puna plateau in the central Andes) are consistent with our models, suggesting that pulses of deformation and magmatism in these areas are related to local lithosphere removal.

Title: Plate Tectonics Beyond Plate Boundaries: The Role of Ancient Structures in Continental Lithosphere on Intraplate Orogenesis

Presenter/First Author: Philip J Heron, University of Toronto, Toronto, ON

Presenter/First Author Email: pjheron@physics.utoronto.ca

Co-authors: Russell N Pysklywec, University of Toronto, Toronto, ON, Canada; Randell Stephenson, University of Aberdeen, Aberdeen, United Kingdom

Abstract Body: The development of orogens that occur at a distance from plate boundaries (i.e., 'intraplate' deformation) infers a more complex argument for lithospheric and mantle interaction than the conventional plate tectonic theory allows. One hypothesis is the amalgamation of continental micro-plates leaves inherent scars on the crust and mantle lithosphere. Previous studies into continent-continent collisions identify a number of scenarios from accretionary tectonics that affect the crust and mantle (namely, the development of a Rayleigh-Taylor instability, lithospheric underplating, lithospheric delamination, and lithospheric subduction). Any of these processes may weaken the lithosphere allowing episodic reactivation of faults within continental interiors. Hence, continental convergence at a time after continental collision may cause the already weakened crust and mantle lithosphere to produce intraplate deformation. In order to better understand tectonic processes away from plate boundaries, we present suites of numerical models to identify the preferred style of deformation during continental shortening. Ancient structures are modeled by applying weak subduction scarring, changing the rheological conditions, and modifying the thermal structure within the lithosphere. The effect of climate-driven erosion and deposition on the tectonic structure of intraplate deformation is also addressed. We explore the relevance of the models to previously studied regions of intraplate orogenesis (including the Pyrenees in Europe, the Laramide and Eurekan orogenies in North America, Tien Shan orogen in Central Asia, and Central Australia). Our findings indicate that there exists a number of tectonic environments that can be produced relating to continental accretion, and that specific observational constraints to the local area (e.g., geological, geophysical, geodetic) are required to be integrated directly into the analyses for better interpretation. The models show that although rheological changes to the lithosphere can produce a range of deformation during continental convergence (i.e., crustal thickening, thinning, and folding), mantle weak zones from ancient subduction can generate more localized deformation and topography.

Title: Lithospheric and Upper Mantle Stratifications Beneath Colombia: Using Receiver Functions from S Waves.

Presenter/First Author: Jose Faustino Blanco Chia, National University of Colombia, Bogota,

Presenter/First Author Email: jfblancoc@unal.edu.co

Co-authors: Carlos Alberto Vargas Jiménez, Universidad Nacional de Colombia, Bogotá D.C., Bogotá D.C., Colombia

Abstract Body: The knowledge of the structure of the lithosphere is an important parameter to understand the evolution of the Earth and plate tectonics behavior. Seismic recordings of RSNC*/IRIS** stations are processed with S receiver function (SRF) technique to determinate the asthenosphere lithosphere boundary (LAB). The technique uses distant seismic events, 65° to 85° from the station, to detect the S wave and its Sp wave conversion at broadband-three component stations. To isolate the recorded phase is necessary to apply a rotation process to the components; this process takes the ZNE into the ZRT components through the back azimuth of the event, and then is necessary an extra rotation through the incident angle to obtain the LQT components. The L-component is almost free of the transverse energy from the S-wave and it is de-convolved from the Q-component to obtain the SRF. Once the FRS are gotten for all the events, it is performed a migration and move out correction to be able to stack the FRS. According to the distribution of the seismological stations, the structure of the lithosphere obtained is expected to be highly inhomogeneous; in fact the LAB depends on the azimuthal orientation. The results show that the LAB in Colombia is found between 90 and 120 km, the shallower is found under the stations located at the Caribbean Ocean and the subduction zone, whilst the deeper are on the continent. Also for each FRS appears two lobes in the records, showing two different structures that could be the Moho and the Conrad discontinuities.

Title: India's Fast Mesozoic Drift Linked to Continental Mantle Lithosphere Delamination: New Insights From (U-Th)/He Thermochronology of Dharwar Craton Kimberlites

Presenter/First Author: Sebastian Tappe, University of the Witwatersrand, Johannesburg,

Presenter/First Author Email: sebastian.tappe@debeersgroup.com

Co-authors: Manoko Marokane, , , ; Jaclyn S Baughman, University of Colorado at Boulder, Boulder, CO; Rebecca Marie Flowers, Univ of Colorado, Boulder, Boulder, CO; Katie A Smart, , , ; Bruce M Eglington, University of Saskatchewan, Saskatoon, Canada; Sojen Joy, , ,

Abstract Body: Periods of significant continental uplift and erosion are believed to be caused by processes that operate within Earth's mantle. Among these processes are strong thermochemical upwelling and convective erosion of mantle lithosphere. Peninsular India is comprised of a collage of Archean cratonic blocks bounded by Proterozoic mobile belts. The basement blocks are overlain by remnants of thick sedimentary successions of Proterozoic basins ranging from 1.9 to possibly 0.7 Ga. Basin formation was accompanied by pronounced kimberlite magmatic activity across Peninsular India between 1.4-1.0 Ga. However, the tectonic setting of the Proterozoic basins and associated kimberlites remains poorly understood. In particular, the relationship to the coeval mobile belts, for which subduction processes have been invoked, is enigmatic. We are studying the (U-Th)/He systematics of a variety of kimberlite-derived minerals from across the Dharwar craton in an attempt to understand the burial and unroofing history of these small diamond-bearing magmatic bodies. Whereas previous studies suggested that basin inversion occurred during the Late Proterozoic, our novel perovskite (U-Th)/He thermochronology results suggest that the Dharwar craton crust was affected by nearby tectonothermal events during the Early Paleozoic assembly of Gondwana. Our apatite (U-Th)/He results indicate that diatreme root-zones of the once-buried 1.1 Ga Dharwar craton kimberlites were unroofed to within ~1 km of the Earth's surface during the Mesozoic, most likely during the Early Cretaceous. This timing corresponds to the break-up of Gondwana after which the Indian plate drifted for several hundred kilometers with record speed toward its current position. India's fast drift during the Mesozoic has been explained by significant plume-related delamination of its cratonic mantle lithosphere, which also appears to be the root-cause for km-scale uplift and erosion across Peninsular India during the Mesozoic.

Title: Hydraulic Fracture Growth Geometries in Unconventional Reservoirs: Closing Gaps among Perceptions, Predictions, and Reality

Presenter/First Author: Andrew Bunger, , ,

Presenter/First Author Email: bunger@pitt.edu

Abstract Body: One of the challenges to informing the current discussion on the economic and environmental sustainability of the process of extracting hydrocarbons from unconventional reservoirs is the preponderance of gaps among our perceptions, model predictions, and the real geometries of hydraulic fractures. The basic problem starts with the fact that real geometries are never fully observed at reservoir scale. However, a synthesis of mapping data from mine-through experiments, monitored field experiments, natural and laboratory analogues, and coupled models that account for the role of the pre-existing fracture network on hydraulic fracture growth do provide an emerging picture, albeit still far from complete, of the basic drivers that lead to complex, network-like hydraulic fracture geometries in some cases but not in others. A similar synthesis is able to give at least a rudimentary understanding of conditions in which hydraulic fractures are expected to be well-contained within the targeted reservoir layer. Furthermore, there is a growing, yet far from complete, understanding of the dynamics that determine whether the idealized uniform division of injected fluid among multiple possible entry points can be achieved. But in spite of what is understood, or at least thought to be understood, about the drivers of various hydraulic fracture geometries, idealized and/or artistically-rendered sketches dominate the images of hydraulic fracture geometry that underpin not only the current public and technical discussions, but in many cases also the fracture geometries that are used as inputs to reservoir simulators upon which well design and production decisions hinge. This talk will synthesize data with modeling results with the aim of bringing closer alignment between the perceived and actual growth geometries achieved in hydraulic fracturing stimulations of unconventional reservoirs.

Title: AN OVERVIEW OF INDUCED SEISMICITY IN NORTHEAST BRITISH COLUMBIA: REGULATOR RESPONSE AND LESSONS LEARNED

Presenter/First Author: Dan Walker, British Columbia Oil and Gas Commission, Victoria, BC

Presenter/First Author Email: Dan.Walker@bcogc.ca

Co-authors: Jeff Johnson, British Columbia Oil and Gas Commission, Victoria, BC, Canada

Published Material: Some of this presentation has appeared in the British Columbia Oil & Gas Commission's December, 2014 report 'Investigation of Observed Seismicity in the Montney Trend'. Parts of this report were picked up by the media.None of this presentation has been submitted for publication to scientific journals.

Abstract Body: Since 1985, northeast British Columbia has experienced induced seismicity triggered by waterflood injection, waste water disposal and fluid injection during hydraulic fracturing. In December, 2014, the British Columbia Oil & Gas Commission (Commission) published its 'Investigation of Observed Seismicity in the Montney Trend'. This report summarizes induced events recorded since August 2013 and covers seven areas in northeast British Columbia currently being monitored for induced events. Two of these areas have clusters triggered by waste water disposal in the Mississippian Debolt zone. The other five areas, all within the Triassic, Montney shale gas trend, have event clusters triggered by fluid injection during hydraulic fracturing. The Commission's response to induced events has varied with the causal mechanism. Eagle waterflood induced events were successfully mitigated when the operator reduced injection rates. For the two waste water disposal wells currently triggering events in northeast British Columbia, the Commission is working with operators to reduce injection rates and find alternative disposal zones and locations. Hydraulic fracturing induced events present a unique mitigation problem. Injection pressure is much greater than at disposal wells and flowback is not practical until the well is put on production. Responding immediately to hydraulic fracture induced events is limited to avoiding known active faults, altering hydraulic fracture parameters or suspending operations. From a regulatory perspective, lessons learned since 1985 would include the following: 1) Sufficient regional and localized seismograph monitoring must be in place to characterize the events 2) Effective event reporting and mitigation strategies should be formalized and implemented. 3) The seismic history for operational areas should be

reviewed and the seismicity risk assessed 4) Procedures should be in place for the collection, sharing and release of seismological data 5) Research partnerships should be set up and supported to study the relationship between the operations and seismicity 6) Areas considered to be high risk for induced seismicity should be considered for exclusion from development.

Title: Shale Gas and Tight Oil Potential in Eastern Canada: Some Numbers and What Lay Behind Them

Presenter/First Author: Stephan Sejourne, Organization Not Listed, Montreal,

Presenter/First Author Email: ssejourne.geo@gmail.com

Abstract Body: Unconventional reservoirs with variable potential for shale gas or tight oil have been identified in most provinces of eastern Canada. The resources are hosted primarily in onshore Late Cambrian to Early Carboniferous rocks although some speculative offshore potential also exists.

Where resource estimates have been proposed the numbers are invariably large, but in the absence of production history this potential is always qualified as an undiscovered, initially-in-place resource rather than a discovered reserve. While these estimates are based on strict geological, petrophysical and geophysical criteria, considerable uncertainties remain due to the scarcity of data and their possible lack of representativeness as it is often the case in initial stages of exploration. Beyond the initial resource assessments, key prospectivity drivers include the recovery rates, the geographical and regulatory constraints, the energy market and the political and social stability. Of course none of these parameters should be considered constant through time.

Overall, the current understanding of the shale gas and tight oil potential in eastern Canada is a necessary step forward but must be considered as a preliminary, semi-quantitative appraisal and should not bear an excessive weight in the debate over the pros and cons of a possible development of these unconventional resources. Regional, provincial-scale estimates convey the misleading impression that an entire basin will be ultimately covered with drill-holes while in practice only a few specific areas will prove to be worth developing in the long-term. Other – indirect – potentials are also part of the equation and have the benefit to strengthen the overall competitiveness of the provincial economies.

Title: Assessment of Potential Impacts of Shale Gas Development on Shallow Aquifers in the St. Lawrence Lowlands, Quebec, Canada

Presenter/First Author: Christine Rivard, Natural Resources Canada, , ON

Presenter/First Author Email: crivard@nrcan.gc.ca

Published Material: Preliminary data have been presented in other conferences.

Abstract Body: The Upper Ordovician Utica Shale in the St. Lawrence Lowlands has a shale gas production potential, which was assessed by the industry between 2007 and 2010, until a *de facto* moratorium was imposed on shale gas exploration in Quebec. A total of 29 wells were drilled in this shale, of which 18 were subjected to hydraulic fracturing. Due to this limited number of wells, the Utica Shale is considered a frontier play and, therefore, the St. Lawrence Lowlands are viewed as a “virgin” area with regards to fracking. The Geological Survey of Canada initiated a project in 2012 in the St-Edouard area, 65 km south-west of Quebec City, to investigate whether this region is geologically at risk before drilling and fracking activities resume. This area was selected because the Talisman St-Édouard well is the most promising one drilled in the Utica Shale and it is also located in a region where several faults are present. Multi- source data are being used for this study and extensive fieldwork has been carried out, including sampling of groundwater, soil, core and drill cuttings, shallow seismic surveys (~800 m), borehole geophysics in shallow wells (30 to 150 m deep) and hydraulic tests in sediments and bedrock. Furthermore, geomechanical lab tests and chemical lab analyses, as well as interpretation of acoustic logs and deep seismic profiles are being done.

The anticipated outcomes of this work are two-fold. First, this work will provide a better understanding of potential impacts of shale gas development on shallow aquifers through the identification of possible natural connections between deep and shallow geologic formations. Second, the development of a methodology for the estimation of aquifer vulnerability relative to activities occurring at depth will be initiated based on this work. This methodology could serve as a basis for permit allocation and regulations to insure that needed studies are being conducted by the industry along with exploration activities.

Title: Induced seismicity from hydraulic fracturing and large volume wastewater injection: Revising the assessment criteria using results from recent swarms

Presenter/First Author: Katie M Keranen, Cornell University, Ithaca, NY

Presenter/First Author Email: keranen@cornell.edu

Co-authors: Cliff Frohlich, Univ Texas, Austin, TX

Published Material: This presentation summarizes results of recent published studies in a number of journals, and discusses the need for revised criteria for induced seismicity.

Abstract Body: The United States midcontinent has experienced a dramatic increase in seismicity over the past seven years, led by Oklahoma, and accompanied by unusual earthquakes in England and Canada. During this time frame, the new technologies (and the expanded use of existing technologies) used to increase hydrocarbon production have significantly increased the fluid volume injected into the subsurface both for hydraulic fracturing and for wastewater disposal. Studies of these recent earthquake sequences have increased our understanding of fluid triggering. Rare cases also motivate modification of the commonly used criteria (Davis and Frohlich, 1993) for induced seismicity, specifically in the expectations for temporal and spatial correlations between injection rates, well locations, and seismicity. Recent potentially-triggered swarms have grown to cover hundreds of square kilometers: In the well-documented case of seismic triggering in the Paradox Valley region of Colorado, earthquakes occur up to 16 km from injection wells (King et al., 2014). Similarly, hydrogeologic models for central Oklahoma indicate that the region affected by increased pore fluid pressure (sufficiently high to trigger earthquakes) likely extends tens of kilometers from disposal wells (Keranen et al., 2014). Earthquakes in both cases have migrated and continued over 24 and 7 years, respectively. These swarms deviate substantially from existing criteria, though the majority of other cases of apparently triggered earthquakes near disposal wells and hydraulic fracturing operations are more closely aligned. Rapid, near-well seismic responses near hydraulic fracturing operations (e.g., Skoumal et al., 2014; Holland et al., 2012) imply high

hydraulic connectivity between the fault zone and injection wells. In contrast, sustained fluid injection at disposal wells, without accompanying fluid extraction, can create a migrating zone of perturbed fluid pressure capable of either activating seismogenic faults near the well on similarly short time frames, or at greater distances over years. Though challenging to compose criteria to encompass both scenarios, modifying to include long-term effects and net volume changes will aid regulators and be relevant for seismicity in regions of production, gas storage, and carbon sequestration.

Title: The new Science Plan of ICDP: Achievements and Challenges in Continental Scientific Drilling

Presenter/First Author: Uli Harms, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam,

Presenter/First Author Email: ulrich.harms@gfz-potsdam.de

Abstract Body: Understanding the complex System Earth is despite great progress in deep geophysical sounding and modeling advances depending on samples and observations at depth. The rocks and fluids of our ever-changing planet contain matter, heat, energy, and life as well as archived records of what has gone before. These precious relicts and living systems need to be probed and monitored in situ and need to be collected and analyzed. The scientific results obtained by scientific drilling cover the spectrum of the earth sciences from climate change, natural hazards and earth resources to the origins and evolution of life on Earth. The need to drill has never been greater and requires addressing the needs of our growing population for energy, sustenance, and quality of life.

The International Continental Scientific Drilling Program, ICDP addresses these questions in terrestrial environments. It is an infrastructure for scientific drilling that facilitates outstanding science at globally important sites bringing together scientists and stakeholders from 24 nations. The new science plan for the ICDP addresses five scientific key topics including: Active Faulting and Earthquakes, Global Geodynamics, Global Cycles Effecting Climate And Environmental Change, Heat And Mass Transport, The Ubiquitous Hidden Biosphere, and Cataclysmic Events. Each of these themes is tackled with respect to socioeconomic relevance, past achievements are described and fundamental open issues, future scientific targets and recommendations are presented. Potential future science goals include man-made earthquakes, borehole observatories in active environments, drivers, feedback and tipping points of Earth climate, deep time studies of global cycles, harvesting magmatic geothermal heat at shallow depth, deep hard-rock and geothermal microbiology, basin-size impact craters. In addition, ICDP is planning to cooperate closely with other programs to open new joint targets such as land-sea drilling transects.

Title: Scientific Achievements of the Integrated Ocean Drilling Program (2003-2013) and International Ocean Discovery Program (2013-present)

Presenter/First Author: Keir Becker, Univ Miami - RSMAS, Miami, FL

Presenter/First Author Email: kbecker@rsmas.miami.edu

Published Material: Overview of results of first IODP in chapter by presenter in late 2013 Elsevier Book on IODP highlights, book title "Earth and Life Processes Discovered from Subseafloor Environments: A Decade of Science Achieved by the Integrated Ocean Drilling Program (IODP)", editors R. Stein, D. Blackman, F. Inagaki, and H.-C. Larsen

Abstract Body: This talk will present an overview of scientific and programmatic highlights of the Integrated Ocean Drilling Program (IODP, 2003-2013) and initial results from the first two years of the follow-on Integrated Ocean Discovery Program (also IODP). Results from the first IODP will be summarized with respect to the three main themes and eight initiatives of the IODP Initial Science Plan (ISP) “Earth, Oceans and Life.” The first IODP made significant contributions in the ISP objectives related to past greenhouse climates, rapid climate change and sea level history in the current icehouse world, subseafloor hydrogeology and biosphere, subduction zone seismogenesis, and accretion of oceanic crust formed at slow and fast spreading rates. The Science Plan for the second IODP, “Illuminating Earth’s Past, Present, and Future,” builds on the ISP to define four main themes with thirteen important scientific challenges to be addressed over the ten-year period 2013-2023. It is still early in that period, but proposal pressure is already strong across these themes and challenges. Expeditions early in the second IODP have made or will make a strong start at addressing two specific challenges: the role of subduction zones in generating continental crust and the control of regional precipitation exemplified by the Indian Ocean monsoon system. In addition, the new IODP is cooperating closely with ICDP to define a coordinated approach to “amphibious” drilling projects that require both at-sea and on-land drilling to be fully addressed.

Title: Integrating IODP-ICDP Drilling On The Mid-Atlantic U.S. Margin With Deep Sea Isotopic Records: Tectonics Or Eustasy?

Presenter/First Author: Kenneth G Miller, Rutgers University, Piscataway, NJ

Presenter/First Author Email: kgm@rci.rutgers.edu

Co-authors: Gregory S Mountain, Rutgers Univ, Piscataway, NJ; Michelle A Kominz, Western Michigan Univ, Kalamazoo, MI; James V Browning, Rutgers University, Piscataway, NJ; James D Wright, Rutgers University, Piscataway, NJ; Robert E Kopp, Rutgers University New Brunswick, New Brunswick, NJ

Abstract Body: Drilling on the mid-Atlantic U.S. “passive” continental margin (New Jersey to Virginia) by ocean (DSDP/ODP/IODP Legs 150, 174A, & Exp. 313) and continental scientific drilling (Legs 150X, 174AX, and the Chesapeake Bay Impact Structure; funding by ICDP, NSF-EAR, NSF-OCE, the USGS, and various state surveys) has provided unprecedented recovery of Upper Cretaceous to Holocene sequences. Ocean drilling has provided a global array of deep sea coreholes allowing application of the $d^{18}O$ and Mg/Ca proxies for ice volume. Together, margin and deep sea cores allow two approaches for estimating sea-level changes:

1) backstripping of coreholes from the onshore coastal plain and continental shelf, progressively accounting for the effects of compaction, loading, and thermal subsidence; and 2) scaling deep-sea $d^{18}O$ records using Mg/Ca to remove temperature effects. Comparison of the two methods addresses the long-standing debate about the roles of global average sea-level change (eustasy) and tectonism on the stratigraphic record. Our scaled-isotopic and onshore backstripped sea-level estimates changes are remarkably similar on the Myr scale for the past 34 Myr and testify to the importance of glacioeustasy. The dominant beat in the icehouse world of the past 34 Myr is the 1.2 Myr tilt cycle; forcing for the greenhouse world of the Cretaceous-Eocene appears to be the 2.4 Myr eccentricity cycle. However, there are differences between the onshore and offshore and between New Jersey, Delaware, and Virginia on the 1+ Myr scale that we attribute to the influence of mantle dynamics, including effects of the subducting Farallon slab. The amplitudes of the offsets are

consistent with models of mantle dynamic topography that predict observed differences. Such changes in continental elevation explain the patchwork preservation of sequences and regional differences on this passive-aggressive margin; they also complicate estimates of the absolute position of globally averaged sea level, though glacioeustatic changes are well-constrained (better than ±10 m).

Title: IODP-ICDP Expedition 364: Drilling Chicxulub, the K-Pg impact structure.

Presenter/First Author: Richard A F Grieve, Natural Resources Canada, Ottawa, ON

Presenter/First Author Email: rgrieve@nrcan.gc.ca

Co-authors: Joanna V Morgan, Imperial College London, London, SW7, United Kingdom; Sean Gulick, University of Texas at Austin, Austin, TX; Jaime Urrutia Fucugauchi, Universidad Nacional Autonoma de Mexico, Mexico City, Mexico; Ligia L Perez-Cruz, UNAM National Autonomous University of Mexico, Mexico City, Mexico; Mario Rebolledo-Vieyra, CICY, Merida, Mexico

Published Material: Abstract submitted to 2015 Lunar and Planetary Science Conference.

Abstract Body: Joint IODP-ICDP drilling of the Chicxulub impact structure, Mexico is scheduled for early 2016. The current team of multi-disciplinary co-proponents team consists of some 28 researchers from 9 nations. Chicxulub is unique in the terrestrial impact record in that its formation is associated with a mass extinction event (K-Pg) and it has a (albeit buried) preserved peak ring structure. Although peak ring structures occur on the other terrestrial planets, there is no consensual agreement on either the formational mechanism or the nature of the rocks that form a topographic peak ring. A 1.2-1.5 km hole will be drilled offshore that will penetrate the crater's peak ring; thus, providing the first ground-truth data on a peak ring. Geophysical data indicate that the peak ring at Chicxulub is characterized by relatively low velocity and density material, suggesting that the rocks are highly fractured. Numerical models of large impacts require that target rocks behave temporarily in a fluid-like manner to facilitate the dramatic modification of a large bowl-shaped transient cavity resulting from the cratering flow-field to form a broad, flat final complex craters. Competing hypotheses for weakening include so-called thermal softening and acoustic fluidization. Sampling material at Chicxulub will allow the first study of the actual rocks of a peak ring, and better constrain the weakening mechanism and large crater formation. Other science goals include: detailed lithology and porosity of the target rocks, which are fundamental input parameters to models of ejecta interaction with the atmosphere and volumes of soot, dust and climatically-active gases essential for evaluating post-impact environmental change; mineralogical and geochemical studies related to post-impact hydrothermal systems and identification of the impactor type; and a series of biological and sedimentological studies of both the impact and post-impact lithologies.

Title: The Paleomagnetic Record of Continental and Ocean Drilling: The Only way Forward

Presenter/First Author: Joseph Stephen Stoner, Oregon State Univ, Corvallis, OR

Presenter/First Author Email: jstoner@coas.oregonstate.edu

Published Material: I will summarize our present understanding of the field and then I will present new ideas on how we can move the field forward.

Abstract Body: Drilling provides the unique opportunity to sample otherwise inaccessible archives, acquiring otherwise unobtainable information. Paleomagnetism is often used to date such records, yet from a paleomagnetic perspective often the most exciting results are the information it provides on the past history of the geomagnetic field. These paleo-geomagnetic observations provide fundamental models of the core and the geodynamo, telling how and possibly even why the geomagnetic field changes. Because geomagnetic change is what all paleomagnetic stratigraphies are based upon, an improved understanding of the geomagnetic field influences how we can use it to tell time, as well as improving the precision and accuracy of standard techniques. Because sediment paleomagnetic records preserve only a low pass filtered version of the geomagnetic field and the largest extreme events only occurred in the more distant past, critical observations needed to study the geomagnetic field such as long, high-resolution, directional and intensity time series and expanded intervals of polarity transitions (reversals, excursions), can only be routinely obtained through drilling. Here I will discuss this symbiotic relationship between paleo-geomagnetism and drilling; outlining opportunities for future understanding, strategies for improved stratigraphies, and how such records will allow a more complete understanding of the geomagnetic field and all the processes that it governs.

Title: From Patagonia to Tasmania: Paleo- and Environmental Magnetism of Long Continental Records in the Southern Hemisphere

Presenter/First Author: Agathe Lisé-Pronovost, La Trobe University, Fitzroy,

Presenter/First Author Email: a.lise-pronovost@latrobe.edu.au

Co-authors: Michael-Shawn Fletcher, , , ; Guillaume St-Onge, University of Quebec at Rimouski UQAR, Rimouski, QC, Canada; Andy IR Herries, La Trobe University, Bindoore, VIC, Australia; Pierre Francus, Inst Nat Recherche Sci, Québec, QC, Canada; Bernd Zolitschka, University of Bremen, Bremen, Germany

Published Material: Published work on PASADO: Lise-Pronovost et al. 2013, 2014 and 2015.

Abstract Body: The sedimentary archive from Laguna Potrok Aike (52°S), Argentina, is the only continuous paleoenvironmental record from continental Patagonia that reaches back to the Last Glacial Period (106 m; 51,200 cal BP). On the other side of the hemisphere, Darwin Crater (42°S) in Tasmania, Australia, contains another long lacustrine sediment sequence (60 m) that spans several glacial cycles (< 780,000 cal BP). These two sites are critically located at the northern and southern limit of the Southern Hemisphere westerly wind belt, thus providing a unique opportunity to reconstruct past changes in aeolian activity and paleoclimate at both regional and hemispheric scales. Here we present rock-magnetic proxies of dust and wind intensity from the recent Potrok Aike Maar Lake Sediment Archive Drilling Project (PASADO) within the framework of the International Continental Drilling Program (ICDP). We also discuss preliminary results for a future continental drilling project at Darwin Crater in Tasmania. We will overview how the magnetic properties and physical grain size data from the PASADO record were used to develop magnetic proxies of dust and wind intensity in Patagonia. We will then evaluate the potential of using similar magnetic proxies in Tasmania by presenting preliminary data from Lake Selina, a low-resolution lacustrine

record that is proximal (50 km north) to Darwin Crater and which spans several glacial cycles. Preliminary results from the Lake Selina sedimentary archive reveal two magnetic mineral components: one of low coercivity (likely iron oxides such as magnetite) and one of high coercivity (likely iron sulfides). The high coercivity component is likely to reflect environmental changes, suggesting an excellent potential for paleoenviromental reconstruction based on the magnetic properties. Importantly, the low coercivity component displays a strong and stable magnetization with a geomagnetic inclination varying around the geocentric axial dipole value, indicating a likely genuine geomagnetic record that will significantly bolster the development of a robust and independent chronology at the site using an integrated dating strategy.

Title: Geophysical Studies of a Deep Borehole in the Canadian Shield in NE Alberta

Presenter/First Author: Douglas R Schmitt, University of Alberta, Edmonton, AB

Presenter/First Author Email: dschmitt@ualberta.ca

Co-authors: Judith Chan, University of Alberta, Calgary, AB, Canada; Jochem Kueck, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam, Germany; Mohammedreza Malehmir, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam, Germany; Inga Moeck, , , ; Tom Chacko, University of Alberta, Edmonton, AB, Canada; Randy Kofman, , , ; Greg Nieuwenhuis, University of Alberta, Edmonton, AB, Canada; Thomas Wiersberg, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam, Germany; J A Majorowicz, Northern Geothermal Cons, Edmonton, AB, Canada; Martyn Jonathan Unsworth, University of Alberta, Edmonton, AB, Canada

Published Material: Parts of this talk will be given at the DGG conference - Hannover, Germany in March. The VSP component has been published in the Int. J. of Geosciences.

Abstract Body: With the support of the German-Canadian Helmholtz-Alberta Initiative we were able to obtain support to carry out an extensive suite of geophysical investiations of a nearly 2.4 km deep borehole drilled through the sedimentary cover into 1.9 km of metamorphic rocks of the Taltson Magmatic Zone in NE Alberta. This geological unit is primarily a biotite gneiss. This work was motivated as part of geothermal reconnaissance studies in the search for low-enthalphy geothermal resources in Alberta. Regrettably, the temperature at the bottom of the well is only about 50 °C. Despite this, however, there are a number of pertinent findings of more general interest. Geophysical logging and borehole seismic investigations were jointly conducted by the GFZ-Potsdam and the University of Alberta, withadditional data provided by the owner of the borehole and in later commerical logging. Logs acquired are resistivity, magnetic susceptibility, full waveform sonic, dipole sonic, density, neutron, and ultrasonic televiewer. High resolution zero offset VSP data were obtained with a receiver spacing of 2.5 m from 1800 m to surface. A number of walk-a-way VSP measurements were also obtained simultaneous to surface seismic acquisition. A number of fracture zones are encountered along the borehole and correlate well with normal electrical logs, full waveform sonic logs, and image logs. These fractures, too, appear to be filled with highly saline brines as they correspond to sharp peaks in the electrical conductivity. These fractures may provide pathways for fluid flow in an engineered geothermal system. The fracture zones may be related to dipping seismic reflectors seen in deep profiles adjacent to the borehole site. An alternative explanation could be the existence, on the basis of high magnetic susceptibility, of mafic sills with differing impedance contrasts. Analysis of this exceptional geophysical data set is still underway. This includes detailed analysis of the walka-way VSP data to measure seismic anisotropy of the crust and of the image logs to provide measures of in situ stress directions and possibly magnitudes. We hope in future to develop this site into a long term deep observatory.

Title: The solidification of obsidian glass during drilling of the IDDP-1 drill hole

Presenter: Donald B Dingwell, Ludwig Maximilian University of Munich, Munich,

Presenter Email: dingwell@lmu.de

First Author: Kai-Uwe Hess, Ludwig Maximilian University of Munich, Munich,

First Author Email: hess@lmu.de

First Author Student?: No

Co-authors: Felix W. von Aulock, University of Liverpool, Liverpool, L69, United Kingdom; Yan Lavallée, University of Liverpool, Liverpool, United Kingdom

Published Material: European Geosciences Union General Assembly 2015 Vienna | Austria | 12 – 17 April 2015

Abstract Body: Understanding the thermal fate of magmatic rocks during scientific high temperature drilling represents a contribution to their interpretation in terms of magmatic state and their mechanical response to the drilling process.

Chips of black crystal-poor unfoamed calc-alkaline rhyolitic obsidian have been obtained from a depth of 2100m in the IDDP-1 borehole. Five samples (20-40 mg) have been subjected to scanning calorimetry in order to evaluate the glass transition temperature, viscosity and cooling history of these obsidians that are believed to have been quenched by the drilling process. In addition to scanning runs on the raw glasses, their controlled cooling/heating cycle behavior has been determined at 5, 10 and 25K/min.

The glass transition temperatures of the raw samples lie in the range of 500-525°C. The glass transition temperature shifts with controlled cooling/heating rates yields an activation energy of 335 kJ/mol. The absolute value of the glass transition temperature has been compared with the Hess and Dingwell (1996) viscosity model for calc-alkaline rhyolite. The comparison allows the inference that the obsidian contains water contents consistent with those reported by Elders et al. (2011) Furthermore, the activation energies obtained from the Tg peak shift with cooling/heating rate are entirely consistent with those water contents. The cooling rate estimated for the raw samples are higher than 25K/min. A relatively high cooling rate for a “natural” obsidian.

These glasses have been interpreted to have been quenched from temperatures of 940-760°C (based on water content). From the present glass transition analysis it would appear that the first 200-400K of cooling of these magmas occurred above the glass transition in a plastic state, followed by ca. 500K of solid-state (glassy) cooling.

These results demonstrate that it is possible to use glassy materials derived from the drilling-induced quenching of magma to evaluate the physical state and thermal conditions attendant on deep scientific drilling of these systems.

Title: Towards an ICDP drilling at Lake Nam Co (Tibet)

Presenter/First Author: Torsten Haberzettl, Friedrich Schiller University of Jena, Jena,

Presenter/First Author Email: Torsten.Haberzettl@uni-jena.de

Co-authors: Gerhard Daut, Friedrich Schiller University of Jena, Jena, Germany; Junbo Wang, ITP Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China; Liping Zhu, ITP Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China; Thomas Kasper, Friedrich-Schiller-University, Jena, Germany; Roland Maeusbacher, Friedrich Schiller University of Jena, Jena, Germany; Peter Frenzel, Friedrich Schiller University of Jena, Jena, Germany; Klaus R Reicherter, RWTH Aachen University, Aachen, Germany; Antje Schwalb, Technical University of Braunschweig, Braunschweig, Germany; Volkhard Spiess, University of Bremen, Bremen, Germany; Thomas Wilke, Justus-Leibig University Gießen, Gießen, Germany

Abstract Body: Nam Co is one of the largest and deepest lakes on the Tibetan Plateau (TP). Seismic data show an infill of >800 m of well layered undisturbed sediments in the central part of the lake. Sediment accumulation rates measured on a 10.4 m reference core, seismostratigraphic investigations, and molecular clock analyses suggest an age of the seismically imaged sequence between 460 and 1,900 ka. However, no basement reflector has been found indicating even older sequences. Multiproxy studies on the reference core provide an excellent high-resolution paleoclimate record covering the past 24 ka cal BP validated by extensive modern process studies and multi-dating approaches.

Situated on the central part of the TP, Nam Co is at an ideal location filling a gap in two ICDP/IODP transects. Due to this location at the intersection of Monsoon (increased precipitation) and Westerlies (increased evaporation) paleoclimate proxies clearly reflect the spatial and temporal interplay and thus the dominance of one of the two circulation systems. Considering that almost one third of the population of the world depends on the water supply from the TP the future hydrological development which is dependent on the interplay of the two systems will clearly have a major societal impact. To define parameters for future climate change scenarios and their consequences for ecosystems, it is of paramount importance to improve our knowledge of timing, duration, and intensity of past climatic variability and environmental impact, especially on long time scales.

Furthermore, the TP is characterized by a high degree of endemism of organisms that are dependent on continuously existing water bodies. Nam Co likely served as a dispersal centre for these organisms, as other shallower lakes desiccated during dry glacial periods of the Cenozoic. Nam Co appears to be a first class example for studying the link between geological and biological evolution in highly isolated TP ecosystems over long time scales.

Title: Biostratigraphy, climate and ocean changes in the Gulf of Alaska during the Plio- Pleistocene

Presenter/First Author: Coralie Zorzi, GEOTOP-UQAM, Montréal,

Presenter/First Author Email: coraliezorzi@gmail.com

Co-authors: Anne de Vernal, University of Quebec at Montreal UQAM, Montréal, QC, Canada

Abstract Body: The Pliocene (5.33 and 2.59 Ma) was a relatively warm epoch characterized by high atmospheric CO_2 concentration (about 400 ppmv) and the absence of continental ice sheet in the Northern Hemisphere. It contrasted with the ensuing Pleistocene Epoch, characterized by lower atmospheric CO_2 concentrations and the onset of glaciations in North America and Eurasia. The present study focuses on the Gulf of Alaska with the aim to document climatic and circulation changes in the subarctic Pacific Ocean in relation with the development of glaciers in northwest North America. More specifically, the aims are to provide clues on the vegetation history of the adjacent land from pollen assemblages, and to reconstruct sea-surface conditions with special attention to productivity and salinity linked with the onset of upwelling from dinocyst assemblages. Marine sediments from sites ODP 887 (54°21.9'N ; 148°26.8'W ; 3645 m) and IODP U1417 (56°95.9'N ; 147°10.9W ; 4187 m) are currently being analyzed for their palynomorph content to reconstruct environmental . Preliminary data indicate very large amplitude change in concentrations of both pollen (from 20 to 1780 grains/cc) and dinocyst (from 0 to 280 cysts/cc) suggesting very large change in biogenic fluxes from terrestrial origin and marine production. In general, Pliocene samples contain more pollen than dinocysts, which suggest large fluxes from the terrestrial vegetation, but low marine productivity. Many Pleistocene samples reveal barren, but some samples record high diversity contrasting with Pliocene intervals marked by the dominance of *Brigantedinium* spp. and moderately abundant dinocysts, which suggest episodes characterized by high marine productivity. The Plio-Pleistocene being marked by important biostratigraphic changes, the interpretation of palynological data is challenging. Our study is part of a multi-proxy collaborative project involving sedimentology, diatom and biomarker analyses. Hence, in addition to document environmental impact of both local and regional drivers on local vegetation and climate, the multi-proxy study should contribute to develop a comprehensive picture of regional changes during the Plio-Pleistocene climate transition.

Title: Rationale and Methods for Regional 3D Geological Mapping

Presenter/First Author: Harvey Thorleifson, Organization Not Listed, Minneapolis, MN

Presenter/First Author Email: thorleif@umn.edu

Abstract Body: Geological mapping yields economic, social, and scientific benefits, so jurisdiction-wide, multi-resolution, seamless, and updated 2D mapping remains needed. In addition, 3D geological mapping will greatly increase scientific and societal benefits, by more explicitly accounting for properties of subsurface materials. For layers whose thickness can be inferred throughout their extent, the requirement is for depiction and prediction of the extent, thickness and properties of all mappable lithologic strata in a jurisdiction, to support applications such as groundwater management, engineering, and sedimentary basin assessments. Facies modeling and basin analysis guides this mapping of lithology which is needed for inference of properties such as hydraulic conductivity. Combined lithostratigraphic and allostratigraphic approaches may apply, the number of stratigraphic names should be minimized, and the work needs to extend to hydrostratigraphy. Compilation includes topography, bathymetry, soil mapping, plan view geological mapping, and drillhole

data. Data acquisition includes geophysics and new drilling. Model construction methods vary depending on resolution and data adequacy, with depth to bedrock or depth to basement maps being early efforts that motivate data compilation and clarify data collection priorities. With lithological data, the model is anchored at stratigraphic benchmarks, and strata are drawn by a geologist through lithological data, as a facies model guides interpolation; strata are drawn to the extent supported by data. With stratigraphic data, modeling may proceed directly from regularly spaced, correlated data. Appropriate geostatistical methods will be used at various phases of projects. Upon depiction of layers, heterogeneity, properties, and uncertainty are added. Concurrently, a basement map is needed, accompanied by increasing depiction of predicted 3D geometry of key structures, along with discretized basement physical properties. Programs should focus on societal needs, assess status of data and mapping, raise expectations among users, engage in long term planning, build institutional databases, reconcile stratigraphy, harmonize 2D mapping, launch geophysics and drilling, choose an appropriate approach, make a plan, and build support.

Title: Robust 3D Geological Models: Hard Data is Key

Presenter/First Author: Francine Fallara, Organization Not Listed, Val-d'Or,

Presenter/First Author Email: francine.fallara@innovexplo.com

Published Material: This presentation is based on my past 15 year experience in 3D geological modelling. Presently, I have no work under review.

Abstract Body: Understanding and incorporating 2D data, whether from surface field work or underground mine mapping, should always be the starting point of an integrated and coherent 3D geologic model, especially for areas with great geometric contrasts. Without this valuable data, 3D modelling is essentially performed with blinders on, and its absence results in a model that is too theory-driven, and lacks input from geologists and "real" field data.

Three-dimensional geologic models require complete, homogeneous and valid databases. The resulting 3D models are directly based on and rely on high-quality data. The data comprises both surface and underground observations. "Raw" or "hard" data should always be assigned more weight and act as rigid control points in 3D models. Hard data should always be distinguishable from interpreted data in 3D models. Investing the necessary time to learn how to homogenize and structure raw data in a rigorous way will be paid back during the 3D interpretation process.

Once 3D models are completed, they should be used as an exploration tool, populating their cells with user-chosen properties. Both quantitative and qualitative properties can be interpolated throughout the cells of the 3D model for further querying and questioning. Thus, the extra benefit of 3D map models is their use as dynamic interactive tools to help define new mineral exploration targets at depth.

A 3D map model is not a goal but a tool that should be dynamic, modified, questioned, shared and updated. Its future usefulness is determined by how well it can be utilized by a multi-disciplinary team of geologists, geophysicists, geochemists, engineers, metallurgists and environmental experts.

Title: 3D exploration targeting based on mineral deposit model: A case of study in Luanchuan district

Presenter/First Author: Gongwen Wang, China University of Geosciences Beijing, Beijing,

Presenter/First Author Email: gwwang@cugb.edu.cn

Abstract Body: According to the geological setting (structure, magma, and stratum) and mineral deposit features (material origination, mineral spatial distribution, orebody geometry, and deposit type), geologists can construct metallogenic genesis/model which is base knowledge for exploring new mineral deposits or exploration targets at depth and surround in the deposit. Exploration targeting was not simply the application of concepts, including both genetic and deposit models, from economic geology research, but was rather the integration of such concepts with geophysics, spatial analysis, mineral economics, decision science and probability theory.

Luanchuan Mo district as a study, it is famous for three large magma-skarn type Mo deposits in China. However, the maximum exploration depth is not more than 1.2 km, the depth zones are need to integrated decision-making for new exploration targets. In this paper, the ground gravity and magnetic data inversion additional a borehole dataset analysis was implemented to identify potential targets, and the methodology is as follow: (1) 1:2000 geological and topographic maps and 282 borehole data was used to construct 3D geological model of Nannihu and Sandaozhuang deposit; (2) 3D models of magma and skarn orebodies, granite (porphyry) stock, and alternation objects were constructed using borehole data additional surface survey; (3) 3D kriging interpolation calculation for 3D Mo grade modeling using geochemical 65500 assay of borehole data; (4) fractal modeling (Hurst exponent and multi-fractal method) using borehole data to identify the orebody continuity and concentration features; (5) 3D buffer analysis integrating 3D granite (porphyry) bodies, the Formations with dolomitic marble, gravity and magnetic anomaly models for prediction potential targets at depth in this district (5.0×4.0×2.5 km). The research results show that both depth of the Northwestern of Nanihu and the Northeastern of Sandaozhuang deposits have skarn-type Mo potential targets, and the depth of former is deep to 2.1 km, and the depth of latter is deep to 2.5 km.

Published Material: Two of three examples cited in this presentation are referred to two publications below. The third work is in preparation for publication this year. Cheng L. Z., Richard S., Allard M., Keating P., Chouteau M., Lemieux J., Vallée M.A., Bois D., and Fountain D., 2006. Geophysical case study of the Iso and New Insco deposits, Québec, Canada: Part II, modeling and interpretation. *Exploration and Mining Geology* (CIM), vo. 15 (1-2), p65-74. This paper is also Geological Survey of Canada contribution 2004295. Boszczuk Pierre, Li Zhen Cheng, Hanafi Hammouche, Patrice Roy, Sylvain Lacroix and Alain Cheilletz, 2011. A 3D gravity data interpretation of the Matagami mining camp, Abitibi

Subprovince, Superior Province, Québec, Canada. Application to VMS deposits exploration. *Journal of Applied Geophysics*, p77-86.

Abstract Body: Searching for a common geological model from multiple geoscience data interpretations not only reduces the ambiguity in single data interpretation, also complement information each other. The role of geophysical methods in such integrated multi-data sets interpretation is as useful tool for subtracting spatial information from the Earth interior. The important task of geophysicists is to be able to quantify the nature, volume and location of geophysical anomalous sources and make links between variations in geophysical field and the structural geology; or to define a specific geological significance from geophysical anomalies (e.g. information about the mineralization).

From geophysical observation we can recover a physical property distribution; further to find out its geological implication which is an inverse procedure. With the computation technology advancement, geophysical data inversions now can be realized from one dimension to three or four dimensions (later includes time scale). The key question for geophysicists is how much similarity or consistency between geophysical model and that of geology? To be better integrated geophysical interpretation and geological reality, the knowledge of petrophysics and the team work of geophysicists with geologists become obviously more than more important.

Through 3 examples we would show 1) sometimes geophysical methods detect directly ore bodies, therefore we could discriminate ore-rich zones from 3D geophysical data inversions. 2) We may contribute to structural geology by reconstructing the main geological units at the depth, estimating 3D morphology of intrusion and faults from geophysical data interpretation. 3) We could also do advanced 3D modeling of multiple geophysical data sets and, integrate geological and geochemical information together to build up a common geological model.

Title: Three-dimensional (3D) geologic map of the San Andreas Fault Zone, Central California, U.S.A. - revelations and lessons learned

Presenter/First Author: Russell Walter Graymer, Organization Not Listed, Menlo Park, CA

Presenter/First Author Email: rgraymer@usgs.gov

Co-authors: Michelle Roberts, , Menlo Park, CA; Darcy McPhee, USGS California Water Science Center Menlo Park, Menlo Park, CA; Richard G Stanley, USGS, Baltimore, MD

Abstract Body: Using geologic map, petroleum well, and potential-field geophysical data we constructed a 3D geologic map of the San Andreas Fault and adjacent rock units from Pinnacles National Park (about 36°32´48˝N, 121°08´10˝W) to Gold Hill (about 35°49´27˝N, 120°21´10˝W) in a volume roughly centered on the fault, about 30-50 km wide, 15 km deep, and 107 km long. The 3D map reveals that, in addition to large strike-slip offset, the volume east of the fault has undergone significant fault-normal compression, resulting in a large basement antiform adjacent to the fault in the southern half of the model, as well as active thrust faulting associated with the 1983 M6.5 Coalinga earthquake. Fault-normal compression is also present west of the fault, but to a much lesser extent, with much of the volume undergoing only broad uplift and slight westward tilting since the start of the Pliocene. In contrast, the 3D map also reveals strata from at least two pull-apart basins. The northern end of the 3D map shows a large pull-apart basin west of the San Andreas Fault associated with early transtensional tectonism along the fault. Diatoms as old as ~14 Ma from basin fill constrain the timing of initiation of the fault zone, while rocks correlated with the upper part of the basin fill are found east of the fault roughly 200 km to the south. Adjacent to that pull-apart basin, east of the fault, is a thick but distinct sedimentary package (made up of different, in part younger, units) interpreted to be a strike-slip juxtaposed sliver of a younger pull-apart basin, the bulk of which now lies about 100 km to the north.

During the construction of the 3D map we were initially misled by the existing geologic maps, which use the same unit name for rocks of similar lithology but quite different age and stratigraphic level. In addition, the Waltham Canyon Fault, which appears to be a single structure in map view, was revealed to be composed of multiple, overlapping structures in 3D.

Title: Synchrotron X-Ray Microtomography Techniques Applied to the 3D Morphological and Textural Analysis of Geomaterials

Presenter/First Author: Lucia Mancini, Elettra-Sincrotrone Trieste, Basovizza,

Presenter/First Author Email: lucia.mancini@elettra.trieste.it

Published Material: SGI-SIMP Congress (Milano, Italy, 2014)EGU General Assembly (Wien, 2013)

Abstract Body: Imaging techniques play an important role in several research fields of the geosciences. The well known optical and scanning electron microscopy techniques are widely adopted tools for the investigation of the texture and morphology of rock samples. X-ray based techniques are also of particular interest and X-ray microradiography has proved to be useful for the analysis of soils.

In the last years a great interest has been posed on X-ray computed microtomography (micro-CT) techniques, based on both laboratory and synchrotron radiation sources, producing 3D images of the internal structure of objects with a spatial resolution at the micron- and submicron-scale. Investigations, performed directly in the 3D domain, overcome the limitations of stereological methods usually applied to microscopy-based measurements and enable to get images of the internal core of a sample by a non-destructive method, more suitable for further analyses and for precious or unique samples (archeological finds, fossils etc...). An intriguing challenge related to the use of micro-CT methods is to extract quantitative measures and indices directly from images data sets. Porosity and specific surface area as well as connectivity, tortuosity and anisotropy are interesting descriptors of a 3D model. To this purpose, we used the *Pore3D* software library developed at the Elettra-Sincrotrone Trieste laboratory (Italy) and specifically conceived for the handling of large 3D data sets. An open and customized software assures a complete control of the algorithm implementation and permits different strategies of analysis as a function of the specific scientific application.

Several applications of synchrotron X-ray micro-CT methodologies for the extraction of quantitative information from 3D images of geomaterials will be presented.

Title: Quantifying Internal Properties of Geologic Materials by Image Analysis

Presenter/First Author: Dork L Sahagian, Lehigh University, Bethlehem, PA

Presenter/First Author Email: dos204@lehigh.edu

Co-authors: Alexander A Proussevitch, University of New Hampshire Main Campus, Durham, NH

Published Material: Some were reported at previous AGU meetings. This is intended as an invited review of image analysis techniques in support of the session.

Abstract Body: As imaging techniques are refined, and new technologies emerge, our ability is enhanced to quantify size, shape, internal structure, and other morphological characteristics of geological materials. Internal structure has been particularly problematical at small scales (< cm).

3D information can be obtained using stereological methods on thin section or polished sections, but can only be used for simple convex shapes. For more complex shapes (with concavities, voids, etc.) it is necessary to use fully 3D techniques, such as those provided by Computed X-ray Tomography (CXT). Extracting quantitative information requires measuring the number of voxels within an object of interest. In order to determine the position of the boundary between internal objects (e.g. void vs. glass) "segmentation" of the images is a first step. Oftentimes, the resolution of the x-ray generated voxels is insufficient to resolve thin films between objects, and many small objects are imaged as a single very large, interconnected object. The volumes of the bubbles in pumices before coalescence can thus be reconstructed by sequentially "peeling" away the outer layer, then reconstructing vesicles with individual identities. Once this is accomplished, sizes, shapes, orientations, and proximity to neighbors can all be quantified.

Some geological materials are so small that imaging requires SEM techniques (e.g. ash, clay, etc.). Digital elevation models can be constructed for particles using Stereo SEM images. This is enabled by "dirty" surfaces that enable multi-directional reflection from the surfaces of the particles. For volcanic ash, the sizes of the bubbles that burst during fragmentation to form the ash can be determined by the radii of curvature of concavities on ash surfaces. SSEM can still only image the top of an ash particle, so if a reconstruction of the entire particle is desired, the lower half must be numerically reconstructed from the morphology of the upper half.

In sum, there are various techniques for obtaining quantitative information from a suite of imaging technologies, and specific approaches must typically be developed to answer specific research questions regarding geological materials.

Title: Eruptive shearing revealed by tomography

Presenter/First Author: Yan Lavallée, University of Liverpool, Liverpool,

Presenter/First Author Email: ylava@liv.ac.uk

Co-authors: Kai-Uwe Hess, Ludwig Maximilian University of Munich, Munich, Germany; Jackie Evan Kendrick, University of Liverpool, Liverpool, United Kingdom; Kate J Dobson, University of Manchester, Glasgow, United Kingdom; Paul A Ashwell, University of Canterbury, Christchurch, New Zealand; Ben Kennedy, University of Canterbury, Christchurch, New Zealand; Fabian B Wadsworth, Ludwig Maximilian University of Munich, Munich, Germany; Jeremie Vasseur, LMU Munich, Munich, Germany; Donald B Dingwell, Ludwig Maximilian University of Munich, Munich, Germany

Published Material: this presentation will include a wide dataset, including some of the data presented in the following 2 studies under review- Dingwell D.B., Lavallée Y., Hess K.-U., Flaws A., Marti J., Nichols A.R.L., Gilg H.A., Schillinger B., in review. Eruptive shearing in tube pumice: pure and simple. *Nature Geosciences*. -Ashwell P.A., Kendrick J., Lavallée Y., Kennedy B.M., Hess K.-U., von Aulock F.W., Wadsworth F.B., Vasseur J., Dingwell D.B., in review. Permeability of compacting porous lavas: no impermeable plugs? *Journal of Geophysical Research – Solid Earth.*

Abstract Body: Magma ascent and eruption dynamics are regulated by changes in deformation mechanisms and the ability of magma to release gas. Recent advances in (neutron and x-ray) tomographic analyses provides us with a mean to image the internal structure of magma (especially its pore phase), allowing 3-D characterisation of sample. Here, we present the result of tomographic reconstruction of natural volcanic rocks (tube pumice, tuffisites and dome rocks) as well as crystal-poor and crystal-rich rocks experimentally deformed at magmatic condition to describe the evolution of the porous permeable network upon eruptive shearing relevant to different volcanic scenarios. The image reconstruction shows how bubble elongation and occasionally coalescence dominate crystal-poor magmas whilst micro-fracture coalescence dominates the permeable network of crystal-rich magmas. The permeable structure is further analysed to derive information regarding shearing conditions (pure vs simple) and fracture distribution depending on deformation modes (ductile vs brittle). We discuss our findings with respect to eruptive shearing during Plinian as well as lava dome eruptions.

Title: Bubble-Crystal Interactions in a Young Basalt Lava Flow – Preliminary Data from 3D X-Ray Microtomography

Presenter/First Author: Pia Pleše, Université du Québec à Chicoutimi, Chicoutimi, QC

Presenter/First Author Email: pia.plese1@uqac.ca

Co-authors: Michael Higgins, Univ Quebec a Chicoutimi, Chicoutimi, QC, Canada; Don R Baker, McGill University, Montreal, QC, Canada

Published Material: The first 3 sentences in the abstract refer to Higgins, M. (2009): The Cascadia megathrust earthquake of 1700 may have rejuvenated an isolated basaltvolcano in western Canada: Age and petrographic evidence. Journal of Volcanology and Geothermal Research. Volume 179, pp. 149–156.

Abstract Body: The Tseax monogenetic volcano lies at the southern margin of the Northern Cordillera volcanic province, BC, Canada. Its last eruption (1691±23 CE) produced a 32 km long basaltic lava flow which may have been triggered by the Cascadia megathrust earthquake in 1700 CE (Higgins, 2009).

The lava contains a framework of tabular plagioclase crystals with smaller interstitial equant olivine crystals, all set in a glassy matrix. Samples a few mm in diameter were imaged by X-ray µ-CT at APS Chicago, with the aim of studying the relations between the crystals and the gas bubbles (vesicles).

Olivine crystals are accompanied by small bubbles, located on their surface asperities, or within them, impeding crystal growth in that direction. Large bubbles, perhaps a first generation that had more time to grow and coalesce, are defined and restricted in size and shape by a framework of plagioclase crystals. They adhere perfectly to the longer plagioclase faces (010) but there is a melt film between them and the shorter faces as well as in the corners of two touching plagioclase crystals. This suggests that we should perhaps distinguish the process of nucleation of bubbles on crystal surfaces and their enlargement by surface wetting, for different crystals and different faces.

The texture of the large bubbles suggests that the pressure wave of the Cascadia megathrust earthquake may have enabled the growth of bubbles by wetting of plagioclase surfaces even if no new bubbles nucleated. The reduction in density of the magma could then have triggered the eruption.

Our next stage is to further quantify the morphological relations and to measure the contact angles between bubbles and different mineral phases. Combining these with mineral composition and structure differences will hopefully lead to a better understanding of bubbles and non-oxide crystal dynamics.

Title: Characterization of Bioaccessible Porosity in Soil Aggregates by Micro-CT Scanning

Presenter/First Author: Ali Akbari, McGill University, Montreal,

Presenter/First Author Email: ali.akbari@mail.mcgill.ca

Co-authors: Subhasis Ghoshal, McGill Univ, Montreal, QC, Canada

Abstract Body: In this study we characterized soil aggregate micro-structures in terms of pore network characteristics and evaluated the potential role of the micro-structure on biodegradation of petroleum hydrocarbons in a fine-grained soil obtained from an oil-contaminated site. Bioremediation experiments indicated significant biodegradation of about 50% of the total petroleum hydrocarbons and a relatively high remediation endpoint of about 620 mg/kg soil. It is likely that the residual hydrocarbons were entrapped in pores that were inaccessible to hydrocarbon-degrading bacteria. The intra-aggregate *bioaccessible porosity*, the fraction of aggregate volume constituted by pores that bacteria can access, was determined by X-ray CT scanning. A new image analyses procedure was developed to threshold the images, determine the boundary of aggregate and extract the pore network information. The CT scanning results showed that about 26% of soil aggregate volume was potentially accessible to the hydrocarbon degrading bacteria, whereas, about 1.5% of aggregate volume was attributed to inaccessible pores. The volume of pores smaller than 1 µm could not be determined by CT scanning and was determined by BET analyses. The significant volume of potentially non-bioaccessible pores can explain the observed relatively high remediation endpoint in the studied soil. The procedure for CT image analysis of intra-aggregate porosity developed in this study can be a new approach for a priori assessment of bioremediation performance in oil-contaminated soils.

Title: Thermodynamic Optimization of the Li_2O-Na_2O-CaO-FeO-Fe_2O_3-Al_2O_3-SiO_2-P_2O_5 System

Presenter/First Author: Pierre Hudon, McGill University, Montreal, QC

Presenter/First Author Email: pierre.hudon@mcgill.ca

Co-authors: In-Ho Jung, McGill University, Montreal, QC, Canada

Abstract Body: P_2O_5 is an important oxide component in the late stage products of igneous rocks such as granites and anorthosites, for example. Most of the time, P_2O_5 combines with CaO and crystallizes in the form of apatite, while in volatile-free conditions, Ca-whitlockite is formed. In spite of their interest, the thermodynamic properties and phase diagrams of P_2O_5-bearing systems are still not well known yet. As a result, we critically reviewed and optimized the structural, thermodynamic and phase diagram data belonging to the system Li_2O-Na_2O-CaO-FeO-Fe_2O_3-Al_2O_3-SiO_2-P_2O_5. This system contains numerous compounds including the phosphate minerals lithiophosphate (γ-Li_3PO_4), Ca-whitlockite (β-$Ca_3(PO_4)_2$), silicocarnotite ($Ca_5SiP_2O_{12}$), nagelschmidtite ($Ca_7Si_2P_2O_{16}$), grattarolaite (α-$Fe_3(PO_4)O_3$), and rodolicolite (α-$FePO_4$). The liquid phase was parametrized using the Modified Quasichemical Model while solid solutions such as spinel and FeO were modelled using the Compound Energy Formalism and the Regular Solution Model, respectively. All available thermodynamic and phase equilibrium data were simultaneously reproduced and discrepancies in the available data resolved in order to obtain one set of model equations for the Gibbs energies of all phases as functions of temperature and composition at 1 atm. The CaO-SiO_2-P_2O_5 liquidus projection is shown below as an example. This is part of a larger research project to develop the thermodynamic database of the Li_2O-Na_2O-K_2O-CaO-MgO-MnO-ZnO-FeO-Fe_2O_3-Al_2O_3-SiO_2-P_2O_5 system at room pressure.

Title: Computing dynamic titania activities through metamorphic evolution and implications on Ti-in-quartz thermobarometry

Presenter/First Author: Kyle T Ashley, Virginia Polytechnic Institute and State University, Blacksburg, VA

Presenter/First Author Email: ktashley@vt.edu

Co-authors: Richard Derek Law, Virginia Tech, Blacksburg, VA

Published Material: A manuscript on this work was submitted to Contributions to Mineralogy and Petrology, with a revised draft currently being processed by the editorial board.

Abstract Body: Meaningful metamorphic *P-T* estimation is made difficult due to susceptibility of minerals to chemical modification during retrogression and complex cation partitioning that occurs in some crystal systems. The simple exchange of Ti for Si in quartz and slow diffusion of Ti during retrogression makes Ti-in-quartz a potentially powerful thermobarometer. Calculation of temperature is dependent on estimating titania activity at the time of quartz growth. In metapelites this may be reasonably estimated if ilmenite or rutile is stable. However, due to participation of quartz in solution-transfer processes and metamorphic

reactions throughout the *P-T* history, calculating temperatures while only considering peak paragenesis may be erroneous. Here we calculate TiO_2 chemical potentials for known bulk rock compositions relative to that of a rutile-containing system (i.e., a standard state system) through the thermodynamic calculation package Perple_X and pseudosection generation. When projected in *P-T* space, a titania activity map is generated which allows for assessment of Ti solubility in quartz under various geologic conditions. Calculated activities are used to adjust the Ti-isopleth projection in *P-T* space. For an average sub-aluminous pelite composition, results are in good agreement with previous studies that found ilmenite-bearing assemblages buffer high TiO_2 activities (nearly 1.0), with lower activities for titanite-bearing assemblages (≥0.5). At high temperatures, significant deviation from an assumed pelite titania activity of 1.0 exists; here, assuming a dynamic activity results in Ti concentrations in quartz up to 400% different from assuming a standard state. This is due, in part, to sequestering Ti in biotite and destabilization of Ti-oxides at higher *T*. These large Ti discrepancies result in large temperature uncertainties. Therefore, our modeling approach may provide a method to better refine titania activities for quartz growth throughout the *P-T* history.

Title: Experimental investigation and optimization of the thermodynamic properties and phase diagrams of the $CaO-MgO-Al_2O_3-SiO_2-ZrO_2$ system

Presenter/First Author: Sunyong Kwon, McGill University, Montréal, QC

Presenter/First Author Email: sunyong.kwon@mail.mcgill.ca

Co-authors: Pierre Hudon, McGill University, Montreal, QC, Canada; In-Ho Jung, McGill University, Montreal, QC, Canada

Abstract Body: Zirconia-bearing systems are of great importance in geology. The minerals baddeleyite and zircon, for example, are quite useful in geochronology thanks to their refractory nature, capacity to contain trace amounts of uranium and thorium, and occurrence in numerous igneous and metamorphic rocks. Zirconia-bearing compounds are also quite used as refractory materials in the industry. Recently, numerous new thermodynamic property and phase diagram data were published for ZrO_2-containing systems which prompted a re-evaluation of the thermodynamic properties of the ZrO_2 unary system. In this study, new experimental phase diagram data were also collected and a critical evaluation and optimization of the thermodynamic properties and phase diagrams of the $CaO-MgO-Al_2O_3-SiO_2-ZrO_2$ system was performed. As an example, the optimized ZrO_2-SiO_2 binary system and $ZrO_2-CaO-MgO$ ternary system are shown in Figures 1a and 1b, respectively. The liquid phase was parametrized using the Modified Quasichemical Model while solid solutions were optimized using the Bragg-Williams Random Mixing Model with a polynomial expansion of the excess parameters. The optimized model parameters were incorporated to the oxide database of the FactSage software.

Title: Thermodynamic Optimization of the $MgO-MnO-Mn_2O_3-SiO_2$ System

Presenter/First Author: Sourav Kumar Panda, McGill University, Montreal, QC

Presenter/First Author Email: sourav.panda@mail.mcgill.ca

Co-authors: Zhanmin Cao, , , ; In-Ho Jung, McGill University, Montreal, QC, Canada

Abstract Body: The $MgO-MnO-Mn_2O_3-SiO_2$ system is of great importance in metallurgy and geochemistry. It contains many important minerals of geological interest such as the clino-, ortho-, and proto-pyroxenes ($MgSiO_3$), the pyroxenoids rhodonite ($MnSiO_3$) and pyroxmangite ($MgSiO_3$-

$MnSiO_3$), olivine (Mg_2SiO_4-Mn_2SiO_4) and braunite (Mn_7SiO_{12}), some of which being major constituents of the Earth's mantle. In order to develop a self-consistent thermodynamic database for the above system at 1 atm total pressure, all phase diagram (e.g. Fig 1a) and thermodynamic data (e.g. Fig 1b) available in the literature were critically evaluated. The Gibbs energies of liquid and solid solutions were described using thermodynamic models reflecting the structures of solutions. The liquid solutions were described using the Modified Quasichemical Model (MQM) while the solid solutions, such as the pyroxenes and olivine, were parametrized using the Compound Energy Formalism (CEF). For rhodonite, pyroxmangite and monoxide solid solutions, a simple Bragg Williams random mixing polynomial model was used to describe the solutions. The complex phase relationships in the system have been elucidated, and discrepancies among the data have been resolved. The database of the model parameters can be used along with Gibbs energy minimization software in order to calculate any phase diagram section or thermodynamic property.

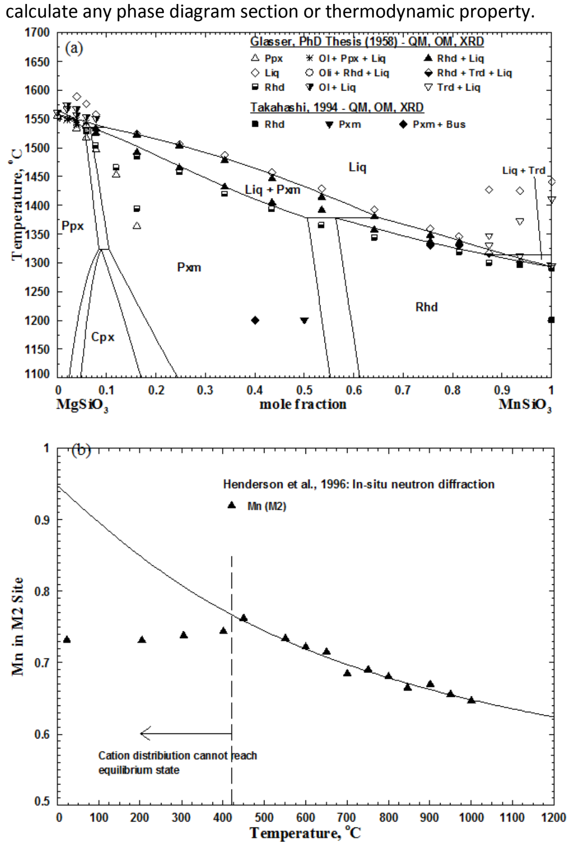

Figure 1. (a) Calculated phase diagram of the $MgSiO_3$-$MnSiO_3$ metasilicate section at reduced atmosphere ($P_{O2} = 10^{-15}$ atm) under 1 atm. total pressure, and (b) calculated cation distribution in $MnMgSiO_4$ olivine as a function of temperature.

Abstract Body: The CONSONORM_HG norm provides a standardised solution to approximate metamorphic parageneses for mid- to high-grade metamorphic rocks. This norm integrates ternary phase diagrams computed using the Perple_X software developed by J. Connolly and collaborators (cf. http://www.perplex.ethz.ch/). What the CONSONORM_HG losses in precision, when compared to pseudo-sections and other types of diagrams abundantly used by metamorphic petrologists, it gains in simplicity and universality, as the CONSONORM_HG can be applied to any type of metamorphic rocks, whether their protoliths have the mafic or felsic composition of sedimentary, magmatic or hydrothermally altered rocks.

The CONSONORM_HG is designed for silicate, Fe-Ti oxydes and/or carbonate-dominated rocks, and it approximates the main parageneses of metamorphic rocks for pressures < 10 kbars and for the greenschist, blueschit, amphibolite and granulite facies. For each of the 17 P-T conditions modelled and depending on the Fe-Mg-Mn composition of the sample, the norm calculates silicate assemblages using one among three Al-Ca-NaK-FeMgMn tetrahedrons that are a convenient way to represent a large amount of silicate assemblages. In addition to silicates, the CONSONORM_HG calculates accessory minerals, Fe-Ti oxides, sulphides from analysed sulfur and/or from analysed metals and carbonates from analysed CO2 or from normative CO2 estimated from the LOI, following the NORMAT method. The CONSONORM_HG also integrates many reactions to address silicon deficits, as well as quartz-carbonates reactions, to better approximate natural parageneses.

The CONSONORM_HG was initially intended to facilitate the recognition of hydrothermally altered rocks in high-grade metamorphic area. This tool has also the potential to serve for the classification of metamorphic rocks, as the CIPW norm served the classification of magmatic rocks. This presentation will focus on the calculation sequence of the CONSONORM_HG.

Abstract Body: The molar volume of an oxide melt is determined by its atomic packing which is a function of bond lengths, orientation, and atomic scale interactions. Molar volume is a calculated property obtained from density and composition measurements. The molar volumes of metallurgical slags and geological melts in particular, are difficult to determine due to the extreme experimental conditions required. Modeling the available experimental data with semi-empirical models reproduces the available experimental data while also providing meaningful predictions to composition ranges where no experimental measurements currently exist. Typically, in the geological literature, linear molar volume models are used. However, linear models have been shown to reproduce the experimental data only within certain composition range. That is, a linear model is incapable of describing the molar volume of oxide melt in all composition ranges. In this work, a non-linear structural molar volume model was developed to accurately reproduce the molar volume of molten oxides, of importance for geological and metallurgical applications. In the present structural model, the silicate tetrahedral Q-species calculated from

the Modified Quasichemical Model with the FactSage FToxid database were used as basic structural units and their unit volumes were used as binary model parameters along with the volume of pure oxides. All available experimental data for binary and ternary systems in the literature were critically evaluated based on their experimental techniques and experimental conditions to identify the most reliable data. From the optimized unary and binary model parameters, the present structural molar volume model can accurately calculate the molar volume and thermal expansion of the Li2O-Na2O-K2O-MgO-CaO-MnO-PbO-Al2O3-SiO2 melts at any composition and temperature under 1 atmosphere pressure.

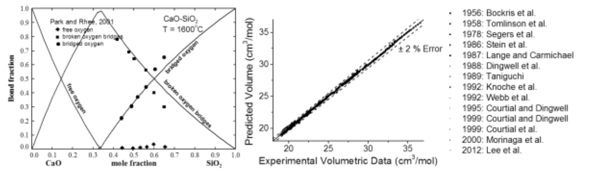

Figure 1. (a) Calculated bond fractions in binary CaO-SiO$_2$ melts from the Modified Quasichemical Model with optimized thermodynamic parameters, and (b) the accuracy of the present model for multicomponent system in comparison to the experimental data in literature.

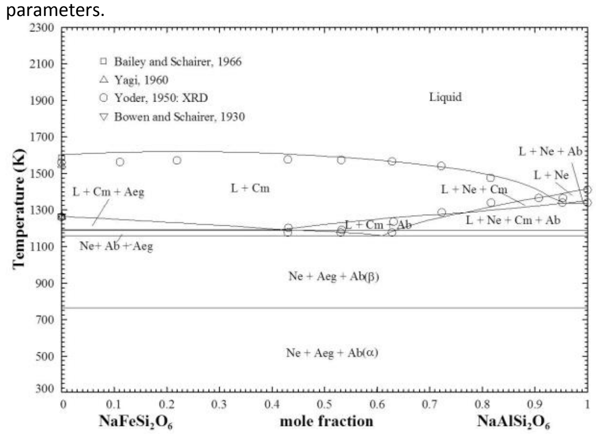
Title: Experimental Investigation and Thermodynamic Optimization of the Na_2O-FeO-Fe_2O_3-Al_2O_3-SiO_2 System

Presenter/First Author: Elmira Moosavi-Khoonsari, McGill University, Montreal, QC

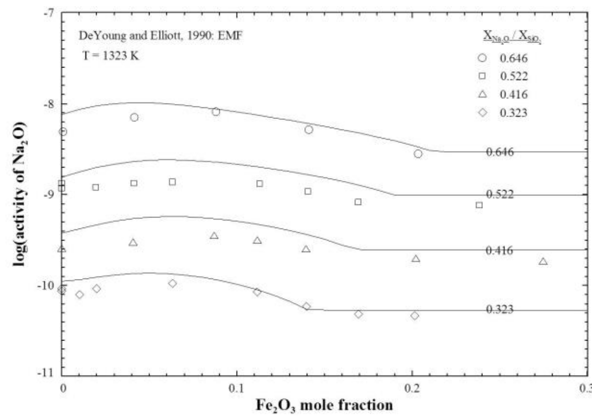
Presenter/First Author Email: elmira.moosavikhoonsari@mail.mcgill.ca

Co-authors: Pierre Hudon, McGill University, Montreal, QC, Canada; In-Ho Jung, McGill University, Montreal, QC, Canada

Abstract Body: The Na_2O-FeO-Fe_2O_3-Al_2O_3-SiO_2 system possesses many minerals of importance for geology and metallurgy such as wüstite, spinel, corundum, aegirine, nepheline (carnegieite), albite, jadeite, fayalite, and silica (quartz, tridymite, cristobalite). Phase equilibria among these minerals and other compounds of this system are indeed very complex due to the change in Fe oxidation state with oxygen partial pressure and the substitution of Fe by Al. In the present study, a coupled experimental study and thermodynamic modeling approach was used to optimize the phase diagrams and thermodynamic properties of the whole system at 1 atm. New experiments were carried out in the Na_2O-FeO-Fe_2O_3-Al_2O_3 system in air and at Fe saturation, a critical evaluation of all experimental phase diagrams and thermodynamic property data available in the literature was performed, and new thermodynamic models were developed to create a new thermodynamic database that describes the Na_2O-FeO-Fe_2O_3-Al_2O_3-SiO_2 system. All the data were reproduced within experimental error limits from 298 K to above liquidus temperatures for all compositions and oxygen partial pressures from metallic Fe saturation to air. The phase equilibria and thermodynamic properties of this multi-component system at 1 atm were reasonably predicted using only binary and ternary model parameters.



Calculated optimized aegirine – jadeite section in air.



Calculated activity of Na_2O with reference to liquid standard state in the Na_2O-Fe_2O_3-SiO_2 system in air.

Title: Thermodynamic modeling of metal transport in H_2O-CO_2 vapours: CO_2-Fluxing Crashes Metal Mobility

Presenter/First Author: Vincent van Hinsberg, McGill University, Montreal, QC

Presenter/First Author Email: V.J.vanhinsberg@gmx.net

Co-authors: Kim Berlo, University of Oxford, Oxford, United Kingdom; Artaches A Migdissov, Los Alamos National Laboratory, Los Alamos, NM; Anthony E. Williams-Jones, McGill University, Montreal, QC, Canada

Abstract Body: Magmatic systems host many types of ore deposits, including world-class deposits of copper and gold. It is now generally accepted that magmas are the source of metals and ore-forming fluids, although in some cases their input may be restricted to introducing thermal disturbances and associated hydrothermal circulation. In these magmatic-hydrothermal systems, low-density solutions, or vapours, are an important carrier of metals. Such vapours are water-dominated at low pressure, but CO_2 becomes a progressevely important conponent in vapours exsolved from magma at depth, especially for mafic magmas. Fluxing of these CO_2-rich vapours through the more shallow parts of the magmatic-hydrothermal plumbing system is now recognized as ubiquitous during open-system magma degassing.

In this contribution, we show that such CO_2-fluxing leads to a dramatic drop in element solubility in the previously water-dominated vapour, up to a factor of 10,000 for Cu, as calculated from new thermodynamic stability constants for metal species in vapour, and a new model for understanding metal solvation. The predicted drop in metal solubility far exceeds that which would be calculated for the temperature and pressure gradients expected in magmatic-hydrothermal systems. CO_2-fluxing thus potentially represents a highly efficient, but as of yet unrecognised mechanism for metal deposition in magmas and host rocks.

Title: Recrystallization and New Growth of Radiation-Damaged Zircon

Presenter/First Author: John M. Hanchar, Memorial University of Newfoundland, St John's, NL

Presenter/First Author Email: jhanchar@mun.ca

Co-authors: Wanda Aylward, , , ; Mark David Schmitz, Boise State University, Boise, ID; Richard Wirth, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam, Germany

Published Material: About 20% was presented at the Fall 2012 AGU meeting in san Francisco

Abstract Body: Nearly metamict zircon crystals from the Saranac Prospect near Bancroft, Ontario were ground to a fine powder for powder XRD measurements, HR-TEM imaging and analyses, and CA-TIMS analyses. Aliquots of the ground zircon powder were annealed in situ using a Pt furnace during which time simultaneous powder diffraction data were acquired starting at 25 C, at elevated temperature (from 500 C to 1400 C) at selected time intervals. The powder XRD results indicate that below ~900 C the recrystallization of zircon is incomplete, even after 36 hours. At 1150 C the zircon powder shows significant recrystallization in less than one hour. Before annealing the zircon powder consisted of clear, transparent to brown, translucent, complexly zoned fragments. After heating at 900 C the majority of material had transformed to white opaque microcrystalline fragments. The clear fragments are thought to be preexisting original minimally radiation damaged crystalline zircon, the brown complexly zoned fragments are likely preexisting extremely metamict zircon, and the white opaque fragment newly recrystallized zircon and ZrO2. At 1150 C all that remained after heating were dominantly white opaque fragments and extremely rare clear fragments. A variety of fragment types from the unannealed, 900 C, and 1150 C anneals were chemically abraded at 190 C for 12 hours. After chemical abrasion, all unannealed material, nearly all material from the 900 C anneal, and all white opaque microcrystalline material from the 1150 C anneal, dissolved. Only the rare residual clear, transparent fragments from the 1150 C anneal remained and yielded concordant U-Pb ID-TIMS dates of 1064 Ma confirming the hypothesis that low-U closed system domains are preserved through annealing up to 1150 C and can be extracted via chemical abrasion from even dominantly metamict zircon crystals. By contrast, newly formed post-annealing recrystallized zircon appear to be quite soluble during chemical abrasion process.

Title: Deformation of Zircon Under High Pressure

Presenter/First Author: Ievgeniia Morozova, University of Western Ontario, London,

Presenter/First Author Email: imorozov@uwo.ca

Co-authors: Sean R Shieh, University of Western Ontario, London, ON, Canada; Desmond Moser, Western University, London, ON, Canada; John M. Hanchar, Memorial University of Newfoundland, St John's, NL, Canada

Abstract Body: Zircon ($ZrSiO_4$) is a strong and refractory mineral and can retain trace elements such as U, Th and Pb for age determination and evolution of early Earth. Isotopic data obtained from zircon can provide insightful information about evolution of crust and mantle differentiation. Moreover, zircon can be used as an indicator for impact deformations. It is believed that zircon age determination may correlate with its microstructures. Deformation of zircon can affect diffusion and thus result in uncertainties in age determination. Therefore, deformation study of zircon may have significant implications for the dynamics and evolution of planets. Study of zircon under high pressure can help us to understand mechanical and elastic properties of zircon and determine the nature of deformations at mantle conditions.

Angle-dispersive X-ray diffraction in a radial geometry using a diamond anvil cell was performed at beamline X17C, National Synchrotron Light Source, Brookhaven National Laboratory. Our results showed that zircon is sensitive to stress and weak deformation was observed even at 1 GPa. Ratios of differential stress to shear modulus (t/G) are in the range of 0.002- 0.008 at pressure to 30 GPa. Differential stress supported by zircon showed that (200) is the weakest plane and could be responsible for the onset of deformation. Zircon to reidite transformation was found at above 18 GPa, which is slightly lower than previous studies. Our results suggested shear strength may play a key role for the transition. Our volume data fitted to Birch-Murnaghan equation of state yielded a bulk modulus of 270.03±4.6 GPa (K_0=4), in broad agreement with previous reports. Weak texture in (100) was observed at low pressure and became more profound with pressure. At pressure above 11-13 GPa, (100) texture rotated towards to (111) due to the applied stress.

Title: *In situ* Microstructural and Mechanical Analysis of Zircon and Monazite Using Type Sections for U-Pb Strain Chronometry

Presenter/First Author: Giancarlo A Jones, University of Western Ontario, London,

Presenter/First Author Email: gjones47@uwo.ca

Co-authors: Desmond Moser, Western University, London, ON, Canada; Ivan Barker, University of Western Ontario, London, ON, Canada

Abstract Body: Direct radiometric dating of deformation in the lithosphere has been a longstanding goal in geochronology. Moser et al. (2009) have demonstrated that zones within textured zircon grains from the lower crust beneath the Vredefort impact structure in South Africa date a lower-crustal flow event. The material setting(s) that gave rise to zircon deformation and Pb loss are yet not well understood. We explore the relationship between *in-situ* material properties, textural features in zircon and monazite grains and their petrologic setting in these type sections of the mylonitic mafic lower-crust. Methods used include EBSD mapping, and texture analysis with commercial and MTEX software. In one thin section we have identified 64 zircons ranging in size between 4 and 190 microns. The largest grains are enclosed in garnet macrocrysts and more abundant smaller grains are in the matrix and garnet coronae. A total of 145 monazites were identified between 4 and 49 microns in size. Monazites were mostly restricted to the matrix. Textures in BSE imaging have proved useful as a predictor of deformation microstructures. Using this proxy, deformed grains were found exclusively in the matrix and are typically

larger, anhedral and non-equiaxed. Low-angle grain boundaries were measured in these grains using EBSD. Monazites are less textured than zircons. It remains to be determined whether these are primary or secondary phases. Comparisons will be made with samples from other high-grade terranes including the Central Gneiss Complex of Norway and the Kapuskasing Uplift in Ontario. LA-ICP/MS will be used to investigate spatial relationships of age-resetting and texture. We hope that this work will increase our predictive capacity for locating ideal rock types and environments for U-Pb strain chronometry.

Title: Untangling impact ages and crustal processes in highly shocked planetary materials using accessory minerals

Presenter/First Author: James Darling, University of Portsmouth, Portsmouth,

Presenter/First Author Email: james.darling@port.ac.uk

Co-authors: Desmond Moser, Western University, London, ON, Canada; Kim Tait, Royal Ontario Museum, , Canada; Ivan Barker, University of Western Ontario, London, ON, Canada; Kevin Chamberlain, University of Wyoming, Laramie, WY; Axel K Schmitt, University of California Los Angeles, Los Angeles, CA

Published Material: Some of the results were presented at IMA2014, but this presentation will add significant new data and insight.

Abstract Body: Separating the effects of shock metamorphism from endogenic crustal processes continues to be a major challenge for the study of meteorites and terrestrial impact structures.

Here we show that in highly shocked Martian and Lunar meteorites this evolution can be resolved by combining electron nanobeam techniques (CL, EBSD, TEM) with in-situ U-Pb isotope analyses by SIMS or LA-ICP-MS. We focus upon the effects of shock metamorphism on the U-Pb systematics of baddeleyite (ZrO_2) and zircon ($ZrSiO_4$) – micron-scale phases common to achondrites and terrestrial impact structures. Unlike zircon, the relationship of shock heating and deformation with retention of radiogenic Pb in baddeleyite is poorly known.

In both NWA 5298 (shergottite) and NWA 2200 (Lunar anorthositic breccia), baddeleyite grains from individual polished thin-sections show a wide array of deformation microstructures. These include fracturing, varying degrees of amorphization and granulation, plastic deformation, and recrystallization: reflecting local variations in shock pressures and waste heat. SIMS U-Pb isotope analyses reveals variable degrees of age resetting in both samples. For NWA 5298, variable Pb loss (as high as 80 %) can be directly correlated with observed microstructures and with the extent of post-shock zircon rims that are linked to release of Si-rich fluids during quenching of shock melt pockets during transit to space. In NWA2200, the range of baddeleyite $^{207}Pb/^{206}Pb$ ages (ca. 4050 to 3850 Ma), is significantly younger than zircons with shock microstructures from the same sample (ca. 4400 to 3950 Ma), reflecting either a distinct provenance or differing shock-response of the two phases.

These findings, contrary to the results of shock loading experiments, indicate that baddeleyite U-Pb ages can be reset under certain shock metamorphic pathways. The combined microstructural and U-Pb data therefore provide a powerful tool for determining both the primary age of the meteorite assemblages and bracketing the time of impact events.

Title: Testing for age correlation among the young shergottites

Presenter/First Author: Matthew R Izawa, University of Western Ontario, London, ON

Presenter/First Author Email: matthew.izawa@gmail.com

Co-authors: Kim Tait, Royal Ontario Museum, , Canada; Desmond Moser, Western University, London, ON, Canada; Thomas J Lapen, University of Houston, Houston, TX; Brendt C Hyde, Royal Ontario Museum, Toronto, ON, Canada; Ian Nicklin, , , ; Anthony J Irving, Univ Washington, Seattle, WA; Ivan Barker, University of Western Ontario, London, ON, Canada

Abstract Body: Recent investigations have demonstrated that the application of ion and nanoscopic electron beam analysis to highly refractory U-bearing minerals in martian meteorites can reveal the complex petrogenetic history of these rocks, including igneous crystallization and shock ejection. We are evaluating the extent to which the geochemical grouping of the shergottites according to depleted-intermediate-enriched REE compositions and mafic-permafic-ultramafic major element composition axes are reflected in the crystallization ages of shergottites measured by in situ U-Pb dating of igneous Zr-rich minerals and phosphates. We are also evaluating the extent to which martian phosphate minerals record post-crystallization alteration (e.g., by fluids and by impact heating), and searching for launch-generated assemblages (e.g., zircon) that can constrain the timing of the impact events which delivered the shergottites to Earth. Our study encompasses a wide range of shergottites, many of which yield mineral crystallization ages from the last several hundred million years. Phase mapping using SEM-EDS has demonstrated a common association of igneous baddeleyite with ilmenite-dominant oxide assemblages. Primary igneous phosphates, predominantly Mg-merrillite can show partial replacement by chlorapatite in association with pockets of glassy SiO_2-K_2O-rich shock melt. Despite shock effects, all the shergottites in this study exhibit dominantly igneous textures, including core-to-rim zoning of pyroxene and olivine from Mg-rich to Fe-rich and igneous zoning in plagioclase. Isotopic and trace element analyses, spatially correlated with primary and secondary microstructures will test for age correlation and potential comagmatic samples of young martian magmatism.

Title: Atom Probe Tomography of Zircon and Baddeleyite Geochronology Standards

Presenter/First Author: David A Reinhard, Cameca Instruments Inc., Madison, WI

Presenter/First Author Email: david.reinhard@ametek.com

Co-authors: Desmond Moser, Western University, London, ON, Canada; Ivan Barker, University of Western Ontario, London, ON, Canada; David Olson, Cameca Instruments Inc., Madison, WI; Isabelle Martin, Cameca Instruments Inc., Madison, WI; Katherine P Rice, , , ; Yimeng Chen, , , ; Daniel F Lawrence, Cameca Instruments Inc., Madison, WI; Ty J Prosa, Cameca Instruments Inc., Madison, WI; David J Larson, Cameca Instruments Inc., Madison, WI

Abstract Body: Atom Probe Tomography (APT) is an analytical technique whereby the positions of elements, and their isotopes, can be reconstructed in 3D, shedding light on nano-scale trace element mobility in geochronology minerals. The sample is extracted from the bulk material and milled using a dual-beam FIB SEM into a needle shape with an apex radius of 50-100nm. Single atoms (or small groups of atoms) are ionized by

UV laser pulse from the surface while under the presence of a large electric field and removed from the surface one-at-a-time. Each removal (field evaporation event) is synchronized to a timing pulse and projected to a 2D position-sensitive detector providing ion identification through time-of-flight mass spectroscopy and, ultimately, a composition map of the surface. Done iteratively over many millions of ions, the evolving surface information is reconstructed as a 3D map of individual ions from which information can be extracted for a for a variety of real-space analyses. In general, optimal APT acquisition conditions are material dependent. As APT is a destructive technique, it may be advantageous to perform optimization on non-precious, geochronology standard materials to optimize both data quality and analysis yield prior to sacrificing the true material of interest. In the present work, we explore the effect of various laser-pulse energies on zircon (BR266) and baddeleyite (Phalaborwa) standards. Because limited analysis yield is an issue for APT, possibly exacerbated by deformation microstructure, we also explored some post-specimen-preparation treatments (such as annealing) on both the baddeleyite standard and shocked terrestrial baddeleyites in an effort to increase sample yield and test for induced chemical segregations. Transmission EBSD (TKD) mapping of microtips was also explored to integrate lattice orientation(s) with the 3D APT map. We will show APT analyses from these materials and report on our efforts to improve analysis yield to date.

Title: Combining Nano Scale Microstructural Analysis and U-Pb Geochronology of Terrestrial Baddeleyite to Unravel Crustal and Bombardment Chronology

Presenter/First Author: Lee Frances White, University of Portsmouth, Portsmouth,

Presenter/First Author Email: lee.white@port.ac.uk

Co-authors: James Darling, University of Portsmouth, Portsmouth, United Kingdom; Desmond Moser, Western University, London, ON, Canada; Dean Bullen, , , ; David A Reinhard, Cameca Instruments Inc., Madison, WI; Peter Clifton, Cameca Instruments Inc., Madison, WI; David J Larson, Cameca Instruments Inc., Madison, WI; David Olson, Cameca Instruments Inc., Madison, WI; Ty J Prosa, Cameca Instruments Inc., Madison, WI; Daniel F Lawrence, Cameca Instruments Inc., Madison, WI; Isabelle Martin, Cameca Instruments Inc., Madison, WI

Abstract Body: Baddeleyite (monoclinic-ZrO_2) commonly crystallizes in mafic and ultra-mafic rock types where zircon ($ZrSiO_4$) does not, rendering it a key geochronometer within these silica under-saturated lithologies more prevalent on the Moon and Mars. It is an especially important geochronology mineral when examining *ex-situ* meteoritic samples derived from other planetary bodies, as many grains within an igneous population survive ejection and give the timing of primary crystallization whereas others experience shock heating and fluid alteration to cause partial to complete age re-setting to the time of an impact event. Discrimination of these scenarios in other samples so as to best interpret U-Pb age will benefit from a fuller knowledge of the shock metamorphic response of baddeleyite to known natural and experimental conditions. Here we present our first ground-truthing efforts toward this goal with an analysis of the evolution of orientation and isotopic microstructure of baddeleyite from the Sudbury impact structure - a globally unique, terrestrial example of these impact processes. Micro-baddeleyite grains (<15µm) within the 2.45 Ga Matachawan diabase dyke swarm, subjected to shock metamorphism as a result of the 1.85 Ga ~200km diameter Sudbury impact structure are being comprehensively analysed along a (near linear) transect across the Superior province radiating out from the boundary with the melt sheet. Electron Backscatter Diffraction (EBSD) mapping reveals typical igneous cooling twins parallel to [100] but also lattice misorientations up to <15°. Atom probe tomography of coherent material (i.e. no apparent fractures or phase discontinuities) reveals nanoclusters of Fe, Al and Ca presently interpreted to have been introduced following shock metamorphism. Distribution analysis of trace elements including U and Pb is underway and will be compared to isotopic analysis of residual grain material using complimentary mass spectrometry methods. Baddeleyite is a common, though tiny, crustal phase that has great potential to improve inner solar system crustal and impact chronologies.

Title: EBSD and Atom Probe Geochronology of Zircon and Baddeleyite from Early Mars

Presenter/First Author: Desmond Moser, Western University, London, ON

Presenter/First Author Email: desmond.moser@uwo.ca

Co-authors: Ivan Barker, University of Western Ontario, London, ON, Canada; David A Reinhard, Cameca Instruments Inc., Madison, WI; David Olson, Cameca Instruments Inc., Madison, WI; Peter Clifton, Cameca Instruments Inc., Madison, WI; Ty J Prosa, Cameca Instruments Inc., Madison, WI; David J Larson, Cameca Instruments Inc., Madison, WI; Anthony J Irving, Univ Washington, Seattle, WA

Published Material: A minor component (10%) of these findings was presented at Goldschmidt 2013 in Florence, IT.

Abstract Body: A rare record of the earliest history of Mars is accessible in the crystal and lithic clasts of meteorite NWA 7475, one of a group of recently discovered relatively water-rich stones from Rabt Sbayta, Morocco, interpreted to be a suevite-like regolith breccia [1]. SIMS U-Pb dating of the related meteorites by other workers [2,3] has identified zircons as old as 4.44 Ga making them invaluable physical evidence of martian crustal processes. The zircon population experienced a Pb-loss event approximately 3 billion years later, the cause of which is still being investigated. Here we present in-depth examination of the chemical and orientation microstructure of zircon and baddeleyite by EBSD and atom probe tomography (APT) in an effort to gain additional information on Early Mars bombardment history and subsequent metamorphism. FEG-SEM mapping of accessory phases in a thick section identified several hundred small zircon grains in the size range of 4 µm to 25µm in longest dimension (mean= 7µm) and over 100 baddeleyite grains of similar size distribution. A 3D APT map of an approximately 80nm x 80nm x 350nm volume of zircon was homogeneous with respect to trace elements including Li; however, U and Pb were below detection. EBSD mapping of an igneous zircon crystal clast revealed amorphous, U-rich domains that are now metamict, signifying a lengthy upper crustal residence. An APT map from an unfractured, crystalline domain reveals chains of nanoclusters of Fe, Al, Ca. These are interpreted, by analogy with terrestrial observations, to be due to fluid-assisted contamination along fractures during regolith metamorphism. APT geochronology of an anhedral baddeleyite crystal clast yields a Pb isotope ratio consistent with ≥4 Ga formation. A metamorphic nano-scale rim of zircon on this grain appears in a second APT map, and points to martian Si metasomatism of the regolith at some point prior to the meteoroid launch event. These and other nanoscale crystal histories of U-Pb dating phases will be presented to add to our growing picture of martian crustal processes preserved in these rare specimens. Title: Processing of X-ray microtomography images to investigate crystallized volcanic rock textures

Presenter/First Author: Fabio Arzilli, Organization Not Listed, Washington, DC

Presenter/First Author Email: arzilli.fabio@gmail.com

Co-authors: Margherita Polacci, INGV, Pisa, Italy; Don R Baker, McGill University, Montreal, QC, Canada; Patrizia Landi, , , ; Daniele Giordano, , , ; Lucia Mancini, Elettra-Sincrotrone Trieste, Basovizza, Italy

Abstract Body: X-ray computed microtomography has become a fundamental tool in geosciences to study rock textures directly in 3D. This technique is useful to study the vesiculation of pumices [1], but only recently there has been more interest to study the crystallization process using volumetric datasets. Crystal and silicate glasses often have similar density and absorption contrast, therefore, image processing requires more sophisticated procedures to separate them.

Feldspars are one of the most abundant crystalline phases of igneous rocks, hence their crystallization conditions and abundance are intensely investigated by geologists. Moreover, feldspar is one of the most difficult phases to segment during image analysis, making the separation of feldspars from the silicate glass a challenge.

Here we show that the crystallinity of natural pumice of Stromboli and synthetic trachyte from Campi Flegrei magma can be studied using microtomographic datasets. Data were collected using the propagation-based synchrotron X-ray phase contrast microtomography technique at the SYRMEP beamline of the Elettra-Sincrotrone Trieste Laboratory (Basovizza (Trieste), Italy). Although X-ray phase contrast imaging can improve the visualization of weakly absorbing features, making visible the edge of feldspars, the segmentation of these crystals cannot be directly obtained from the raw phase contrast X-ray images. Phase-retrieval methods are needed for extracting phases of interest. A single distance phase-retrieval algorithm [2] was applied to the dataset to improve the contrast between feldspar and glass. Through this technique we are able to isolate feldspars both in natural samples and in synthetic ones, and to perform quantitative analysis of these phases using volumetric datasets. Our preliminary results have demonstrated that phase retrieval processing will be an invaluable tool for geologists to study rock textures.

Abstract Body: Recent studies based on field and laboratory data have documented the effects of Deformation Bands (DBs) in fluid flow in porous rocks. The hydraulic properties of porous carbonates rocks could change abruptly due to the presence of DBs. The inner structure of DBs could show high variability in terms of textural and petrophysical properties, which have been traditionally assessed with 2D microscopy techniques.

The aim of this work is to perform a quantitative 3D image analysis of the microstructure of DBs hosted in porous carbonate grainstones by using a non-destructive 3D-imaging technique. The experiments consisted of the synchrotron X-ray computed microtomography (micro-CT) characterization of rock samples prepared in small parallelepipeds (4x4x40 mm size) and corresponding to grainstones highly affected by DBs exposed in San Vito Lo Capo peninsula (Sicily, Italy), Favignana Island (Sicily, Italy) and Majella Mountain (Abruzzo, Italy). For the analysis, the data is segmented in two main components porous and solid phases. The properties of interest are porosity, connectivity, a grain and/or porous textural properties, in order to differentiate host rock, DBs and their inner structure.

The preliminary results of the quantitative X-ray micro-CT image analysis indicate trends of porosity and connectivity for host rock, DB and zones therein. San Vito Lo Capo's sample presents the most complex structure of DB, which is composed by three inner zones. Wherein, the porosity and connectivity are reduced from the outer to the inner zone of the DB due to grain compaction, cementation and grain size reduction. For the samples of Favignana Island and Majella Mountain, no differentiated zones within the DBs were found. However, for the Majella Mountain's sample we observed a low porosity zone surrounding the DB that could be the result of water interaction. In general, we noted that the porous space within DB is poorly connected and it is about five times less than in the surrounding host rock. The preliminary results presented in this study and future analysis may be helpful for better understanding the inner structure of deformation bands and their implications to fluid flow in porous carbonates.

Title: INSIGHTS INTO THE ANALYSIS OF MICROMETRE-THIN RIMS USING LA-ICP-MS: DEPTH-PROFILE AND GRAIN MAPPING OF UNPOLISHED CRYSTALS

Presenter/First Author: Colter Joseph Kelly, University of Ottawa, Ottawa, ON

Presenter/First Author Email: colter.kelly@hotmail.com

Co-authors: David A Schneider, University of Ottawa, Ottawa, ON, Canada; Christopher RM McFarlane, University of New Brunswick, Fredericton, NB, Canada; Simon Jackson, Natural Resources Canada, Geological Survey of Canada, Ottawa, Canada

Published Material: Kelly, C.J., McFarlane, C., Schneider, D.A., and Jackson, S.E. (2014) Dating micrometre-thin rims using a LA-ICP-MS depth-profiling technique on zircon from an Archean metasediment:comparison with the SIMS depth-profiling method. Geostandards and Geoanalytical Research, DOI: 10.1111/j.1751-908X.2014.00314.x

Abstract Body: Zircon, in the presence of alkaline fluids, can undergo coupled dissolution-reprecipitation. This fluid mediated alteration manifests itself as µm-scale rims on the outer surfaces and within existing imperfections of zircon crystals. Laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) was examined as a tool to interrogate the lateral and depth variation of isotopic (U-Pb) and elemental (REE) distributions within the rims of unpolished zircons from an Archean metasediment. Our LA-ICP-MS U-Pb depth profile technique was able to identify micron-thin (<3 µm), concordant, isotopically distinct mineral domains (rims) characterized by a ca. 100 m.y. younger $^{207}Pb/^{206}Pb$ age associated with 2σ age-uncertainties as low ~0.2%, as well as elevated U content relative to the zircon interior (up to an order of magnitude). Our calculated penetration rate suggests that each laser pulse excavates depths of ~0.06 µm. Ages resolved through the LA-ICP-MS U-Pb depth profile method overlap, within 2σ uncertainties, the $^{207}Pb/^{206}Pb$ ages measured using SIMS U-Pb depth-profiling on the same population of zircon. The rims are further evinced by the presence of a relative enrichment (>3 orders of magnitude) in REE measured using an independent LA-ICP-MS depth-profiling technique on the same zircon. The enrichment of REE was used as an indicator of rim material. LA-ICP-MS techniques were developed to generate trace element concentration maps, with a lateral spatial resolution of 7 µm, of the outermost 3 µm of unpolished zircon grains. These maps demonstrate the heterogeneous nature of the crystallization of rim material, commonly demonstrating preferred growth along fractures or within isolated domains on the grain surface. The LA-ICP-MS techniques are capable of quickly identifying, and chemically and isotopically characterising zircon rims, which are an indication of low temperature, yet geologically significant, fluid events that may otherwise remain unidentified.

Title: Microstructural response of U-Pb dateable phases across the Vredefort impact structure, South Africa.

Presenter/First Author: Connor Lawrence Davis, University of Western Ontario, London,

Presenter/First Author Email: cdavis59@uwo.ca

Co-authors: Desmond Moser, Western University, London, ON, Canada; Ivan Barker, University of Western Ontario, London, ON, Canada

Abstract Body: The precise chronology of impact events on planetary surfaces has implications for Earth's crustal and bio-evolution. U-Pb isotopic dating of accessory phases such as zircon has proved valuable in the pursuit of an enhanced impact chronology, as sufficient shock damage and heating can cause up to 100% Pb-loss while preserving microstructures diagnostic of specific shock environments. Other geochronology phases (e.g. baddeleyite, monazite) also have the potential to contribute to the understanding of shock processes. However, there have been few systematic studies of how zircon and these minerals respond microstructurally and isotopically in a crater environment relative to benchmark shock indicator minerals such as quartz and plagioclase. Here we present initial findings of such a comparison across a known shock metamorphic gradient of ~60 GPa and 900 °C at the 2.020 Ga Vredefort dome, South Africa. Electron nanobeam techniques using a FEG-SEM were applied to map, contextualize and analyze various coexisting accessory phases and measure chemical and orientation microstructures (e.g. CL, EBSD) along with impact-induced melt inclusions. We report preliminary results from low, medium and high shock metamorphic grades of the deeply eroded crater floor. Coexisting phases at the low-grade site include zircon, baddeleyite and titanite, while the high-grade site hosts zircon, monazite and apatite. In all samples, accessory phases entirely enclosed by rock forming minerals (e.g. albite) show less shock damage than those along grain boundaries, revealing the heterogeneity of shock effects within a given sample. Shock microtwins are pervasive, whereas other diagnostic shock effects such as glass inclusions have only been identified in high and medium-grade samples. A more complete understanding of the microstructural and U-Pb response at Vredefort will become a reference for interpreting age and provenance of shocked detrital or *ex-situ* minerals from Earth, meteorites, Apollo breccias and future sample return missions.

Title: Thermodynamic modeling of the Li_2O-Na_2O-Al_2O_3-SiO_2 system under atmospheric pressure

Presenter: Pierre Hudon, McGill University, Montreal, QC

Presenter Email: pierre.hudon@mcgill.ca

First Author: Bikram Konar, McGill University, Montreal, QC

First Author Email: bikram.konar@mail.mcgill.ca

First Author Student?: No

Co-authors: Marie-Aline Van Ende, McGill University, Montreal, QC, Canada; In-Ho Jung, McGill University, Montreal, QC, Canada

Abstract Body: The system Li_2O-Na_2O-Al_2O_3-SiO_2 contains numerous minerals of geological interest such as eucryptite ($LiAlSiO_4$), spodumene ($LiAlSi_2O_6$), petalite ($LiAlSi_4O_{10}$), nepheline ($NaAlSiO_4$), jadeite ($NaAlSi_2O_6$) and albite ($NaAlSi_3O_8$) which are present in alkali-rich granites and pegmatites, for example. A critical assessment of the Li_2O-Na_2O-Al_2O_3-SiO_2 system was conducted using all available literature data. All the thermodynamic properties (like enthalpy, entropy, heat capacity, heat content, etc.) and phase diagram data (e.g. $LiAlO_2$-SiO_2 in Fig. 1a) were thermodynamically optimized and compared with experimental data. The solubility of SiO_2 in $NaAlO_2$, $LiAlO_2$, eucryptite, spodumene, nepheline, jadeite and albite was successfully modelled (e.g. in Fig. 1a) by taking into account the complex crystallographic structure of all the polymorphs involved. A set of optimized model parameters was obtained for all the phases of the system which could reproduce all reliable thermodynamic and phase equilibria data within experimental error limits over the entire temperature and composition range. Our database can be used along with Gibbs energy minimization software to calculate unknown thermodynamic properties and any phase diagram (such as the Li_2O-Al_2O_3-SiO_2 ternary

liquidus projection shown in Fig. 1b).

Title: TCInvestigator: Automated Calculation of Contours for THERMOCALC Pseudosections

Presenter/First Author: Mark A Pearce, CSIRO Earth Science and Resource Engineering Perth, Kensington, WA

Presenter/First Author Email: mark.pearce@csiro.au

Co-authors: Alistair White, CSIRO Mineral Resources Flagship, Perth, Australia; Michael F Gazley, CSIRO Mineral Resources Flagship, Perth, Australia

Published Material: A preliminary version of this software was presented on a poster at EGU 2014

Abstract Body: Forward modelling of bulk-rock compositions to constrain pressures and temperatures (P-T) of metamorphism based on mineral assemblage is a commonly used technique. The pseudosections produced contain a wealth of information about predicted mineral compositions and abundances that goes far beyond variations in mineral assemblage. In practice, utility of these parameters is limited because calculation of compositional isopleths and contours of modal mineral abundance are time consuming to calculate for THERMOCALC pseudosections. Our new software called TCInvestigator provides a quick and user friendly way to contour all compositional parameters and mineral modes across a THERMOCALC pseudosection.

TCInvestigator takes the postscript pseudosection diagram and creates a grid of points at a user-specified resolution. THERMOCALC is then used to calculate the equilibrium mineral assemblage at each point using an initial starting guess provided by the user (this can be calculated during initial pseudosection calculation). Once all points have been tried, any that failed to calculate are re-tried using interpolated starting guess values from the surrounding points. This procedure is iterated until no more solutions are found. Any remaining unsolved points are then interpolated numerically from surrounding solutions to produce a fully quantified set of mineral modes and compositions. Following calculation, the dataset can be contoured and output as figures, output as a Matlab readable binary structure or selected compositions written to an ASCII text file. Automated contouring using TCInvestigator allows the user to consider easily all compositional variables at one time. As new P-T conditions and bulk compositions are explored using improved thermodynamic datasets this software will provide a quick and simple way to identify key compositional and modal variations in the newly-modelled systems.

Title: Thermodynamic Properties of Dilute Aqueous Electrolytes and Non-Electrolytes at Elevated Temperatures, from Molecular Dynamics Simulations

Presenter/First Author: Matthew J Steele-MacInnis, ETH Zurich, Zurich,

Presenter/First Author Email: mjmaci@vt.edu

Co-authors: Denis Zezin, , , ; Noah Bieler, , , ; Philippe Hünenberger, , , ; Thomas Driesner, ETH Swiss Federal Institute of Technology Zurich, Zurich, Switzerland

Abstract Body: Thermodynamic properties of aqueous solutes are key parameters in geochemical modeling of fluid-driven and fluid-mediated processes. Properties at infinite dilution comprise the most commonly used solute standard state convention, and are thus required for essentially all fluid-rock reaction modeling. In this study we use classical molecular dynamics simulations to estimate thermodynamic quantities for ions, ion pairs and non-electrolytes at elevated temperatures and low to high pressures (i.e., from vapor-like to liquid-like fluid densities). Simulations are done using the SPC/E water model, and solutes including Na^+, Cl^-, $NaCl^0$and Ar are included with concentrations set to 0.01 molal. Hydration free energies for atoms, ions or ion pairs are calculated by lambda dynamics.

Hydration free energies of aqueous solutes at near-critical and super-critical temperatures show a systematic dependence on fluid density under isothermal conditions, with more pronounced density dependence at low pressures and only weak density dependence at high pressures. Hydration

free energies also show relatively weak isochoric temperature dependence at super-critical temperatures. The density dependence seems to reflect short-range and long-range density fluctuations resulting from solvation. Free energies of hydration for non-electrolytes show trends opposite to those for electrolytes. Differences in hydration free energies for neutral ion pairs compared to free ions are used to estimate dissociation constants at these conditions.

One advantage of the methods used here is that experimentally determined solvation free energies of electrolytes are difficult to deconvolute into cation and anion contributions due to the charge balance restriction, whereas the present data are implicitly resolved into contributions from individual ions. Moreover, thermodynamic data (hydration free energies) can be linked to other calculated properties, such as the solvation structure around ions and non-electrolytes. Correlations between free energies and structural data thus can be used to interpret the factors controlling thermodynamic properties.

Title: How to choose solution models for phase equilibria modeling of migmatitic metapelites?

Presenter/First Author: Pierre-Henri Trapy, Ecole Polytechnique de Montreal, Montreal,

Presenter/First Author Email: ptrapy@gmail.com

Co-authors: Felix Gervais, École Polytechnique, Montreal, QC, Canada

Abstract Body: Phase equilibria modelling is a widely used tool to investigate the evolution of metamorphic rocks. One approach consists in fixing the bulk chemical composition and calculating the mineral phase assemblages by minimizing the Gibb's free energy. Because mineral phases share chemical elements and compete with each other's, the choice of mineral solution models is of uttermost importance. Despite their wide use, few studies have tested the reliability of this technique by reproducing well-controlled cases, such as experimental studies and none have investigated whether a set of solution models performs better than others. In this study, we investigate these issues by calculating phase equilibria in the Na-Ca-K-Mn-Fe-Mg-Al-Si-H-Ti-O chemical system for three partial-melting experiments using different set of solutions models. These experiments span a range of pelitic bulk compositions and were conducted between 500 and 1000 MPa, as well as between 750 to 1050°C. The software Perple_X is used because it is the only one offering total flexibility for the choice of models. The stability field, compositions, and proportions of the various mineral phases for each calculation are compared with experimental results. We focus on biotite, garnet and plagioclase, for which the compositional isopleths are most commonly used for thermobarometry conducted with phase equilibria modeling. We show that it is possible to reproduce experimental results with relatively good accuracy (discrepancies generally varying by 20 to 50°C for a given pressure), notably for the biotite-in, the melt-in and Ti-oxides equilibria However, a specific set of solution models is required, and it is not necessarily composed of the models generally used.

Title: Multicomponent Diffusion Modelling Applied to the Sudbury Igneous Complex

Presenter/First Author: Quincy M C Poon, University of Toronto, Toronto, ON

Presenter/First Author Email: quincy.poon@mail.utoronto.ca

Co-authors: James E. Mungall, University of Toronto, Toronto, ON, Canada; Kirill Kompaniets, University of Toronto, Toronto, ON, Canada

Abstract Body: Chemical diffusion is an essential transport mechanism for many magmatic processes. Diffusion across interfaces separating liquid layers with initially stable density distributions may engender unstable density distributions leading to rapid homogenization of the layers. We developed a finite difference model to simulate diffusion in a multicomponent silicate melt in order to better understand the evolution and differentiation of igneous systems, in particular, the Sudbury Igneous Complex in Ontario, one of the largest meteorite impact craters on Earth. The Sudbury impact melt was differentiated into norite cumulates, quartz gabbro, and granophyre. Within the granophyre unit, there exists a second layer of quartz gabbro which suggests a reversal in the crystallization sequence. This reversal might be explained as a boundary between two melt bodies, separated by either temperature or composition or both, that must have allowed diffusion-driven chemical exchange.
The diffusion partial differential equation is modelled using the semi-implicit Crank-Nicolson finite difference scheme, which involves spatial discretization and solving a system of equations to advance in time. The diffusion coefficient is a proportionality constant between the molar flux and the concentration gradient. The matrix of diffusion coefficients is called the diffusion matrix and is obtained from empirical experiments on the five-component K20-Na20-Al2O3-SiO2-H2O system. Taking an average composition of the granophyre above the boundary and an average composition of the Copper Cliff offset dikes and projecting them onto the five component system, we ran the model at 1200 degrees at 5000 bar. Preliminary results show an overstable density distribution when the magmas are dry and fingering instabilities when >3 weight percent water is added to the upper layer; however, at approximately 2 weight percent water, the upper layer is able to diffuse stably with the lower layer, allowing the two magma bodies to evolve without being rapidly homogenized by diffusion-driven convection.

Title: Petrological Insights on the Northern Canadian Cordillera Lithosphere: in the Footsteps of Don Francis

Presenter/First Author: Benjamin R Edwards, Dickinson College, Carlisle, PA

Presenter/First Author Email: edwardsb@dickinson.edu

Co-authors: Kelly Russell, University of British Columbia, Vancouver, BC, Canada

Published Material: Presentation is synopsis of published (GSA Bull, Lithos, Bull Volc) and unpublished data

Abstract Body: Geochemical, petrological and volcanological studies of the Neogene to Recent volcanic rocks distributed across the northern Canadian Cordillera by Don Francis and coworkers have contributed greatly to our current understanding of the origins, architecture and dynamics of the Cordillera lithosphere. Their work has generated many critical new hypotheses concerning: (I) the sources for the highly undersaturated magmas (e.g., nephelinites), especially highlighting the potential role of amphibole for influencing their trace element characteristics, (II) using melt chemistry to map lithospheric structure, and (III) geochemical and geophysical properties of peridotite xenoliths to aide interpretations of lithospheric structure from broad-scale geophysical studies (i.e., LITHOPROBE). Here we summarize our recent research progress in the northern Cordillera that over the past 20 years has been informed and inspired by Don's work and that also addresses these three broad topics.

(I) MAGMA ORIGIN, TRANSPORT & ERUPTION: uses of thermodynamic modeling to constrain the intensive properties (e.g., activity of silica and oxygen fugacity) of the source regions, the petrogenetic relationships between nephelinites, basanites and alkali olivine basalts, and the depths of initiation of phenocryst crystallization and magma storage.

(II) XENOLITH STUDIES OF THE MANTLE LITHOSPHERE: combining peridotite geothermometry with models for lithospheric geotherms to constrain depths of xenolith entrainment, identification of 'cryptic' metamorphic events in high grade quartzofeldspathic metamorphic xenoliths, and comparison of peridotite-hosted amphibole veins to inferred lithospheric melt compositions.

(III) GLACIOVOLCANIC INSIGHTS ON PALEOCLIMATE: constraining the timing of formation and decay of the Cordilleran ice sheets, as well as the potential fundamental isostatic controls of ice-loading on hot, possibly melt-laden crustal and mantle lithosphere.

Title: Delving into density and its role in magmatic processes

Presenter/First Author: Nicholas T Arndt, , Meylan,

Presenter/First Author Email: Nicholas.Arndt@ujf-grenoble.fr

Co-authors: Silvano Sinigoi, , ,

Abstract Body: Density difference between liquid and solid causes convection in magma chambers, controls mixing between primitive and evolved magmas and influences where minerals crystallize. Magmas leave their mantle source and move upwards because most silicate liquids are less dense than surrounding rocks. But this is not always the case. Fe-rich liquids produced by plagioclase crystallization are denser than normal crustal rocks, and following accumulation of plagioclase in anorthosite massifs, they migrate downward to accumulate deeper in the crust.

In the mafic-ultramafic conduits that host Ni-sulfide deposits, magma flows in two directions. The segregation of mafic minerals (olivine, pyroxene) and immiscible Ni-Fe sulfide liquid produces low-density evolved liquid, which continues towards the surface, and a dense slurry of crystals plus sulfide and silicate liquids. These slurries normally accumulate on the floor of the conduit, but if the floor is steeply sloping, the slurries slump downwards, depositing their load of crystals and sulfide liquid deeper in the conduit system. The latter process may play an important role in generating Ni sulfide ore deposits.

Many mafic-ultramafic intrusions; e.g. the Uitkomst intrusion in South Africa and the mafic complex in the Ivrea zone of Italy, contain remarkable rafts of sedimentary rock midway through the intrusion. The rafts have a near-horizontal orientation and separate lower ultramafic cumulates from overlying gabbroic rocks. In the Uitkomst intrusion, the rafts are aligned with strata with the same lithology in the surrounding rocks. These features suggest that magma was emplaced slowly and passively between layers of more resistant sedimentary rocks. Differentiation arises from the input of dense mafic magma into the lower portions of the intrusion while less-dense evolved liquids penetrate higher in the intrusion.

Title: Primitive replenishment of Neoproterozoic Franklin Sills on Victoria Island

Presenter/First Author: Jean H J Bedard, Geological Survey of Canada, Quebec, QC

Presenter/First Author Email: jbedard@nrcan.gc.ca

Co-authors: Ben Hayes, , , ; Charlie Beard, , , ; Johan C J Lissenberg, Cardiff University, Cardiff, United Kingdom; Dominique Weis, University of British Columbia, Vancouver, BC, Canada; James S Scoates, University of British Columbia, Vancouver, BC, Canada; Boswell A Wing, McGill University, Montreal, QC, Canada; H Richard Naslund, Binghamton University, Binghamton, NY

Published Material: The basic story is in 3 papers, 1 accepted in press, 2 submitted.

Abstract Body: The Neoproterozoic (~723-716 Ma) Franklin Large Igneous Province on Victoria Island, Arctic Canada, has a sill-dominated magma plumbing system. Franklin magmas ascended along fault-guided feeders, some reaching the surface to erupt as the Natkusiak flood basalts. We investigated three sections through a 20-40m thick sill, separated by a total distance of >50 km, and emplaced at the same stratigraphic horizon. This sill is geochemically equivalent to the basal Natkusiak lavas, and has a basal olivine-enriched layer containing ≤ 55% olivine, overlain by an internally-differentiated gabbroic unit. Pb, Sr and S isotopic data show that the olivine basal layer is not consanguineous with the gabbro, which implies that this sill is a composite intrusion. We suggest that the olivine-enriched basal layer originates from a slurry replenishment event injected into a partially crystallized gabbroic sill. A gradual westward shift towards more Fe-rich olivine zone bulk compositions suggests that this olivine slurry gradually mixed with the resident gabbroic mush as it propagated westward. Along strike comparisons of Pb isotopic compositions suggest that at least three chemically distinct magmas were injected into this sill, each of which assimilated different crustal contaminants prior to emplacement. Near the inferred conduit feeder, Pb isotopic compositions and an abundance of calc-silicate reaction products suggest that magmas assimilated small amounts (<10%) of dolostone. We infer that much of the assimilation occurred within the feeder conduit because these commonly contain cataclastic breccias, so increasing surface area and reactivity. We suggest that the high-Fo content of some olivine crystals records buffering of melt MgO/FeO during dolostone assimilation.

Title: THE ASCENT OF KIMBERLITE: INSIGHTS FROM OLIVINE

Presenter/First Author: Kelly Russell, University of British Columbia, Vancouver, BC

Presenter/First Author Email: krussell@eos.ubc.ca

Co-authors: Curtis Brett, , , ; Graham D Andrews, California State University Bakersfield, Bakersfield, CA; Thomas Jones, , ,

Published Material: We have a paper in review with EPSL and presented a earlier form of this material at the 2014 Goldscmidt meeting (I was an invited speaker)

Abstract Body: Kimberlite magmas derive from ultra-deep (≥200 km) mantle sources and transport high loads (>25 vol. %) of mantle-derived xenoliths and xenocrysts to the Earth's surface. A distinctive trait is their high abundance of ellipsoidal-shaped olivine grains derived from disaggregation of mantle peridotite. Russell et al. (2012) provided a simple model for the rapid ascent of these enigmatic magmas involving deep-

seated fluid production driven by preferential assimilation of orthopyroxene (Opx) by parental carbonatitic melts [1]. Here we expand on this model using evidence embedded in morphological (rounding) [2,3], textural (sealed/healed cracks) [2], and surface (smooth and flakey) [3] properties of xenocrystic olivine. These features develop during transit through the cratonic mantle lithosphere. The ascent process operates as a "*kimberlite factory*" (Fig. 1) wherein progressive upward dyke propagation of the carbonatitic melt fractures, entrains and disaggregates peridotitic mantle. Opx xenocrysts are preferentially assimilated causing deep-seated exsolution of a CO_2-rich fluid providing buoyancy for the accelerating and turbulent ascent of the magma. Individual olivine xenocrysts undergo abrasive milling in the fluid-rich head of the dyke and decompression cracking over ascent distances of 15-25 km. Continued chemical modification of the carbonatitic melt by Opx assimilation results in a silica-enriched, olivine-saturated *kimberlitic* melt that crystallizes olivine to form overgrowths on milled and rounded olivine xenocrysts. The lack of decompression cracks within olivine overgrowths indicates that the melt becomes saturated with respect to olivine at depths < 25 km from the Earth's surface.

Title: CO_2-rich arc volcanism on the early Earth

Presenter/First Author: Norman H Sleep, Stanford University, Stanford, CA

Presenter/First Author Email: norm@stanford.edu

Co-authors: Francis Albarede, Ecole Normale Supérieure Lyon, Lyon, France; Dennis K Bird, Stanford University, Stanford, CA; Peggy A O'Day, University of California Merced, Merced, CA; Minik Thorleif Rosing, Natural History Museum of Denmark, Copenhagen, Denmark; Everett Shock, Arizona State University, Tempe, AZ

Published Material: 30% in various journals

Abstract Body: The moon-forming impact left the Earth with a dense (ca. 100 bar) and hot (ca. 200 C) CO_2-rich atmosphere. The Earth did not become habitable until the bulk of this CO_2 subducted into the mantle. Specially, thermophile conditions (ca. 100 C) existed when 25 bar of CO_2 remained and clement conditions with a few bars remaining. Oceanic crust was likely thick ca. 20 km. Rapid episodes of subduction and spreading likely produced most of the oceanic crust. Axial magma chambers existed beneath basaltic lids. Circulating seawater fully carbonatized the uppermost basalt. There was net subduction of CO_2 into the mantle, but CO_2-rich arc volcanics were likely common. Peralkaline volcanism has been rare since the Hadean as these conditions have never returned. Modern peralkaline rocks and published laboratory experiments provide a guide to the composition of these rocks. Seawater and meteoritic water reacted with the arc rocks to produce alkaline, reducing brines. Elements that both preferentially entered the arc lavas and dissolved into surface water built up in the ocean and the crust. By 3.8 billion years ago, CO2 subduction was nearly complete. Life had originated and atmospheric CO_2 had waned to near modern levels.

Title: Early differentiation processes recorded by ^{142}Nd and ^{182}W in Eoarchean rocks from Isua

Presenter/First Author: Hanika L Rizo Garza, Carnegie Inst Washington, Washington, DC

Presenter/First Author Email: hrizo@ciw.edu

Co-authors: Richard J Walker, Univ Maryland, College Park, MD; Richard W Carlson, Carnegie Institution for Science, Washington, DC; Mathieu Touboul, University of Maryland College Park, College Park, MD; Mary F Horan, Carnegie Inst of Washington, Washington, DC; Igor S Puchtel, University of Maryland College Park, College Park, MD; Maud Boyet, Laboratoire Magmas et Volcans, Clermont-Ferrand Cedex, France; Minik Thorleif Rosing, Natural History Museum of Denmark, Copenhagen, Denmark

Published Material: Part of the results were presented in the AGU Fall Meeting 2014.

Abstract Body: The earliest phases of Earth's evolution can be investigated using the short-lived ^{182}Hf-^{182}W and ^{146}Sm-^{142}Nd isotopic systems. Tungsten is siderophile while Hf is lithophile, so metal-silicate segregation fractionates the Hf/W ratio of both planetary mantles and cores. Both daughter nuclides, W and Nd, are more incompatible than the parent nuclides Hf and Sm, so modification to Hf/W and Sm/Nd ratios in the silicate Earth can also be caused by crystal-liquid fractionation. Because of the short half-lives of ^{182}Hf and ^{146}Sm (8.9 Ma and 103 Ma, respectively), variations in ^{182}W and ^{142}Nd can only be produced, respectively, during the first ~ 50 Ma and ~ 500 Ma of Earth's history. Here we present data from 3.8-3.3 Ga mafic samples from the Isua supracrustal belt (ISB, SW Greenland). The mantle source of these rocks was characterized by ^{182}W and ^{142}Nd excesses, relative to terrestrial standards and modern rocks, of up to 15 ppm and 13 ppm, respectively. Possible models to explain the ^{182}W excesses include: 1) the ISB rocks derived from portions of the post-core formation mantle that were isolated from late accretionary additions. However, this model is not supported by the HSE abundances in these rocks. 2) ISB rocks derive from portions of the mantle that differentiated in an early magma ocean. This last model implies that high Hf/W domains can survive for over 1 Ga in the convecting mantle. The ^{182}W/^{184}W and ^{142}Nd/^{144}Nd ratios in the Isua rocks are not correlated. This suggest that either the differentiation of the magma ocean took place within the first ~ 60 Ma of the Earth history or, because of the different time scales for ^{142}Nd and ^{182}W growth, two or more differentiation events are responsible for the isotopic enrichments. Samples from the ISB, with ages between 3.8 Ga and 3.3 Ga, show gradual diminution of ^{142}Nd anomalies until they are no longer resolved by ~ 3.3 Ga. By contrast, there is no diminishment of the ^{182}W variability with time in the ISB suite. Tungsten concentrations of the samples studied range between 0.1 ppm and 3 ppm. The high W concentrations in some of these samples likely reflect the mobility of W in hydrous fluids. The W isotopic composition of the Archean mantle through time is estimated from the samples with W concentrations expected for typical mantle melts of a source with bulk silicate Earth-like (13 ppb) W concentrations.

Title: Trying to see through the metamorphism: trace element zoning in the assemblages of the Nuvvuagittuuq Greenstone Belt, Canada

Presenter/First Author: William G Minarik, McGill University, Montreal, QC

Presenter/First Author Email: william.minarik@mcgill.ca

Co-authors: Mohadeseh Majnoon, McGill University, Montreal, QC, Canada; Jonathan O'Neil, University of Ottawa, Ottawa, ON, Canada

Published Material: 20% presented at the 2011 GAC-MAC.

Abstract Body: The Nuvvuagittuuq Greenstone Belt (NGB), northern Quebec, is some of the oldest preserved crust yet found: it has a minimum age of 3.75 Ga and is possibly as old as 4.3 Ga. The supracrustal units (which include remnant pillow structures) offer a window into Eoarchean crustal formation and seafloor processes if the effects of the intervening history can be characterized. Unfortunately these rocks have been pervasively metamorphosed, probably four times, most recently during a craton-wide thermal event at 2.7 Ga. Several mafic sequences (Ujaraaluk unit) record upper amphibolite conditions with high-variance assemblages of garnet + biotite + plagioclase + quartz (no amphibole) or biotite + amphibole + plagioclase + quartz ± garnet (cummingtonite or anthophyllite or Mg- or Fe-hornblende occurring alone or in combination).

These phases are unzoned with respect to major cations, suggesting a prolonged residence at elevated temperatures. Conventional geothermobarometry applied to both assemblages gives temperatures and pressures clustering around 610°C and 4.2 kbar, respectively. Pseudosection calculations confirmed the results from conventional thermobarometry. No parts of the NGB retain greenschist facies peak conditions.

The pervasive metamorphism has thus largely erased the record of previous metamorphism or the original protolith mineralogy. Garnets from some samples do record multiple concentric yttrium concentration zones, and accessory minerals are complexly zoned. Monazite in particular frequently displays a core with oscillatory zoned thorium and uranium concentrations, surrounded by overgrowths with distinct U, Th, REE concentrations. These slow diffusing trace elements may help constrain earlier parts of the metamorphic history of these rocks, including element mobility.

Title: Mercury abundance in the mantle and relevance to the moderately volatile element budget of the Earth

Presenter/First Author: Dante Canil, University of Victoria, Victoria, BC

Presenter/First Author Email: dcanil@uvic.ca

Co-authors: Peter William Crockford, McGill University, Montreal, QC, Canada; Kevin H Telmer, , Victoria, BC, Canada; Ricardo Rossin, University of Victoria, Victoria, BC, Canada

Abstract Body: Despite a long history of use for Hg as a pathfinder to locate ore deposits, the abundance of Hg remains the most poorly constrained element in the Earth's crust and mantle. We measured Hg concentrations in 37 igneous rocks from an arc crustal section and in 30 mantle peridotites from ophiolite, orogenic massif and xenolith settings. The distribution of Hg in the rock samples shows a 'nugget effect', suggesting it is concentrated in a trace phase, likely sulfide. The abundance of Hg in the crustal samples varies from 0.9 - 8 ppb and correlates with S and Cu but no other index of differentiation. The mean of our data produces 2.9±2.6 Hg for the bulk crust, a factor of 10 lower than previous estimates. The mantle peridotites contained 0.2 - 5 ppb Hg and a correlation of Hg with Al, Cu, S or loss on ignition (LOI) depending on sample type. Secondary uptake of Hg due to low-temperature alteration or mantle metasomatism is evident in the ophiolite and orogenic massif samples, respectively. The primitive upper mantle (PUM) is estimated to contain 0.4 - 0.6 ppb Hg based on a depletion/enrichment trend in fresh peridotite xenolith samples that demonstrably retained their primary Cu/S during emplacement. During mantle melting to produce the crust, Hg behaves as a mildly incompatible element similar to Cu with D_{Hg} residue/melt ~ 0.1. For a chondritic abundance of 310 ppb Hg, our estimate for Hg in the mantle shows this element has a similar depletion to Se, Te or S in the bulk silicate Earth. As in the case of Se or Te, the bulk silicate earth depletion in Hg may be due to siderophile behaviour during accretion but this remains to be tested by experiment.

Title: Se-Te fractionation by sulfide–silicate melt partitioning: Implications for the late accretion history of Earth

Presenter/First Author: James M Brenan, University of Toronto, Toronto, ON

Presenter/First Author Email: brenan@geology.utoronto.ca

Co-authors: Neva Fowler-Gerace, University of Toronto, Toronto, ON, Canada

Published Material: preliminary results have been presented in past meetings, and a paper in EPSL is in the final revision stage

Abstract Body: Selenium and tellurium are geochemically unique, being both volatile and strongly siderophile, so their mantle abundances may preserve information on the late accretion history of Earth. However, the effects of melting and crystallization on the mantle Se and Te composition are not well constrained, especially in terms of the role of residual sulfide. To better understand this behaviour, partitioning of Se and Te has been measured between coexisting sulfide liquid, monosulfide solid solution (MSS) and silicate melt at 0.9-1.5 GPa, 1200-1300ºC, FMQ -1.2 to -1.6 and 3-22 wt% FeO in the silicate melt. Se and Te are highly compatible in the sulfide phase relative to silicate liquid (D > 600), with the identity of the sulfide dictating the sense of Se-Te fractionation. Measured D_{Te}/D_{Se} is ~5-9 for sulfide liquid/silicate liquid partitioning, but MSS/silicate melt partitioning yields D_{Te}/D_{Se} of ~0.5-0.8. At fixed fO_2, $D^{SulLiq/SilLiq}$for both Se and Te decrease ~8-fold as silicate melt FeO increases from 3-22 wt%. Assuming a chondritic mantle Se/Te, predicted MSS and sulfide liquid compositions are generally in accord with natural mantle sulfides. Agreement is less so for orogenic and ophiolitic suites, likely owing to Te redistribution in accessory PGM. Notably, Se/Te in subduction-related Yakutian diamond inclusions are significantly lower than values expected from a chondritic mantle, suggesting that the subducted crust, or fluids derived therein, develops Se/Te much lower than chondritic values; subduction may therefore provide a means to lower the Se/Te of the mantle through time. The Se/Te ratio of silicate melt derived from a sulfide liquid-saturated mantle is significantly higher, and more variable, than for silicate melt in equilibrium with residual MSS. The relatively high Se/Te in MORB is therefore consistent with derivation from a chondritic mantle containing residual sulfide liquid. Model results for sulfide-saturated melting residues predict little deviation in Se/Te or Se and Te abundances relative to initial values. In contrast, sulfur-free, refractory orogenic harzburgites show a range of Se/Te (both sub and suprachondritic), the origin of which is unclear. Experiments are in progress to assess the trajectory of residual solids after sulfide exhaustion.

Title: The Origin of Fe-rich Domains in the Earth's Mantle

Presenter/First Author: Dejan Milidragovic, Laval University, Quebec City, QC

Presenter/First Author Email: dejan.milidragovic604@gmail.com

Co-authors: Don Francis, McGill University, Montreal, QC, Canada

Abstract Body: Primitive lavas, mantle xenoliths, and melting experiments indicate that the bulk of the Earth's mantle has a limited range of Mg-numbers, centered at ~0.90. The relatively low FeO content of the Earth's mantle (~8 wt. %) contrasts with the relatively high inferred FeO contents of the Martian mantle and of the basaltic meteorites derived from the asteroid belt. Rare, predominantly Neoarchean (ca. 2.7 Ga), ultramafic lavas and plutonic rocks (ferropicrites) on Earth resemble the FeO-rich SNC and HED meteorites and require mantle sources with significantly lower Mg-numbers (<0.81) than those of the bulk of the Earth's mantle. The occurrence of ferropicrites on Earth suggests the existence of volumetrically minor, but widespread, FeO-rich heterogeneities in the mantle during the Archean.

The origin of inferred FeO-rich heterogeneities in the Earth's mantle remains poorly understood, but their existence may be of fundamental importance to the understanding of the Earth's accretion history and chemical evolution. A number of hypotheses have been proposed to explain the petrogenesis of ferropicrites and the anomalous FeO-enrichment in the Earth's mantle. Models invoking mantle metasomatism by Fe-rich melts/fluids do not account for the relatively flat trace element profiles of "subalkaline" ferropicrites, nor the absence of correlation between trace-element and FeO enrichments in the "alkaline" ferropicrites. Similarly, producing FeO-rich residual peridotite by ancient garnet fractionation in a Hadean magma ocean is inconsistent with the Archean Nd model ages of ferropicrites. These limitations suggest that the Fe-enrichment of ferropicrite mantle sources may be primary. The major element similarities between the ferropicrites and basaltic meteorites favour a model involving the late addition of Fe-rich peridotite via meteorite bombardment.

Title: An Archean Ferropicrite Conundrum

Presenter/First Author: Claude T Herzberg, Rutgers Univ, Piscataway, NJ

Presenter/First Author Email: herzberg@rci.rutgers.edu

Abstract Body: The iron content of the mantle plays an important role in mantle geodynamics owing to its impact on buoyancy. Xenolith and outcrop occurrences indicate Earth's bulk mantle is similar to peridotite having about 8% FeO, although it can be subsequently modified by a variety of processes. Experimental petrology and calculations show that many primitive olivine-phyric lavas are consistent with partial melting of normal mantle having 8% FeO; Phanerozoic examples are modern MORB and many, but not all, magmas in ocean islands and large igneous provinces; Archean examples are common basalts in greenstone belts and komatiites. Rare Archean ferropicrites in lavas and sills have the highest FeO contents on Earth, they are distributed in all cratons [1], and their importance has been underappreciated. They have been interpreted as melting of an iron-rich mantle source which itself was produced by late meteorite infall of Mars-like compositions [1, 2], by solidification of Earth's magma ocean [3] or other processes [2]. However, calculations show that the FeO content of a primitive lava is actually compatible with a range of mantle FeO contents [4]. For example, it is possible that some ferropicrites were produced by partial melting of normal mantle peridotite having 8% FeO, but this would have required unusually high pressures. One approach to the problem involves testing the plausibility of a high pressure origin; if it can be excluded from other lines of evidence, then an iron-rich mantle origin will be much more secure. Title: Experimental investigation of the mantle sources and melting conditions for Mercury's basalts

Presenter/First Author: Olivier Namur, University of Hannover, Hannover,

Presenter/First Author Email: o.namur@mineralogie.uni-hannover.de

Co-authors: Max Collinet, , , ; Bernard Charlier, University of Liège, Sart Tilman, Belgium

Abstract Body: Chemical measurements of Mercury's surface by MESSENGER have been used to distinguish two geochemical provinces: (1) the Northern Volcanic Plains (NVP) made up of low-Mg basaltic komatiites and the Intercrater Plains and Heavily Cratered Terrains (IcP-HCT) made up of high-Mg komatiites. Here we present intermediate- to high-pressure and high-temperature phase relationships of two compositions relevant to Mercury's surface (NVP and IcP-HCT). Assuming that the mantle source is polymineralic, we use experimental data to infer the multiple saturation point (MSP) of surface lavas, i.e. pressure and temperature of melt generation in the mantle based on the co-saturation of forsterite (*Fo*) and enstatite (*Ens*) as liquidus phases. Starting compositions were based on X – Ray Spectrometer (XRS) data from solar flares. Given the relatively high sulfur concentration of Mercury's lavas, we performed experiments on sulfur-free and sulfur-saturated starting compositions. We ran experiments for 4-8 hours at 1310-1650°C. All experiments show a large proportion of quenched melt with a variable, but generally low, proportion of crystal phases. For the sulfur-free NVP composition, experiments are saturated with *Fo* from 0.1 to 1.0 GPa (1310-1410°C), *Fo* and *Ens* at 1.2 GPa (1440°C) and *Ens* at 1.5-2.0 GPa (1450-1470°C). These data suggest that the position of the MSP is situated at ca. 1.2 GPa and 1450°C. For the IcP-HCT composition, the MSP is located at 1.8 GPa (1650°C). The presence of sulfur in starting composition changes significantly the conditions of the MSP (NVP: 0.75 GPa, 1370°C; IcP-HCT: 0.75 GPa, 1450°C) due to the depression of the liquidus in the presence of volatiles. The MSPs that we obtain, together with the major element compositions of surface lavas, indicate that at least two contrasted mantle sources contributed to volcanic activity at Mercury's surface. Mercury's mantle may therefore be vertically or possibly laterally stratified with a lherzolitic mantle at great depth (>1.5 GPa) and a harzburgitic shallower mantle.

Title: Hydrous Phase Equilibria of the Upper Martian Mantle: Constraining Water Saturated Solidus to 4 GPa

Presenter/First Author: Aleksandar Miskovic, University of British Columbia, Yellowknife, NT

Presenter/First Author Email: amiskovic@eos.ubc.ca

Published Material: Presented at the Goldschmidt 2009 conference in Davos in an alternate form

Abstract Body: The melting behaviour of an undegassed Martian mantle was investigated to explore the potential influence of water on the mode of early planetary differentiation. Mars is a particularly interesting planet given that it accreted from a chondritic mix richer in volatile elements than other terrestrial bodies and because its size is equivalent to a proto-planet just before the giant impact stage suggesting that Mars might have escaped the formation of a magma ocean which would have largely obliterated the evidence of early accretion and differentiation. Experimental phase relations from terrestrial studies predict storage of significant amounts of water deep inside the planetary interior in the form of hydrous Mg-silicates (talc, chlorite, antigorite) and nominally anhydrous minerals such as stishovite, majorite or the high-pressure olivine polymorphs wadsleyite and ringwoodite. A majority of the experimental work however, is based on the simplified terrestrial mantle analog compositions and little is known about the effects of Fe, Al, Cr, P that are both important constituents of the Martian mantle and may significantly influence phase equilibria. For example, apatite and spinel will be stabilized to higher pressures in Mars than in Earth as a consequence of the higher mantle phosphorus and chromium contents. The reduced, Fe^{2+}-enriched and Al-deficient mantle of Mars will also restrict the stability of olivine to lower pressures while hydrous Mg-silicates such as amphibole and chlorite will break down at considerably lower temperatures in the less magnesian Martian mantle. Furthermore, the position of H_2O-saturated solidus relative to the stability fields of hydrous minerals has only been closely scrutinized at relatively low pressures below 3.0 GPa (Médard and Grove, 2007). The melting relations of dense hydrous silicates, and in turn the dominant phase regimes in deep mantle of early Mars depend on where and to what extent the slope of the wet high-pressure solidus reverses to positive dP/dT in deep Martian mantle. Recent results of experimentally determined hydrous phase equilibria and melting relations from wet Martian mantle above 3 GPa are shown and compared to the existing thermal models of planetary evolution.

Title: A Planetary Perspective on the Origin of Fe-rich Basalts

Presenter/First Author: Don Francis, McGill University, Montreal, QC

Presenter/First Author Email: donald.francis@mcgill.ca

Co-authors: Dejan Milidragovic, Laval University, Quebec City, QC, Canada

Published Material: Part of this has been presented orally at the GSA Fall Meeting in Vancouver

Abstract Body: The basalts of the terrestrial planets document a radial increase in the Fe content of their mantle sources that likely reflects the fractionation of Fe during the condensation of the Solar nebula. Orbital dynamic arguments for wide feeding zones during the accretion of the terrestrial planets have overshadowed the classic demonstration by Lewis (1972) that the metal/silicate ratios of the planets are broadly consistent with those predicted by the solar condensation sequence for a radial decrease in temperature in the Solar nebula. As predicted by Lewis, recent planetary basalt data indicates that the Fe content of the Mercurian mantle appears to be the lowest in the Solar system, whereas the mantles of Mars and 4 Vesta (Eucrite meteorites) have the highest Fe contents. In keeping with numerical simulations of planetary accretion, however, this radial increase in mantle Fe is not continuous. The Venusian and modern Terrestrial basalts have similar intermediate Fe values, whereas there is a discontinuous increase to the Fe contents of the basalts of Mars and 4 Vesta. A similar discontinuity in Fe exists between Archean komatiites and ferropicrites on the Earth, and between Highland and Mare basalts on the Moon, with the latter two in both cases having Fe contents similar to those of Mars and 4 Vesta. Broadly, there are 2 distinct basalt populations. One poor in Fe, but high in Al, characteristic of the inner terrestrial planets, and the other rich in Fe, but poor in Al, characteristic of Lunar Mare basalts, Archean ferropicrites on the Earth, and the basalts of Mars and the inner asteroids. This dichotomy may reflect the existence of a "sulfide line" in the early Solar nebula at approximately 700K between the orbits of the Earth and Mars. Sunward of the sulfide line, the Fe content of silicate condensates reflects equilibria with metallic Fe and increases radially with decreasing temperature. Outward of the sulfide line, however, the Fe content of silicate condensates will be buffered at a relatively high value determined by the relative Solar abundance of Fe and S. The mantle sources of Archean ferropicrites on the Earth and Lunar Mare basalts may reflect the addition of Fe-rich material during the late heavy bombardment via the destabilization of the inner asteroid belt during the outward migration of Jupiter and Saturn.

Title: A hierachial classification of perovskite super-group minerals

Presenter/First Author: Roger Howard Mitchell, Lakehead University, Thunder Bay,

Presenter/First Author Email: rmitchel@lakeheadu.ca

Co-authors: Anton Chakhmouradian, University of Manitoba, Winnipeg, MB, Canada; Mark Welch, , ,

Abstract Body: Some naturally-occurring oxides, fluorides, hydroxides, arsenides and silicates adopt crystal structures based upon, or which are derivatives of, the aristotypic cubic ternary perovskite structure (ABX_3), as exemplified by the synthetic compounds $SrTiO_3$ and $KMgF_3$ and their mineral counterparts, tausonite and parascandolaite. On the basis of the extensive studies of synthetic perovskite-structured compounds it is possible to derive a hierarchy of hettotype structures which are produced

by: (1) tilting and distortion of the BX_6 octahedra; (2) ordering of *A*- and/or *B*-site cations; (3) formation of *A*-, *B*- or *X*-site vacancies. This hierarchical scheme as applied to naturally-occurring minerals results in the proposed recognition of a perovskite super group. Sub-groups include: (1) single ternary (ABX_3) ideal (tausonite, isolueshite) and distorted (bridgmanite, perovskite, loparite, lueshite,lakargiite, megawite, neighborite, parascandolaite) perovskites, and others which exhibit second order Jahn-Teller distortions (macedonite, barioperovskite); (2) *B*-site cation ordered double ($A_2BB'X_6$) perovskites (elpasolite, cryolite, simmonsite, vapnikite); (3) Anion-deficient ($A_2B_2O_5$) perovskites (brownmillerite, srebrodolskite); (4) *A*-site vacant single- and double hydroxyperovskites (dzhalindite, bernalite, schönfliesite, stottite and mopungite subgroups); (5) *A*-site vacant quadruple perovskites (skutterudite subgroup); (6) *B*-site vacant double perovskites (diaboleite). Common ternary oxide perovskites typically exhibit space group variations resulting from solid solution between potential end-member compositions, and complete characterization requires single-crystal structure determination. In some ambiguous cases vibrational spectroscopy (Raman, infrared) can provide critical additional information that allows a correct choice of space group.

Title: Systematics Of Spin Crossovers Across The Rare-earth Cobaltites (RECoO3)

Presenter/First Author: Mehmet Topsakal, University of Minnesota Twin Cities, Falcon Heights, MN

Presenter/First Author Email: metokal@gmail.com

Co-authors: Renata M Wentzcovitch, University of Minnesota Twin Cities, Minneapolis, MN

Published Material: Paper was submitted to Physical Review B. The results will also be presented at APS March Meeting 2015.

Abstract Body: Using first-principles plane-wave calculations, we investigate the structural and electronic properties of rare-earth cobaltites ($RECoO_3$). Structurally consistent Hubbard U treatment was shown to essential for proper description of strongly correlated cobalt-d electrons. We successfully capture the experimentally observed structural trends and give first-principles insights on interesting phenomena related with the cobalt spin state change. It was demonstrated that increase of crystal-field splitting energy between e_g-t_{2g} orbitals and shrinking of unoccupied σ*-bonding e_g bands are responsible for the increase of onset spin-state transition temperature along the series. We believe that Hubbard U values presented in this study will allow further predictive studies of cobaltites.

Title: Crystal Chemistry of Chalcogenide Perovskites and Related Materials

Presenter/First Author: Nancy Ross, Virginia Tech, Blacksburg, VA

Presenter/First Author Email: nross@vt.edu

Co-authors: Jing Zhao, , ,

Abstract Body: There have been numerous studies of oxide perovskites with ABO_3 stoichiometry that show how the flexible structure of perovskite can accommodate a variety of A and B-site atoms, yielding a variety of properties that are exploited in technological applications. Recently, there has been growing interest in ABX_3 (X=S,Se) perovskites including their potential use in photovoltaic applications [1]. Many ABX_3 chalcogenides have been reported that adopt the well-known $GdFeO_3$ perovskite structure with P*nma* symmetry. Examples of sulfide perovskites include $CaZrS_3$, $SrZrS_3$, $BaZrS_3$, $BaUS_3$, $CaHfS_3$, $BaHfS_3$, $EuZrS_3$, and $EuHfS_3$ [2]. Moreover, substitution of sulfur (and selenium) for oxygen in ABX_3 leads to a number of structure types not commonly observed in ABO_3 compounds, including the NH_4CdCl_3 structure which has been observed in $SnZrS_3$, $PbZrS_3$, $SnHfS_3$, $PbHfS_3$, Sn_2S_3, $EuZrS_3$, $LaCrSe_3$ [3 and references therein] and more recently reported in $SrZrS_3$ [4] and $SrZrSe_3$ [5]. In some cases such as $BaTiS_3$, a hexagonal phase belonging to space group P63/mmc with the $BaNiO_3$ structure has been reported [6]. In this presentation, we explore how substitution of A- and B-site atoms in ABS_3 compounds affects the stability of the perovskite and related structures. In addition, we will present bond valence that provide insight into the factors that affect the stabilities of these structures. Thirdly, we will apply the model that our group developed to predict the high-pressure behavior of ABO_3 perovskites [7] to chalcogenide perovskites. This model predicts the site compressibilities from site parameters defined in terms of their coordination number, average bond length at room pressure and bond valence parameters. We will use this model to predict possible high-pressure phase transitions in chalcogenide perovskites.

Abstract Body: Perovskite-group minerals are common accessory constituents of such economically important rocks as kimberlites, lamproites, carbonatites and agpaitic feldspathoid syenites. These minerals accumulate in clastic sediments and can be potentially used as an exploration tool. Because perovskites incorporate a wide range of trace elements specific to their parental magmas and crystallization conditions (including many of the isotopes routinely used in geochronology), mass-spectrometry analysis can be used to track the sources of clastic perovskites and search for unrecognized mineral deposits. In the present work, we conducted a detailed comparative analysis of trace-element distributions in loparite [$(Na,REE,Ca,Sr,Th)(Ti,Nb,Ta)O_3$] and perovskite [$(Ca,Na,REE,Sr)(Ti,Nb,Fe)O_3$] from several well-known occurrences of kimberlite, carbonatite, alkaline silicate and contact-metamorphic rocks. We identified a number of trace-element characteristics that can be used to discriminate among different source rocks, and applied these criteria to detrital perovskite and loparite from clastic sediments of Jurassic age in the eastern part of the East European craton (Veslyana basin, Perm Krai,

Russia). We also used U-Pb dating techniques to constrain the age of the Veslyana samples. Based on these data, the examined perovskite is derived from a Devonian carbonatitic source probably related to Mid-Paleozoic rifting of the margin of the East European platform. The loparite is derived from relatively primitive agpaitic syenites of Ediacaran age, which can be linked to widespread alkaline magmatism in the East European craton and elsewhere, heralding the final stage of Rodinia breakup.

Published Material: 50% in Y. Lin, R. E. Cohen, S. Stackhouse, K. P. Driver, B. Militzer, L. Shulenburger, and J. Kim, Phys. Rev. B 90 (2014).; R. E. Cohen and Y. Lin, Phys. Rev. B 90 (2014).

Abstract Body: We have performed quantum Monte Carlo (QMC) simulations and density functional theory calculations

to study the equations of state and phase transition of MgSiO3 perovskite (Pv, bridgmanite) and post-perovskite (PPv) .[1] The ground-state energies were derived using quantum QMC simulations and the temperature-dependent Helmholtz free energies were calculated within the quasiharmonic approximation and density functional perturbation theory. Agreement with experiments is improved over DFT alone. Furthermore, we obtain statistical error bounds on the results, rather than the unconstrained errors of DFT. The Pv-PPv phase boundary calculated from our QMC equations of state is also consistent with experiments, and better than previous local density approximation calculations. In order to understand the H-phase reported in (Mg,Fe)SiO3 [2], we have performed evolutionary structure searching for FeSiO3.[3] We find a new structure type which may be consistent with the experimental observations. We are now performing QMC and DFT studies of FeSiO3 and (Mg,Fe)SiO3 perovskite and post-perovskites. This work is supported by NSF and the ERC Advanced Grant ToMCaT.

Title: Clues about lower mantle chemistry from natural samples of bridgmanite

Presenter/First Author: Oliver D Tschauner, Univ Nevada, Las Vegas, NV

Presenter/First Author Email: olivert@physics.unlv.edu

Co-authors: Chi Ma, California Institute of Technology, Pasadena, CA

Published Material: Discovery of bridgmanite, the most abundant mineral in Earth, in a shocked meteorite, O. Tschauner, C. Ma, J. Beckett, C. Prescher, V. Prakapenka,G.Rossman, Science 346, 110-1102, DOI: 10.1126/science.1259369 (2014)

Abstract Body: Bridgmanite, $MgSiO_3$ in an ABO_3 perovskite structure, was established in 2014 as a mineral by means of structural and chemical characterization of a natural specimen (ref 1). This natural specimen was identified in a shock melt vein in the Tenham L6 chondrite. By now we have identified bridgmanite in a martian meteorite also. I will show that natural samples of brigdmanite provide a useful complement to experimetal studies of this mineral: Bridgmanite in clasts trapped chondrite shock melt veins inherits the composition of precursor pyroxenes and, thus, samples an extended compositional range, quite beyond of what has been synthesized. This provides relevant information upon endmember compositions and volumes.

Bridgmanite in martian meteorites occurs in assemblies that crystallized from or in contact to melt. These assemblies provide insights in minor-element distribution between melt and lower mantle rock forming minerals. I compare these findings to experimental results and discuss the possible implications for incompatible element differentiation in the mantle.

Title: First-principles Study of Intermediate-spin Ferrous Iron in the Earth's Lower Mantle

Presenter/First Author: Han Hsu, National Central University, Kanagawa,

Presenter/First Author Email: hanhsuphys@gmail.com

Co-authors: Renata M Wentzcovitch, University of Minnesota Twin Cities, Minneapolis, MN

Published Material: About 70% of this talk is published in Han Hsu and Renata M. Wentzcovitch, Phys. Rev. B 90, 195205 (2014).

Abstract Body: Spin crossover of iron is of central importance in solid Earth geophysics. It impacts all physical properties of the Earth's lower-mantle minerals, including ferropericlase [(Mg,Fe)O] and Fe-bearing magnesium silicate ($MgSiO_3$) perovskite, altogether constituting ~95 vol% of the lower mantle, and ferromagnesite [$(Mg,Fe)CO_3$], a potential carbon carrier in the lower mantle. Despite great strides made in the past decade, the existence of an intermediate-spin (IS) state in ferrous iron (Fe^{2+}) (with total electron spin S = 1) and its possible role in the pressure-induced spin crossover in these lower-mantle minerals still remain controversial. Using density functional theory + self-consistent Hubbard U (DFT + U_{sc}) calculations, we investigate all possible types of IS states of Fe^{2+} in these minerals, and this talk will be particularly focused on $(Mg,Fe)SiO_3$ perovskite (also known as bridgmanite). Among the possible IS states in these minerals, the most probable IS state has an electronic configuration that significantly reduces the electron overlap and the iron nuclear quadrupole splitting (QS). These most probable IS states, however, are still energetically disfavored, and their QSs are inconsistent with Mössbauer spectra. We therefore conclude that IS Fe^{2+} is highly unlikely in the Earth's lower mantle.

Title: Transition metal chemistry meets the perovskite structure

Presenter/First Author: Catherine A McCammon, University of Bayreuth, Bayreuth,

Presenter/First Author Email: catherine.mccammon@uni-bayreuth.de

Abstract Body: The perovskite structure is remarkably versatile, incorporating more than half of the stable elements in the periodic table. The wide range of chemical and structural variations as well as possibilities for non-stoichiometry gives rise to a wealth of interesting physical properties, many with important commercial applications. Transition elements in particular provide the capability for variations in oxidation and spin state, enhancing possibilities for transformations brought about by changes in environmental variables such as pressure, temperature or oxygen fugacity. In a similar way that ionic radii provide a simple compositional guide to the stability of perovskite structure variants, crystal field theory can provide an indication of the stable electronic configuration of transition element cations. The lower mantle mineral bridgmanite offers multiple possibilities for iron (two sites times two oxidation states times three spin states) which has complicated the interpretation of results from experimental studies. The presentation will focus on crystal field theory analysis applied to recent bridgmanite data acquired at high pressures and high temperatures to elucidate the state of iron in the deep Earth's interior.

Title: Exploring the Eruptive Sequence and Chemical Evolution of the AD 1730—1736 Timanfaya Eruption, Lanzarote, Canary Islands

Presenter/First Author: James Muller, CUNY Queens College, New York, NY

Presenter/First Author Email: james.muller63@qmail.cuny.edu

Co-authors: Patrick Beaudry, CUNY Queens College, Flushing, NY; Marc-Antoine Longpre, CUNY Queens College, Flushing, NY

Abstract Body: The Timanfaya eruption is one of the largest historical basaltic fissure eruptions, producing an estimated 3—6 km^3 of lava along a 15-km, E-W trending fissure. Previous work identified (I) a preliminary eruption sequence, and (II) an unusual progression of magma composition from basanite to tholeiite, based on mapping and geochemical analysis of distal lava flows [1, 2].

In this work, we present preliminary tephrostratigraphy results and geochemical analyses to better define the eruption (including its volume) and its mantle source. New X-ray fluorescence analyses of tephras sampled at the vents suggest edifices correlate strongly with distal flows, consistent with the associations proposed by [1]. Data also confirm the trends from highly alkaline (1.5 wt% K_2O, ~15 wt% MgO, 42 wt% silica) to tholeiitic (0.5 wt% K_2O, ~7.5 wt% MgO, and 51 wt% SiO_2) compositions. A 1-m-thick, bedded tephra sequence located at a section 4 km south of the fissure is chemically homogeneous. Correlating best with fall deposits from the Caldera de los Cuervos (first and most primitive) eruptive phase, the strata identified thus likely represent intra-phase pulses instead. The identification of these tephras confirms the involvement of that vent in the Timanfaya eruption, despite the edifice's location off-axis of the fissure.

Incompatible trace element ratios, such as Zr/Y, display significant variations in the eruptive sequence that cannot be produced by fractional crystallization. Trace element data help test previous hypotheses on the origin of the syn-eruptive change in magma composition, including differing degrees of partial melting [1], different mantle source compositions [3], and crustal assimilation of sedimentary xenoliths [4].

Title: Plio-Pleistocene volcanic activity in a stable terrain: Implications on magma generation and regional tectonics

Presenter/First Author: James Cesar Avisado Refran, National Institute of Geological Sciences, University of the Philippines, Quezon City,

Presenter/First Author Email: jamesrefran@gmail.com

Co-authors: Carlo A Arcilla, National Institute of Geological Sciences, University of the Philippines, Quezon City, Philippines

Published Material: Some data from Arcilla et al., 2003 (High-Nb Lavas from Northern Palawan: implications for high field strength enrichment in southern Philippine Arc).EGS - AGU - EUG Joint Assembly, Abstracts from the meeting held in Nice, France, 6 - 11 April 2003, abstract #3451

Abstract Body: The presence of volcanism in an island arc setting is often attributed to an ubiquitous subduction. Palawan island, Philippines has been long been a subject of studies involving its origin, aseismic nature (e.g. Yumul et al., 2008), and absence of active, subduction-related volcanism. North of the island, however, a large basaltic lava field is observed. Geomorphologically young (from previous works indicating a Plio-Pleistocene age), the lava flow overlies Permian chert (Pena,2008). Relatively flat topography suggests low viscosity of flow. Preliminary petrography and X-ray Diffraction analyses of rock samples reveal presence of olivine, plagioclase and minor pyroxenes. Total Alkali versus Silica plot falls within basalt to basaltic-andesite field. K_2O vs. SiO_2 - K_2O (from Peccerillo and Taylor, 1976), SiO2 –FeOt /MgO (from Miyashiro, 1974) and AFM ternary plots of samples fall within the Calc-Alkaline series. Spider plots (MORB-normalized, from Pearce, 1983) of basalt samples reveal unusual Nb-enrichment (~25ppm) not observed in typical island arcs (from previous data of Arcilla et al., 2003). Mechanism from Macpherson et al. in 2010 points to a possible small-degree partial melts of an OIB-like source, then interacting with high-degree partial melts from upper mantle (from Reagan and Gill,1989). This paper will restudy the occurrence of the enigmatic lava flow through additional petrographic approach supplementing previous information with recent geochemical data.

Title: An isotopic insight into the role of tuffisite veins during volcanic degassing in rhyolitic systems

Presenter/First Author: Rebecca Paisley, McGill University, Montreal, QC

Presenter/First Author Email: rebecca.paisley@mail.mcgill.ca

Co-authors: Kim Berlo, University of Oxford, Oxford, United Kingdom; Bassam Ghaleb, Université de Québec à Montréal, Montréal, QC, Canada

Abstract Body: Magmatic degassing plays a fundamental role in the style of a volcanic eruption. A better understanding of the mechanisms involved in gas escape is essential for predicting eruption styles, and constraining the associated hazards. Highly silicic rhyolitic systems are prone to explosive activity because of their ability to trap gas bubbles, which expand on ascent and promote fragmentation. Effusive rhyolitic activity is thought to occur where gas can escape from the melt. However, Schipper et al. (2013) witnessed simultaneous effusive and explosive activity at the 2011-2012 eruption of Cordón Caulle, Chile. This suggests a complex open system degassing mechanism. Potential degassing mechanisms include interconnected bubble networks and fractures. These fractures can be infilled and preserved as tuffisite veins, consisting of fine-grained pyroclastic material. They have been shown to weld, heal and refracture in many rhyolitic systems, thus providing a reoccurring path for gas escape, but are they the main degassing mechanism?

We have conducted ^{210}Pb-^{226}Ra radioactive disequilibria analyses, by Alpha Particle Spectroscopy and Thermal Ionisation Mass Spectrometry, on rhyolitic samples from Cordón Caulle, Chile to constrain this. In volcanic rocks, disequilibria between ^{226}Ra and ^{210}Pb, members of the ^{238}U decay series, have been attributed to degassing and accumulation of ^{222}Rn, the gaseous precursor to ^{210}Pb. In the first study of its kind, early results indicate that tuffisite veins, from the 2011-2012 eruption, display ($^{210}Pb/^{226}Ra$) ratios greater than 1. Additionally, vesicular pumice and dense lava flow samples exhibit ^{210}Pb excesses. This indicates significant gas fluxing occurred through the shallow part of the Cordón Caulle system prior to the eruption of both effusively and explosively erupted magma. Further analyses and modelling will be undertaken to assess the relative gas fluxes in samples representing both the effusive and explosive stages of eruption.

Abstract Body: Campi Flegrei caldera, in the Neaples area which is marked by the highest volcanic risk in the world, has experienced, in the last 2000 years, up and down ground movements spanning about 20 m. The largest recent unrest episodes involving huge uplift (up to 3.5 m in 15 years) occurred since 1969 to 1984, but modern uplift episodes likely started in the 50's of the last century. Following the spectacular ground uplift culminated in 1984 (uplift rates up to 1m/year) about 20 years of general subsidence started, interbedded with some small uplift episodes (4-11 cm of maximum elevation) lasting 1-2 months. Such subsidence period ended at about 2004, when a general trend of slow uplift started, with peak rates in 2006, 2012, 2013 and 2014. Since 2011, maximum ground uplift measured at Pozzuoli Bay has been 21 cm. The new slow uplift phase has characters different from the 1969-1972 and 1982-1984 large unrests, because uplift rates are much lower (about two orders of magnitude) and seismicity is much weaker, both in frequency and magnitude of the events. However, geochemical signatures of the on-going unrest are more marked than in previous periods, because a linearly increasing trend of huge deep fluid injection into shallow aquifers is evident from ground emissions. The 'deep' (or magmatic) signature of such injected fluids is even higher than during the previous largest unrests. These contrasting characters of the new unrest phase, when compared with the large unrests experienced 30-45 years ago, call for detailed interpretations of these episodes to discriminate magmatic from deep geothermal effects. This work presents the observational evidences of these peculiar unrest episodes and provides a first attempt to discriminate between magma accumulation effects and deep geothermal fluids injection. Such interpretation, based on thermal-fluid-dynamical modelling, relies on accurate in-situ estimation of permeability at depth operated in the framework of the ICDP-CFDDP (Campi Flegrei Deep Drilling Project).

Title: Investigating magmatic plumbing systems in an off-rift setting on Iceland with geothermobarometry and quantitative textural data

Presenter/First Author: David Burney, University of Iowa, Iowa City, IA

Presenter/First Author Email: david-burney@uiowa.edu

Co-authors: David William Peate, University of Iowa, Iowa City, IA; Morten S Riishuus, University of Iceland, Reykjavik, Iceland

Abstract Body: The emplacement of tholeiitic magmas along two NE-SW trending rift zones is the dominant mechanism of crustal accretion on Iceland. Small volumes of transitional to alkaline magmas are also erupted through older crust in several off-rift settings, including the Snæfellsnes Peninsula in western Iceland where the basement is formed by 6-8 Ma flood basalts. In this study, we are investigating how these off-rift magmatic plumbing systems compare to those in the main rift zones, given the significant differences in crustal structure and degree of crustal extension, through application of quantitative textural analysis and mineral geothermobarometry. Our focus is Vatnafell, a sub-glacial eruptive unit (414 ± 11 ka) at the western end of the off-rift Ljósufjöll volcanic system in the Snæfellsnes volcanic zone. Samples are highly porphyritic (~14% macrocrysts), with large pheno/antecrysts (1-12 mm) of clinopyroxene, olivine, and plagioclase. Crystal size distributions for olivine and clinopyroxene both show kinked profiles, indicating two distinct populations. Glomerocrysts in which large clinopyroxene oikocrysts enclose smaller rounded olivine chadacrysts are common, and a small horizon strongly enriched in large (> 5 mm) olivine and clinopyroxene crystals was found near the base of the unit. These observations suggest incorporation of olivine gabbroic/wehrlitic cumulates by the host magma. Preliminary analyses show a bimodal composition for clinopyroxene (cores: mg# 83-88; rims/groundmass mg# 72-77), and initial calculations suggest crystallization of cores over a range of depths in the deep crust (based on variations in Al_2O_3: 4-7 wt%) More extensive analyses of mineral compositions are in progress and will be used to reconstruct the vertical geometry of an extension-limited off-rift magmatic plumbing system and allow a more detailed comparison with plumbing systems hosted by the extension-dominated main rift zones on Iceland.

Title: A Geoelectrical Model of the Northern Flank of the Popocatepetl Volcano (Central Mexico): A First Approach to Major Structures

Presenter/First Author: Claudia Arango, UNAM National Autonomous University of Mexico, Mexico, D.F.,

Presenter/First Author Email: claudiar@geofisica.unam.mx

Co-authors: Ana Lillian Martin, Universidad Nacional Autonoma de Mexico, Mexico City, Mexico; Leticia Flores-Marquez, Universidad Nacional Autonoma de Mexico, Mexico City, Mexico; Margarita Vidal, UNAM National Autonomous University of Mexico, Mexico City, Mexico; Alejandro Vazquez Del Moral, Instituto de Geofísica, UNAM, Mexico, D.F., Mexico

Abstract Body: Popocatepetl volcano is an active stratovolcano located in the central portion of the Trans-mexican Volcanic Belt, approximately 60 km east of Mexico City, the largest city in the country with over 22 million inhabitants. In December 1994 it resumed its eruptive activity and since then many studies have been carried out in order to understand the eruptive behavior and to assess the volcanic hazard. Nevertheless, no study has been conducted in order to image the distribution of electrical resistivity below the volcano. Thus, this study contributes in expanding the knowledge of the structures of the volcano and their relation to the eruptive activity. Since 1994, eruptive events and seismic monitoring have been improved and it is known that most of the activity is concentrated underneath the southeastern flank and below the crater. However, the largest volcanotectonic event (Mc 4.1) on May 6, 2013 was detected beneath the northern flank. For this reason, we decided to perform a magnetotelluric survey on the northern area with the main goal of spotting the characteristic structures and their relationship to the recent activity. The inversion geoelectrical models show the resistivity distribution below the northern flank and were generated from eight magnetotelluric surveys acquired during May 2014. The results show the existence of a body of high resistivity, on the eastern side of the prospected area, which correspond with the position of the Tlamacas dome. Also, the eastern limit of this resistive anomaly coincides with the location of the hypocenter of the earthquake on May 6, 2013, and probably depicts the presence of a NE-SW fault.

Title: Campi Flegrei Deep Drilling Project: an overview of main results and implications on caldera dynamic.

Presenter: Renato Somma, National Institute of Geophysics and Volcanology, Naples,

Presenter Email: renato.somma@ov.ingv.it

First Author: Stefano Carlino, INGV - Osservatorio Vesuviano, Naples,

First Author Email: stefano.carlino@ingv.it

First Author Student?: No

Co-authors: Claudia Troise, Organization Not Listed, Naples, Italy; Giuseppe de Natale, INGV - Osservatorio Vesuviano, Naples, Italy

Abstract Body: During December 2012, in the framework of the “Campi Flegrei Deep Drilling Project” (CFDDP) a pilot

borehole was sunk into the caldera, to a depth of 501 m, 4.5 km ESE along the coast from Pozzuoli. The

primary purpose of the drilling is the understanding of caldera dynamic and is preparatory for the deeper

drilling at 3.5km of depth. The Campi Flegrei caldera experienced periodic phase of uplift and subsidence

accompanied by small to very large eruptions in the past, since the most recent one, occurred in 1538. Since

then, two main episodes of unrest, in 1969-72 and 1982-84, have resulted in a maximum net uplift at

Pozzuoli of more than 3 m. The second episode was accompanied by elevated rates of local seismicity,

which produced more than 16,000 earthquakes with recorded magnitudes between 0 and 4. The persistent

seismicity damaged older buildings in Pozzuoli and eventually led to the evacuation of 40,000 people. The

caldera is still active and the related high volcanic risk pushed the scientist to improve the knowledge of its

dynamic. In this context the CFDDP is aimed to obtain deep geological, geophysical and geochemical data to

constrain the models of unrest. Here we show the main results obtained from the drilling such as,

stratigraphy inferred from cuttings and coring, new permeability and stress data attained from different bore-

hole hydraulic tests and geochemical data of deep fluids.

Title: 2009-2013 ground deformation at Mt Etna observed with advanced DInSAR: Results and Modelling

Presenter/First Author: Jose Fernandez, Complutense University of Madrid, Madrid,

Presenter/First Author Email: jft@mat.ucm.es

Co-authors: Sergey V Samsonov, Canada Center for Remote Sensing, Ottawa, ON, Canada; Antonio G. Camacho, Institute of Geosciences (CSIC-UCM), Madrid, Spain; Kristy French Tiampo, University of Western Ontario, London, ON, Canada; Pablo J González, University of Leeds, Leeds, United Kingdom

Published Material: Preliminary results will be presented at the 9th International Workshop Fringe 2015 Advances in the Science and Applications of SAR Interferometry and Sentinel-1 InSAR Workshop, Frascati, Italy between 23 and 27 March 2015.

Abstract Body: For studying ground deformation at Mt Etna we collected ascending and descending RADARSAT-2 Standard-3 (S3) data spanning January 2009 – June 2013. The advanced multidimensional small baseline subset method (MSBAS, Samsonov & d'Oreye, 2011) was used to obtain EW and vertical time series of ground deformation. Vertical deformation map revealed localized subsidence and horizontal deformation map revealed broad east-west motion at the fault located north of the volcano with rates <2 cm/year. The nonlinear inversion methodology by Camacho et al. (2011) was used for modeling 3D pressure and mass sources with a free geometry. The method assumes simple homogenous elastic conditions, and models the size and location of pressure/mass sources in a general model, fitting the entire geodetic data set within some regularity conditions. The approach (Camacho et al., 2011; Samsonov et al., 2014) works as a growth process that constructs a very general geometrical configuration. A general framework for the geometry of anomalous bodies is achieved by partitioning the subsurface volume into a dense 3-D grid of point sources. The geometrical description of the extended sources is developed by aggregation of point sources in a 3-D context, allowing for a very general description of the free geometry for the source bodies. For simplicity, it is assumed that anomalous pressure changes are nearly homogeneous within the sources. The inversion process fills cells with the prescribed pressure value (and/or density anomaly), giving rise to the aggregation structure. The nonlinear search is based on an exploratory approach. Simultaneously regional deformation patterns and sliding displacements are obtained. Measured displacement and modeling results are described.

Title: Elemental Concentrations and ^{210}Pb Activity of a Growth-zoned Gypsum Stalactite generate Historical Volcanic Activity Record at Kawah Ijen's Crater Lake, Indonesia

Presenter/First Author: Sri Budhi Utami, McGill University, Montreal, QC

Presenter/First Author Email: sri.budhi.utami@gmail.com

Co-authors: Vincent van Hinsberg, McGill University, Montreal, QC, Canada; Bassam Ghaleb, Université de Québec à Montréal, Montréal, QC, Canada

Published Material: Up to 15% of the total work, such as initial ideas and interpretations on a limited number of elemental concentrations and ^{210}Pb activity, have been reported in an oral presentation at the Cities on Volcanoes 8 Conference in Yogyakarta, Indonesia on 9 September 2014.

Abstract Body: The active Kawah Ijen stratovolcano in Indonesia hosts the world's largest hyper-acidic crater lake, with 32 million m^3 of hot SO_4-HCl brine [1]. The volcano has produced phreatic and phreatomagmatic eruptions, tephra, and lahars in the past [2]. This is exemplified by its 1817 eruption, which resulted in expulsion of the entire lake [3]. At the time, the area was scarcely populated, and the overall impact from the volcano was low. As population density around the volcano has raised dramatically, the risk to nearby inhabitants have also risen markedly. Hence, Kawah Ijen requires monitoring, and monitoring depends on having a continuous record of background activity to identify signals of impending eruptions. Unfortunately, there is currently a severely limited record of volcanic activity of Kawah Ijen available. Gypsum grows continuously on Kawah Ijen's western flanks [4], where it precipitates from crater lake seepage springs as stalactites in chemical equilibrium with its fluids. Given that the brine receives direct elemental input from the degassing magma, including elements such as Tl, As and Sb [4,5], we posit that gypsum can be used to reconstruct a continuous geochemical record of volcanic activity for Kawah Ijen. Trace elements were analysed in a cross-section of a growth-zoned stalactite, as was ^{210}Pb activity. Initial ^{210}Pb activity varies with that of its parent's, ^{222}Rn, flux from the degassing magma. When combining the timing information from growth zoning with concentrations and ^{210}Pb activity, we can produce a continuous geochemical record of activity over time. Sharp increases in volatile element ratios above baseline concentrations likely correspond to significant elemental input from the degassing magma, and hence increased activity. The record of $\delta^{18}O$ disequilibrium between the crystalline H_2O and SO_4[6] is shown to be preserved in gypsum, and thus can be used to track changes in the temperature of and flux through the hydrothermal system. Knowledge of background concentrations and how activity affects these, allows us to pinpoint geochemical signals of impending eruptions and aid the monitoring efforts at Kawah Ijen volcano.

Title: Model of Pattern Formation in Layered Igneous Intrusions

Presenter/First Author: Jade Ghaoui, University of Ottawa, Ottawa, ON

Presenter/First Author Email: jghao023@uottawa.ca

Co-authors: Ivan L'Heureux, University of Ottawa, Ottawa, ON, Canada

Abstract Body: Oscillations in composition and grain size can sometimes be generated in magmatic intrusions, giving rise to characteristic centimeter to meter-scale patterns called cyclic layering. Understanding the genesis of these patterns is essential to understand the geological context in which these bodies are formed. We hypothesize that these patterns result from a nonlinear self-organization process in which the interplay between crystallization dynamics and diffusion causes mineral and crystal size segregation. The mechanism is similar to the one behind the formation of Liesegang bands and leads to comparable features, such as a geometric progression of the band positions. With the goal of obtaining a more complete description of the pattern formation process in

the context of a binary eutectic magmatic system in cooling contact with a host-rock, we present a one-dimensional numerical model of nucleation and growth that generalizes previously available versions. The model includes optionally Ostwald ripening, as well as tortuosity corrections for the porosity. The emergence of cyclic layering is described in terms of key parameters that control the solidification. Moreover, by using a spherically symmetric geometry, the model can be applied to the formation or orbicular granites.

Title: Mantle petrology, mineralogy and major elements geochemistry of the northern Cache Creek terrane – Preliminary results

Presenter/First Author: Anne-Sophie Corriveau, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec,

Presenter/First Author Email: anne.sophie.corriveau@gmail.com

Co-authors: Jean H J Bedard, Geological Survey of Canada, Quebec, QC, Canada; Alexandre Zagorevski, , , ; Marc Richer-Laflèche, Institut national de la recherche scientifique, Québec, QC, Canada

Abstract Body: The northern Cache Creek terrane extends for more than 500 km in north British Columbia and south Yukon. This composite terrane comprises mafic and ultramafic complexes and carbonate and chert assemblages that were previously interpreted as accreted seamounts, spreading centers and rifted arc complexes. Our observations show that mantle facies dominate and are often structurally capped by brecciated hypabyssal and volcanic rocks, with only rare occurrences of mafic and ultramafic cumulates. Geochemical signatures suggest an arc affinity for most volcanic and hypabyssal rocks. Variably serpentinized and metamorphosed mantle rocks were sampled at King Mountain, Dease Lake, Hardluck and Peridotite peaks, Mt. Barham, Atlin and Marsh Lake. Primary mineralogy and textures are often preserved. Foliated mantle harzburgite tectonite dominates, with about 25-35% of porphyroclastic orthopyroxene and subordinate chromite, often with holly-leaf morphology. Chromite shows a wide spectrum from translucent to opaque facies, suggesting a wide range of Cr/Al and variable melt depletion signatures. Rare orthopyroxenitic to websteritic layers are interpreted to be transposed dykes. Dunite dykes are common but subordinate in abundance and contain sub-euhedral chromite. Gabbroic dykes are also common. At Mt. Barham the peridotite shows spectacular anthophyllite dendrites near a late granitic intrusion. Detailed mantle petrology, mineralogy and major elements geochemistry will be used to establish a coherent regional geologic framework for the Cache Creek terrane and its tectonic reconstruction.

Title: Petrogenesis of Mantle Xenoliths in Alkaline Basalts in Southeastern British Columbia

Presenter/First Author: Eyal Friedman, University of Windsor, Thornhill,

Presenter/First Author Email: eyal.jf@gmail.com

Co-authors: Ali Polat, University of Windsor, Windsor, ON, Canada

Abstract Body: Tertiary alkaline basalts diatremes in Southeastern British Columbia are host to a variety of mantle xenoliths, predominantly spinel lherzolites with associated dunites and pyroxenites. Mineralogically, they are composed mainly of olivine, orthopyroxene, clinopyroxene and spinel characterized by forsterite (Fo_{87-93}), enstatite (En_{90-92}), diopside (En_{45-50}-Wo_{40-45}-Fs_5) and Cr-spinel (6-11 wt. % Cr), respectively. All mantle xenoliths are coarse-grained and show triple junctions. Clinopyroxene and spinel show evidence for chemical reactions with percolating melts.

The mantle xenoliths are characterized by 42.8-45.2 wt. % SiO_2, 37.5-42.7 wt. % MgO, 8.2-9.7 wt. % Fe_2O_3. Al_2O_3 (0.85-4.61 wt. %) and TiO_2 (0.02-0.16 wt. %) show moderate variations, resulting in super-chondriting Al_2O_3/TiO_2 (21-72) ratios. CaO values range from 0.61 to 3.8 wt. %, whereas the CaO/Al_2O_3 possess a narrow range (0.54-0.92). They have rather restricted Mg-numbers (89-92). They are strongly depleted in incompatible elements (Ba = 2-12 ppm; Sr = 3-31 ppm; Zr = 6-21 ppm, K_2O = 0.01-0.07 wt. %) and variably depleted in transitional metals (V = 41-94 ppm; Sc = 6-17 ppm). Yttrium (1-3 ppm) is also strongly depleted. On the basis of chondrite-normalized REE patterns, samples are divided into three groups: (1) LREE- depleted (La/Yb_n = 0.34-0.82) samples; (2) moderately LREE- enriched (La/Yb_n = 1.11-1.78) samples; (3) and LREE- enriched (La/Yb_n = 2.20-3.00) samples. N-MORB-normalized trace element patterns display negative Nb and Ti anomalies but exhibit positive Pb, Sr and Zr anomalies. These geochemical characteristics are consistent with a variably metasomatized sub-continental lithospheric mantle source, originated in a subarc mantle wedge.

Title: Stratification within the granophyre of the South Range of the Sudbury Igneous Complex

Presenter/First Author: Kirill Kompaniets, University of Toronto, Toronto, ON

Presenter/First Author Email: k.kompaniets@gmail.com

Co-authors: James Mungall, Univ Toronto, Toronto, ON, Canada; Quincy M C Poon, University of Toronto, Toronto, ON, Canada

Abstract Body: The Sudbury Igneous Complex (SIC) was formed by a meteorite impact, which generated a large quantity of impact melt in a single pulse. Fractionation and crystallization of the impact melt sheet led to formation of three units of the Main Mass of the SIC. On the South Range of the SIC the Main Mass comprises norite cumulates capped by granophyric residues. These two units are separated by a zone called the Transition Zone quartz gabbro which represents a change from plagioclase+orthopyroxene to alkali feldspar+quartz+clinopyroxene+biotite+Fe oxide+apatite crystallization followed by a rapid increase in the amount of trapped liquid.

Mapping and sample collection during the summer of 2013 led to the identification of a lithological reversal expressed as a layer of gabbro exposed near the middle of the granophyre unit. Its mineralogical make up corresponds to that of transition quartz gabbro zone but it occurs more than 1 km above the top of the TZ quartz gabbro. We have mapped this layer over a continuous strike length greater than 5 km between Whitewater Lake and Moore Lake. The contact is a sharp transition from pink granophyre to coarse-grained quartz gabbro with stellate textured clinopyroxene and a sharp increase in the mafic mineral abundance. Geochemically it is characterised by a drop in silica content to 51.72% and an increase in MgO to 2.56% in comparison to the 72.28% silica and 0.55% MgO content of Lower granophyre layer. Subsequent samples were collected (XRF results pending) in order to substantiate field observations. Modeling using MELTS software will be performed for the purpose of evaluation of possible sources of the upper gabbro layer. Existence of the reversal in the lithology of the Main Mass implies a greater complexity in process of evolution of the SIC than has been previously assumed, possibly indicating that the magmatic system evolved as a stably stratified body throughout its existence.

First Author Email: kthesen@ucalgary.ca

First Author Student?: No

Abstract Body: The Trail pluton, located in southeastern British Columbia, is part of a suite of mid-Jurassic granitic rocks of probable continental arc affinity that were transported eastwards as a result of Cordilleran tectonics. Previous work on the nearby Nelson Batholith has suggested that magmatic rocks in this area were subjected to substantial post-equilibration rotation and tilting, possibly as a result of movement on listric faults. Twenty-five samples were collected from the Trail pluton for the purpose of mineralogical description and amphibole-plagioclase thermometry using the HB-PLAG program by Holland and Blundy (1994). The average modal mineralogy of the samples is: quartz 13%, plagioclase 33%, potassium feldspar 20% (late in the magmatic crystallization history), amphibole 14%, biotite 10%, titanite 1%, and a minor amount of alteration minerals such as chlorite and epidote. Many samples show evidence of localized strain, including comminution of grain size in quartz and feldspars and folding of biotite. Most plagioclase crystals fall within the composition range An_{39} to An_{31}. The potassium feldspar is low in Na, suggesting a lower crystallization temperature. All amphiboles are calcic, ranging from magnesiohornblende to tschermakite to pargasite. Nearly all amphiboles have $Al^{vi} > 1.0$, giving them the prefix alumino. Preliminary thermometry calculations using the edenite-tremolite end-member system give an average result of 745°C for amphibole-plagioclase equilibration at P = 5 kbar. This result agrees well with calculations by Ghent et al. (1991) for both the Nelson Batholith and Bonnington pluton. Further work on this project will include barometric calculations as well as an examination of possible differential uplift and tilting of the Trail pluton.

Title: Fe–Ti oxides in the lower crustal xenoliths recording significant magmatic events in the crust–mantle transition zone (North China)

Presenter/First Author: Zhiyong Li, China University of Geosciences Wuhan, Wuhan,

Presenter/First Author Email: zhiyonli@outlook.com

Co-authors: Jianping Zheng, China University of Geosciences Wuhan, Wuhan, China; Qingsheng Liu, China University of Geosciences Wuhan, Wuhan, China

Abstract Body: Ilmenite and rutile are found to be common accessory minerals in the lower crustal xenoliths from the Cenozoic Hannuoba basalts, northern North China Craton. Detailed petrography, major chemical composition and trace elements of these Fe–Ti oxides in four pyroxenite xenoliths are studied. The Fe–Ti oxides occur mainly in the interstice of silicates or as inclusions in pyroxenes, and three types are representative: (1) single rounded homogeneous grain; (2) intergrowth of rutile and ilmenite; (3) slender needle-like grains. The ilmenite is especially rich in MgO (6.36~13.1 %) and poor in Fe^{3+} ($Fe^{3+}/\Sigma Fe$, 0~0.063), which is clearly different from the Mg-poor titanomagnetite (MgO, 2.9~3.31 %) in host basalts. The ilmenite on the rims of rutile grains indicates the reaction of rutile and accessional Fe^{2+}, which possibly came from interstitial melts or melting silicates. This can be evidenced by the needle-like ilmenite penetrating into the partly-melted pyroxenes. These crustal xenoliths have two-pyroxene equilibrium temperatures of 834~884°C, and ziconium-in-rutile temperature of ~825°C (at 1.2 GPa), which suggest that the xenoliths were derived from the crust–mantle transition zone (~24–33 km), and experienced later magmatic reheating events. Hence, the petrological and geochemical characteristics of the Fe–Ti oxides in the pyroxenite xenoliths record significant geological processes in the continental lower crust beneath Hannuoba, and give insights into the tectonic evolution of the North China Craton.

Title: Selfrag: An Effective Tool in Sample Preparation for Geological Research

Presenter/First Author: Agatha Dobosz, Queen's University, Kingston,

Presenter/First Author Email: dobosz@geol.queensu.ca

Co-authors: T Kurtis Kyser, Queen's University, Kingston, ON, Canada; Daniel Layton-Matthews, Queen's University, Kingston, ON, Canada

Abstract Body: Extraction of a pure mineral from a geological sample is often vital to analytical techniques ranging from elemental analysis to radiometric dating. The Selfrag instrument uses high-voltage pulsed power discharges to fragment geological material along grain boundaries, conserving morphology and liberating minerals of interest. A series of case studies prove the Selfrag to be a versatile tool. 1) Athabasca Basin sandstones are composed of over 98% quartz. The minor clay constituent retains a geochemical signature of the near-surface environment that can reflect fluid evolution and uranium mineralization at depth. X-ray diffraction of clay-sized material prepared using conventional methods such as disc-mill crushing and centrifugal clay separation displays significant quartz contamination. The Selfrag liberates the clay minerals with minimal quartz contamination, making the sample ideal for subsequent analysis for trace elements and isotopic ratios. 2) The Kiyuk Lake gold deposit is unusual in that it is hosted in Paleoproterozoic sediments, contrary to metamorphosed Archean terranes that typically host significant Canadian gold deposits. Large crystals of actinolite, quartz, calcite, and magnetite were hand-picked from fragmented samples and imaged using scanning electron microscopy. Each mineral was analysed for $\delta^{18}O$ and $\delta^{2}H$ to further understanding of the chemical evolution of the deposit. 3) MacMillan Pass is home to several sedimentary-exhalative deposits hosted in Late Devonian sediments. Barite and pyrite from a typical vent complex were successfully fragmented for geochemical analysis to determine potential use as vectors in mineral exploration. 4) Typical crushing methods destroy vital spatial information within minerals that display zonation, such as garnets or zircons. Whole zircons from rhyolitic tuffs and eclogites have been extracted for subsequent radiometric dating and geochemical analysis. Whole garnets from mica schists and eclogites have been extracted for trace element analysis and tomography. The Selfrag is capable of simplifying the process of extracting minerals of interest from a complex matrix, and improves confidence in any analytical method that assumes a mono-minerallic material.

Title: Zoisite Eclogites From Faro Area, Yukon: Pressure-Temperature- Fluid Composition Attending Metamorphism

Presenter/First Author: Edward D Ghent, University of Calgary, Calgary, AB

Presenter/First Author Email: ghent@ucalgary.ca

Co-authors: Robert Marr, , , ; Allison Klincker, , ,

Abstract Body: Eclogite occurs as metre-sized lenses within metasedimentary schists and gneisses near Faro, Yukon Territory, Canada. The mineral assemblage in eclogite is quartz-garnet-zoisite-Ca-amphibole-clinopyroxene-rutile-phengite. Secondary minerals include epidote-titanite-chlorite-glaucophane-calcite-K-feldspar and albite. Eclogites have undergone strong deformation, locally producing a mylonitic matrix. Garnet is relatively fresh but contains numerous fractures and little retrogressioni.Estimates of peak pressure (P) and temperature (T) attending metamorphism used Fe^{2+}-Mg fractionation between clinopyroxene and garnet, Zr in rutile, clinopyroxene-garnet-phengite equilibria and isochemical phase diagram sections (also known as pseudosections). Peak P-T conditions are difficult to estimate. Using Zr in rutile the temperature ranges from 580 to 595°C at 20 kbar, with no difference between rutile included in garnet and rutile in the matrix.
For 1.0, the lack of stable lawsonite suggests P<~18 kbar at T~600°C. The P-T path during unroofing and cooling is difficult to estimate but the occurrence of albite suggests that some of the P-T path was in the albite stability field. The host metasedimenary rocks contain zircon-quartz-rutile but suggest equilibration temperatures of about 545°C. Post-peak penetrative deformation promoted some retrogressive reactions but the coarser peak porphyroblasts survived this deformation and retrogression. This implies lack of extensive fluids during cooling and deformation.

Title: Geochemistry and Petrogenesis of the Basement Rocks from Barapaharpur, Rangpur: Implications for Crustal Evolution of the Shallow Basement in the North-West Bangladesh.

Presenter/First Author: Al-Tamini Tapu, Jahangirnagar University, Dhaka,

Presenter/First Author Email: tamini.tapu@gmail.com

Co-authors: S.M. Mahbubul Ameen, , , ; Rashed Abdullah, , , ; Mohammad Nazim Zaman, Bangladesh Council of Scientific & Industrial Research (BCSIR), Joypurhat, Bangladesh; Sudeb Chandra Das, , , ; Md. Sakaouth Hossain, , ,

Abstract Body: Bangladesh is one of the world's largest deltaic plains, almost entirely covered by Tertiary and Quaternary sediments without any surface outcrops of igneous and metamorphic rocks. The crystalline basement drillcore samples from Barapaharpur, Rangpur area in the northwest Bangladesh have been investigated through core logging, petrographic and geochemical study to constrain their origin and to propose a crustal evolution and geodynamic model for the area. The Barapaharpur basement rocks were encountered at a depth of ~1200ft and comprises mostly of diorite, which is dissected by minor granodiorite gneiss and hornblendite dykes. The felsic rocks of Barapaharpur basement are metaluminous with low ASI index, calc-alkaline and have high K_2O and Rb contents. They show progressive depletion in P_2O_5 with increasing silica reflecting a typical internal fractionation trend of I-type granitoid. The Barapaharpur granitoid is characterized by strong enrichment in LREE and distinct negative Nb and Ti and zero to weakly negative Eu anomalies. The source melt of Barapaharpur granitoid has been suggested to have generated in an ocean-continent subduction zone. High La/Yb_{CN} ratios (16.17-17.67) and positive correlation between Sr/Y and La/Yb ratios of the felsic samples imply a deep source melting (upper mantle) at high pressure (10-12Kbar). Dykes of hornblendite suggests a mantle origin, at deeper level than the parental melt of the diorite. This mafic melt occupied the fissure or weak zones within the I-type granitoid forming the late dykes. Comparison between the studied Barapaharpur granitoid and Maddhapara granitoid (55km NW to Barapaharpur) reveals that both of them share remarkably similar geochemical and petrographic signatures, pointing toward a similar source of parental melt for both granitoids. From the geodynamic study based on gravity-magnetic mapping, the location of the granitoids fall within the regional micro-continental block (Dinajpur Block) suggested by a previous work and these two granitoid basements are considered to have represented an unreported part of Palaeoproterozoic supercontinent Columbia. However, U-Pb precise geochronology and high precision geophysical study of the Barapaharpur granitoid are required to establish the precise age, and limit of this new microcontinental block.

Title: Combined Geochemistry and Geochronology Constrains Coupled Subduction of Oceanic and Continental Crust in the Huwan Shear Zone, Central China

Presenter/First Author: Hao Cheng, Tongji University, Shanghai,

Presenter/First Author Email: oahgnehc@gmail.com

Co-authors: Jeffrey D. Vervoort, Washington State University, Pullman, WA

Published Material: Part of the materials present here have appeared in the latest issue of American mineralogist.

Abstract Body: The exposure of the eclogites derived from oceanic subduction and continental subduction at the surface of Earth today record provide different P-T-t records of the subduction process. In this study, Lu-Hf garnet, U-Pb zircon, and Ar-Ar mica ages are combined with geochemical data to understand the origin of two coexisting eclogite bodies exposed along the Xuehe River in the Huwan Shear zone. In total, the results indicate that the two eclogites have different protoliths but experienced a similar metamorphic history. This observation requires new tectonic model for the coupled subduction of oceanic and continental crust in subduction zones. Combined geochemistry and zircon U-Pb geochronology suggest distinct oceanic and continental affinities for the eclogite protoliths. The Lu-Hf dates of the continental-type eclogite and the oceanic-type eclogite reflect garnet growth and are interpreted to closely approximate the age of eclogite-facies metamorphism. Therefore, both the geochemically oceanic- and continental-type eclogites underwent the same episode of Permian eclogite-facies metamorphism. The Permian Lu-Hf ages of *ca*. 262 Ma and the obtained Triassic Ar-Ar ages of the oceanic-type and continental-type eclogites imply coupled subduction and exhumation of oceanic and continental crustal materials in the Hong'an orogenic belt during the Permian and the Triassic. Though limited, the geochemical and geochronological results of this study, together with the discrepant Carboniferous dates for the nearby eclogites of previous studies, apparently suggest that the Huwan shear zone was not always a single coherent unit but instead comprises different tectonic slices that were metamorphosed at different times before final assembly. Some slices of the oceanic and continental crust underwent two subduction cycles during the Carboniferous and the Permian, whereas some eclogites registered only a single subduction-exhumation loop during the convergence between the South China Block and the North China Block in the Huwan shear zone.

Title: Tourmaline's record of fluid history in the Pfitscher Joch, Western Tauern Window

Presenter/First Author: Eleanor Jane Berryman, Technical University Berlin, Potsdam,

Presenter/First Author Email: berryman.eleanor@gmail.com

Co-authors: Martin Kutzschbach, GFZ Potsdam, Potsdam, Germany; Anselm Loges, , , ; Dina Schultze, Technische Universität Berlin, Berlin, Germany; Anette Meixner, Universität Bremen, Bremen, Germany; Gerhard Franz, Technische Universität Berlin, Berlin, Germany

Published Material: Some of the data was presented in September 2014 at the Deutsche Mineralogische Gesellschaft (DMG) annual meeting in Jena as a poster presentation.

Abstract Body: The Pfitscher Joch is a petrologically well-investigated area of the Western Tauern Window in the Eastern Alps. Its basement comprises pre-Variscan amphibolite, serpentinite, and garnet-graphite schist and gneiss intruded by two late Variscan granitoids (Tux and Zillertal Zentralgneis). In the late-Permian to Mesozoic, a sequence of sediments were deposited, starting with conglomerates, fining upward to psammites-pelites, including carbonate-rich schists, possibly interrupted by a horizon of rhyolite. Together, they form part of the Subpenninic nappes, the former European distal margin. In the Alpine orogeny, this succession was folded between the Tux and the Zillertal granitoids, forming a WSW-ENE oriented syncline. During Alpine metamorphism, fluids were released and probably channelled in the Greiner Shear Zone, which runs subparallel to the folded sequence, leading to complex fluid flow in the whole Pfitscher Joch region. Whereas the geodynamics of the area have been well constrained, the fluid flow history is not yet understood.

A striking mineralogical feature in many lithologies of the Pfitsch formation is the presence of black, prismatic tourmaline (schorl-dravite solid solution). It is particularly pervasive in a ~ 25 m thick unit of tourmaline-feldspar-rich gneiss, which is associated with feldspar-dominated segregations. The largest and most abundant tourmalines are in the segregations, suggesting a link between tourmaline crystallization and their formation. These crystals record three growth stages, distinguished by major element chemistry and inclusion mineralogy. Outside the segregations, multi-stage compositional growth zoning is rare and individual grains match usually only one growth stage of the segregation-hosted tourmaline. Comparison of data from different horizons of the Pfitsch formation shows a bulk-rock compositional control on the Fe content of the hosted tourmaline. Conversely, the Ca/Na of the tourmaline is independent of the host rock, and is interpreted as a fluid signature.

The Pfitscher Joch is an example locality of tourmaline serving as a powerful petrogenetic indicator mineral. A combination of textural, isotopic, and major and trace element analysis of tourmaline has allowed part of the Pfitscher Joch's fluid history to be revealed.

Title: Re-Os Geochronology of Bitumen from the Northern Longmen Shan Thrust Belt, Southwest China

Presenter/First Author: Zeyang Liu, Geological Society of America, Wuhan,

Presenter/First Author Email: zeyang_92@163.com

Co-authors: Chuanbo Shen, . Key Laboratory of Tectonics and Petroleum Resources, China University of Geosciences, Ministry of Education, Wuhan, China; David S Selby, University of Durham, Durham, DH1, United Kingdom; Xiaoyan Ruan, , , ; Shouzhi Hu, , , ; Jiayi Du, , ,

Abstract Body: The bitumen Re-Os geochronology as a novel technique has the good potential for wider use to constrain hydrocarbon generation especially in the marine carbonate basin, to identify source units and to determine the activity age of fault within bitumen filling. Six bitumen samples from the Lower Cambrian Changjianggou formation in the northern Longmen Shan thrust belt were selected for Re-Os analysis. Re and Os contents are ~283.3–563.3 ppb and ~4058.2–15347.3 ppt, respectively. These values are significantly elevated from those of the average continental crust and previously reported bitumen samples from both hydrocarbon and metalliferous systems, and also the majority of marine and lacustrine organic-rich sedimentary rocks (REFS), which has also been shown by previous studies. The $^{187}Re/^{188}Os$ values are high, ranging from ~ 230.7 to 718.4, and the Os isotopic composition is radiogenic, with $^{187}Os/^{188}Os$ ratios ranging from 2.79 to 3.48. Repeat analysis yield similar Re and Os concentrations, and $^{187}Re/^{188}Os$ and $^{187}Os/^{188}Os$ values.

All the Re-Os data yield an isochron age of 158 ± 77 Ma with an initial $^{187}Os/^{188}Os$ value of 1.85 ± 0.61 (2σ; MSWD = 76). Calculated initial $^{187}Os/^{188}Os$ ratios at 158Ma are variable and can be divided to two groups. One yield a Re-Os date of 162 ± 14 Ma with an initial $^{187}Os/^{188}Os$ value of 1.87 ± 0.12 (2σ; MSWD = 0.95). The remaining samples yield a Re-Os date of 172.7 ± 8.1 Ma with an initial $^{187}Os/^{188}Os$ value of 1.655 ± 0.056 (2σ; MSWD = 0.000).

Two different initial $^{187}Os/^{188}Os$ values suggest that all the oil generated from different source horizons with different Os isotope compositions. The Re-Os bitumen geochronology was coeval with intense thrust fault movement of the northern Longmen Shan thrust belt, which also provides a new direct absolute age evidence for the Late Mesozoic deformation of the northern Longmen Shan thrust belt.

Title: Early Permian Peperites in the Beishan Region, NW China: Implications for Regional Tectonic and Palaeoenvironmental Setting

Presenter/First Author: Shi Chen, China University of Petroleum, Beijing,

Presenter/First Author Email: chenshi4714@163.com

Co-authors: Zhaojie Guo, Peking University, Beijing, China; Jiafu Qi, College of Geosciences, China University of Petroleum,, Beijing, China; Yuanyuan Zhang, , ,

Abstract Body: Peperites have been identified at the Lower Permian Upper Zhesi group in Beishan, China, which is significant for the reconstruction of Late Paleozoic evolution in the southern part of the Central Asian Orogenic Belt. Five types of peperites are distinguished in the Hongliuhe and Liuyuan profiles and interpreted as the products from basaltic lava bulldozing into wet, unconsolidated sediments at their basal contacts. Laser $^{40}Ar/^{39}Ar$ dating of the basalt yielding an age of 274±11Ma, as well as the occurrence of Early Permian brachiopod fossils in the carbonate sediments interbedded with the basalt confirm that the peperites formed in Early Permian. Identification of the peperites reveals that the basaltic lava flows were derived from autochthonous basaltic magmatism and formed as part of the Lower Permian succession. The peperites also distinguish these subaqueous basaltic lava flows are not dismembered ophiolitic components, formed as a product of oceanization in Early Permian. The clastic rocks in the Lower Zhesi group underlying the basaltic lava and peperites in the Hongliuhe and Liuyuan areas show a general fining-upwards sequence, indicating that they were deposited in a progressively deepening basin overlying the Devonian Hongliuhe suture zone. Therefore, the peperites were probably originated in a progressively subsiding-basin environment as a result of advanced rifting during Early-Middle Permian in the Beishan region. Subaqueous volcanism in rift basins, accompanied by coeval deposition of carbonate sediments and mudstones, built up the peperite-bearing volcanogenic-sedimentary successions. A detailed investigation of Permian peperites in the Beishan region provides a typical application in determining palaeoenvironment and thus constraining regional tectonic setting.

Title: Lithostratigraphy of Nigeria An-Overview

Presenter/First Author: Kazeem A Shitta, Geotechnical Nigeria Limited, Ibadan,

Presenter/First Author Email: kazy1424@yahoo.com

Co-authors: Kazeem A Shitta, , ,

Published Material: World Environmental and Water Resources Congress 2009: Great Rivers

Abstract Body:
Nigeria lies very close to the equator (hot country) West coast Africa between latitude 4N and 14 N degree and longitude 2 E and 15 E degree. The country is located at the Northern end of Eastern branch of west coast of Africa rift system. Nigeria geological set up comprises broadlysedimentary formation and crystalline basement complex, which occur more or less in equalproportion all over the country. The sediment is mainly Upper Cretaceous to recent in age whilethe basement complex rocks are thought to be Precambrian. The studied area lies between latitude12.4" and 11.11"W and longitude 13.81" and 14.13" S. The studied area is underlain byPrecambrian basement complex of southern western Nigeria .The major rock in the area is charnokite and granite rock. The granite rock which are member of the older granite suite occupy about 65% of the total area .The principal granite is petrographic variety are recognized .The fine grained biotite -granite medium coarse, non porphyritic biotite-hornblende granite and coarse-porphyritic biotite-hornblende granite. Also three main textural type of Charnokitic rock are alsodistinguished are coarse grained, massive fine grained and gneissic fine grained .The mode of occurrence of rock is three (1) core of the granite rock as exemplified by study area and few smaller bodies (2) Margin of the granite bodies as seen in Ijare and Uro edemo-idemo Charnokitic bodies and (3) Discrete bodies of the gneissic fine grained Charnokitic rock within the country gneisses as seen in Ilaro and Iju and Emirin village. All the charnokite in the region are dark-greenish to greenish -gray rocks with bluish quartz and greenish feldspar.

Title: Controls on the chemical composition of flood volcanics

Presenter/First Author: Nicholas T Arndt, , Meylan,

Presenter/First Author Email: Nicholas.Arndt@ujf-grenoble.fr

Published Material: The broad ideas have been published in several publications, but new ideas are introduced in this talk

Abstract Body: Continental LIPs are made up of two main types of mafic magma, referred to as high-Ti and low-Ti. The two types are the result of mantle melting under contrasting conditions, and the magmas behaved differently during their ascent through the crust.

High-Ti magmas have high contents of incompatible trace elements and strongly fractionated REE patterns. They result from low-degree melting of a possibly enriched portion of the mantle source – a mantle plume in most cases. Volatile components like H2O and CO2 act like incompatible elements and they are strongly concentrated in the melt. Their presence decreases melt density which drives the magma rapidly into the crust and the ascent accelerates once CO2 exsolves near the base of the crust. These magmas interact minimally with wall rocks and partly for this reason do not contain Ni-sulfide deposits.

Low-Ti magmas have lower contents of incompatible trace elements accompanied by the chemical signature of crustal contamination (negative Nb-Ta anomalies, high 87Sr/86Sr, negative epsilon Nd). They result from high degrees of melting of the hotter parts of the mantle source. Their low volatile content and more primitive composition imparts high densities that cause the magma to be trapped at density discontinuities at the base of, and within, the crust. In magma chambers, the magmas differentiate to less dense evolved melts that continue towards the surface and assimilate wall rocks, a process instrumental to the formation of Ni-sulfide ore deposits.

This type of model explains the geochemical characteristics of magmas in most continental LIPs, including Siberia, Emeishan, Deccan, Karoo and Ethiopia. The Bushveld Complex consists of low-Ti magma that assimilated massive amounts of crustal rock. Interaction with the continental lithospheric mantle had little impact on the major and trace element contents of flood basalts, but might have influenced the concentrations and isotopic compositions of platinum-group metals.

Title: Linkages between the Neoproterozoic Natkusiak basalts and Franklin sills on Victoria Island, Arctic Canada

Presenter/First Author: Charles Duncan Beard, McGill University, Montreal,

Presenter/First Author Email: charles.beard@mail.mcgill.ca

Co-authors: Dominique Weis, University of British Columbia, Vancouver, BC, Canada; Jean H J Bedard, Geological Survey of Canada, Quebec, QC, Canada; James S Scoates, University of British Columbia, Vancouver, BC, Canada; Trent A Dell'Oro, , ,

Published Material: Yes, these data were partially presented by J. Bédard at Goldschmidt 2012, also in Montréal. The interpretations have been refined and revised since this date. A manuscript has been prepared from these data, which will be submitted to Journal of Petrology before the end of January 2015.

Abstract Body: The 724–716 Ma Franklin Large Igneous Province extends >2500 km from Siberia to Greenland and is associated with break-up of Rodinia. On Victoria Island, the Natkusiak flood basalts cap the carbonate-dominated Shaler Supergroup (also with shale, sandstone and sulphate evaporite), which hosts the coeval Franklin sills. The basal Natkusiak basalt unit (50–100 m) is dominated by discontinuous flows and volcaniclastic rocks, and is overlain by voluminous sheet flow basalts (up to 800 m preserved thickness). The layered Type 1 sills have similar chemistry to the basal basalts, whilst the diabasic Type 2 sills resemble the sheet flow basalts. The former are restricted to deeper parts of the intrusive plumbing system.

Weak continental geochemical signatures, such as negative Nb–Ta anomalies, are ubiquitous in the intrusions and basalts, indicating that the Franklin magmas were pervasively, albeit subtly, contaminated during transit through the lithosphere. The basal basalt unit and Type 1 sills are the most contaminated with the lowest initial ε_{Nd} and ε_{Hf} (-6 to +8; -4 to

+5). Basal and sheet flow basalt units define separate trends in trace element plots and cannot be related by closed or open system fractional crystallisation or variable degrees of melting of a single mantle source.

The initial ε_{Nd} and ε_{Hf} of the northernmost Natkusiak basalts (-6 to +5; -4 to +16) are positively correlated along the OIB mantle array, whereas rocks from three southern volcanic sections are displaced toward more radiogenic Nd compositions (ε_{Nd} +4 to +12). The isotopic compositions of the Franklin sills exposed in the Minto Inlier correlate with the northern section basalts. The radiogenic Nd signature of the southern basalts is consistent with source contributions from old oceanic crust. We attribute this geographical control on melt composition to a long-lived heterogeneity in the Neoproterozoic mantle source(s) that was preserved in the basalts by a compartmentalized plumbing system.

Title: Newly discovered 1550 Ma mafic magmatism in the Tobacco Root Mountains, MT USA: An end to the North American Magmatic Gap?

Presenter/First Author: Chris Rogers, Carleton University, Ottawa, ON

Presenter/First Author Email: chris.rogers@carleton.ca

Co-authors: Richard E Ernst, Ernst Geosciences, Ottawa, ON, Canada; Brian Cousens, Carleton University, Ottawa, ON, Canada; Stephen Harlan, Nation Science Foundataion, Arlington, VA; Ulf Söderlund, Lund University, Lund, Sweden

Abstract Body: A new baddeleyite U-Pb age of 1552 ± 6 Ma for a dyke in the Tobacco Root Mountains (TRM) falls in the middle of a “magmatic gap” that was previously noted to exist between 1500 and 1600 Ma in western North America (Ross et al. 2003) based on the detrital zircon record of Proterozoic sedimentary rocks (Finney et al. 2005). Dykes of this age offer a potential local source for ca. 1550 Ma detrital zircons found within the Belt-Purcell Basin. The 1552 Ma age is significantly older than 1470-1430 Ma U-Pb mafic sills within the Belt-Purcell Supergroup and is unknown elsewhere in the Wyoming craton. The new U-Pb age for these intra-plate mafic dykes indicate that this magmatic event may have preceded 1470 to 1400 Ma extension and deposition of the Belt-Purcell Supergroup.

In the TRM, Proterozoic mafic dykes are subvertical, strike NW, and cut foliation of the Archean basement. Geochemical analyses of mafic dykes from the southern TRM and the Ruby Range (RR) by Wooden et al. (1978) identified distinct geochemical groups that they termed A, B, and C. We concur that there are three distinct groups of dykes within the TRM and RR. However, we revised the original groups based on more extensive and modern geochemical analysis. We propose A, B and C group dykes be renamed the Ramshorn Creek Group (RCG; 1552 Ma date applies), 780 Ma Gunbarrel dykes, and the yet undated Mammoth Group (MG), respectively. The very similar geochemical signatures of the RCG and MG dykes indicate deeper melting, more lithospheric contribution and different source(s) than the Gunbarrel dykes.

Paleomagnetic studies by Harlan and others (2005, 2008) yielded dual polarity magnetizations for both the RCG and MG dykes that are supported by both normal and reverse polarity baked contact tests. The definition of a 1550 Ma RCG pole from the southern TRM dykes would contribute to enhanced definition of the Laurentian apparent polar wander path during the Mesoproterozoic.

Title: Chigu Tso intrusions in the remnant Comei large igneous province, SE Tibet: implication for Early Cretaceous Kerguelen plume-Eastern Gondwana lithosphere interaction

Presenter/First Author: Ying Xia, Carleton University, Ottawa,

Presenter/First Author Email: mrxiaying@gmail.com

Co-authors: Di-Cheng Zhu, China University of Geosciences Beijing, Beijing, China; Richard E Ernst, Ernst Geosciences, Ottawa, ON, Canada; Brian Cousens, Carleton University, Ottawa, ON, Canada; Shuangquan Zhang, Carleton University, Auckland, ON, Canada

Abstract Body: Chigu Tso intrusions are found within the Jurassic strata of the remnant Comei large igneous province (LIP), SE Tibet, providing an opportunity to explore how the Early Cretaceous Kerguelen mantle plume interacted with the Eastern Gondwana lithosphere. Chigu Tso intrusions consist of three series: 1) a pyroxenite to low-P_2O_5 gabbro fractional crystallization group; 2) a transitional medium-P_2O_5 diabase-norite-gabbro group; and 3) a high-P_2O_5 gabbro to diorite group. Zircon U-Pb age dating of Chigu Tso intrusions (pyroxenite 130 ± 2 Ma, gabbro 132 ± 1 Ma; Zhu et al., 2009; diorites 132.4 ± 1.0 Ma, 133.7 ± 1.4 Ma; this study) suggest that Chigu Tso intrusions should be part of the magma plumbing system of the remnant Comei LIP. The low $\varepsilon_{Nd}(t)$ value of the pyroxenite (-1.8) is similar to SCLM-derived ultramafic rocks in Sylhet Traps (pyroxenite, -0.1 to -4.2; lamproite, -2.4 to -6.4; and kimberlites,-2.6 to -3.2; Ghatak et al., 2013). Isotope work in progress will resolve between the models of fractional crystallization of high-P_2O_5 gabbro and fractional melting of pyroxenite for the petrogenesis of the diorites. The presence of SCLM-derived ultramafic rocks and a crustal signature in the remnant Comei LIP, Bunbury basalts, Rajmahal-Sylhet traps, and Southern Kerguelen Plateau, suggest that the Eastern Gondwana lithosphere played an important role in the origin of this portion of Kerguelen plume-related magmatism.

Title: A Geochemical Proxy Approach to LIP Forensics

Presenter/First Author: Julian Anthony Pearce, Cardiff University, Cardiff, CF24

Presenter/First Author Email: PearceJA@cf.ac.uk

Co-authors: Richard E Ernst, Ernst Geosciences, Ottawa, ON, Canada; David William Peate, University of Iowa, Iowa City, IA

Published Material: Some background material is taken from Pearce J.A. (Lithos, 2008). Otherwise unpublished.

Abstract Body: One effective way to carry out forensic examination of LIPs is by using geochemical proxies for parameters such as mantle temperature, mantle composition, nature and degree of partial melting, crustal composition, and assimilation-fractional crystallization. In the ideal world, each geochemical proxy would highlight just one petrogenetic variable. Here, we investigate in detail the utility of three immobile element proxies: Th/Nb as a proxy for crustal input (via subduction or assimilation); Ti/Yb in basic rocks as a proxy for the role of garnet in the melting process; and either Sc or Co (depending on melting history) as a proxy for the degree of fractional crystallization. The Th/Nb ratio distinguishes LIP lavas with no crustal input, and hence low ratios typical of MORB and OIB, from those with crustal involvement and hence higher ratios. Of the latter, the crustal input may represent a subducted crustal component stored in sub-continental lithospheric mantle (SCLM), or continental crust assimilated by fractionating magma. Combining the

crustal proxy with the fractionation proxy, provides an opportunity to distinguish between the SCLM and assimilation options in many cases. The Ti/Yb proxy is based on the fact that high ratios are indicative of residual garnet, i.e. of thick lithosphere and/or relatively low mantle potential temperatures. A further consequence is that unusually low Ti/Yb ratios result from remelting of mantle preconditioned by earlier melting in the garnet facies. There are wide variations in the values of these proxies, both within and between individual LIPs. Between LIPs, differences in crustal assimilation, SCLM involvement, and mantle and melting parameters highlight differences in setting and geodynamics. Within LIPs, spatial and temporal variations in both crustal and mantle variables are common and, where exposure and reconstructions allow, these can be highlighted through geochemical mapping based on the Th/Nb and Ti/Yb proxies.

Title: New insights into the relationship between the Central Atlantic Magmatic Province (CAMP) and the End-Triassic extinction from CAMP U-Pb zircon and baddeleyite dates.

Presenter/First Author: Joshua Davies, University of Geneva, Geneva,

Presenter/First Author Email: joshua.davies@unige.ch

Co-authors: Herve Bertand, Laboratoire de Géologie de Lyon, UMR-CNRS, Lyon, France; Nasrrddine Youbi, Cadi Ayyad University, Faculty of Sciences-Semlalia, Marrakech, Morocco; Urs Schaltegger, University of Geneva, Geneva, Switzerland

Abstract Body: The Central Atlantic Magmatic Province (CAMP) is a sequence of flood basalts, dyke swarms and sill complexes , emplaced predominantly into the Triassic and Jurassic basins of Pangea. The exact extent of the flood basalts is unknown, but it is thought to be one of the largest outpourings of basalt magma onto the continental crust during the Phanerozoic Eon. Consequently, the basaltic eruptions has been linked with the End-Triassic extinction, the initiation of Pangea breakup and the opening of the Central Atlantic Ocean. However, the link between the CAMP basalts and the End-Triassic extinction is still unclear, which is in part, due the basalts being stratigraphically above the extinction horizon in all of the basins where they have been discovered. A negative carbon isotope excursion and a spike in fern spore abundance mark the extinction horizon and these are below the lowest basalts in North America, and also just below the basalts in Morocco, where the oldest CAMP basalts are thought to outcrop.

Here we present high precision U-Pb TIMS dates for zircons from the Moroccan and North American CAMP successions that suggest that there was CAMP magmatic activity before the eruption of the first basalts. Antecrystic zircons from a basalt flow in North America suggest a long pre-eruption history of magmatism associated with the CAMP. Baddeleyite and zircon from a dyke in the Moroccan CAMP also suggest a similar pre-eruptive history. Both the zircon and baddeleyite were extracted from coarse gained sections of the flow and dyke in an attempt to avoid zircons crystalizing in late melt segregations which are usually the target for basalt U-Pb dating. We also present hafnium isotope data from the zircons and baddeleyites to support our conclusions. The identification of zircon and baddeleyite antecrysts provide an insight to the pre-eruptive history of the CAMP and have significant implications for the relationship between the CAMP and the End-Triassic extinction.

Title: Lyra Basin and Louisville Seamount Chain: Two Suspects for the Ontong Java Plateau Hotspot Trail?

Presenter/First Author: Maria Luisa G Tejada, JAMSTEC Japan Agency for Marine-Earth Science and Technology, Yokosuka,

Presenter/First Author Email: mtejada@jamstec.go.jp

Published Material: This abstract highlights some findings from three submitted papers: two on Lyra Basin have been accepted for publication in the GSA Special Volume on Oceanic LIPs and one is under review for G-cubed. Partial results (about 50% each) from these papers were presented at IAVCEI in Japan (2013) and at Goldschmidt in Florence (2013).

Abstract Body: The Ontong Java Plateau (OJP) is believed to have formed during the initial or plume-head stage development of a huge mantle upwelling, but its hotspot trail has not been unequivocally defined or found. One of the longest-lived hotspot traces in the Pacific, the Louisville Seamount Chain (LSC), has long been suspected of representing the trail of the OJP. The International Ocean Drilling Program Expedition 330 is one of the more recent attempts to uncover this link between OJP and LSC. Re-Os isotope and platinum group element investigation of samples from three of the five drilled sites give a very weak lead to the possibility of a plume head to tail relationship between the OJP and the LSC [1]. Meanwhile, the less known Lyra Basin in the western margin of the OJP has been shown by geophysical studies to be underlain by unusually thick oceanic crust, believed to result from emplacement of massive flows from the plateau. Geophysical survey and dredging was conducted by Japan Agency for Marine-Earth Science and Technology to test the relationship between Lyra Basin and OJP. Geochemical and geochronological investigation of the dredged rocks from the basin instead show that younger alkalic rocks, which are geochemically akin to those of alkalic rocks and alnoites in Malaita, Solomon Islands in the southern margin of the OJP, may have covered older plateau crust in the basin [2]. Although not directly related to the main plateau volcanism at 120 Ma, the geochemical data and modeling suggest that the origin of the Lyra Basin alkalic rocks may be genetically linked to the mantle preserved in the thick lithospheric root imaged beneath the OJP, with magmatic contribution from the Rarotongan hotspot [3]. Combined with the other alkalic volcanism on and around the plateau, the Lyra Basin alkalic rocks could represent part of the late-stage magmatic development of the OJP.

Title: Changes in the Thermal and Compositional Structure of the Earth's Mantle, High-Mg LIP Magmatism, and Magmatic Ni-Cu-PGE Deposits Through Time

Presenter/First Author: C Michael Lesher, Laurentian University, Sudbury, ON

Presenter/First Author Email: mlesher@laurentian.ca

Published Material: Gave a talk on the temperature changes at the "Great Plume Debate" a few years ago, and have published some of the ideas on the ore deposits. This is an update and overview requested by the convenors.

Abstract Body: There was an abrupt change in the maximum MgO content of mantle-derived magmas at the Archean-Proterozoic boundary: from

Archean high-Mg komatiites with up to 33% MgO erupted at up to 1660^oC (or more if superheated), to Proterozoic low-Mg komatiites/ferropicrites with up to 22% MgO erupted at up to ~1440^oC and Phanerozoic low-Mg komatiites/high-Mg picrites with up to 23% MgO erupted at up to ~1460^oC. The ~10% MgO change in composition corresponds to a ~200^oC change in eruption T and a 170^oC change in the potential temperature of the mantle source regions. The abrupt decrease in maximum magma temperature, along with a wide range of other fundamental changes that occurred at the end of the Archean, indicate a fundamental and irreversible change in the thermal and/or compositional structure of the mantle at that time from one that could produce much hotter plumes but that involved only nominally hotter upper mantle. The origin is still being debated, but the most widely discussed scenarios are: 1) generation of a thermal/compositional boundary layer along the core-mantle boundary, 2) a change from whole-mantle to 2-layered convection, and 3) a change from 2-layered to whole-mantle convection. Regardless of the precise origin, the change profoundly influenced the viscosity of the magmas, their ability to ascend through the crust and therefore their volcanic/subvolcanic settings of emplacement, and the composition of associated magmatic Ni-Cu-PGE mineralization. Archean deposits are predominantly predominantly volcanic to very high level subvolcanic with higher Ni/Cu and lower Pd/Ir, Proterozoic deposits are volcanic with intermediate Ni/Cu and Pd/Ir, and Phanerozoic deposits are subvolcanic to plutonic with lower Ni/Cu and higher Pd/Ir. Most deposits, regardless of age, exhibit relatively flat mantle-normalized metal patterns and appear to be derived from primarily peridotitic mantle sources, but some are enriched in Co-Ni-Cu relative to Au-PGE and appear to be derived from pyroxenitic sources.

Title: A Petrogenetic Model for LREE-Enriched Basalt and Gabbros in the Coldwell Alkaline Complex, Midcontinent Rift, Ontario

Presenter/First Author: David John Good, University of Western Ontario, London, ON

Presenter/First Author Email: dgood3@uwo.ca

Co-authors: Pete N Hollings, Lakehead University, Thunder Bay, ON, Canada; Cundari M Robert, , , ; Doreen E. Ames, , Ottawa, ON, Canada

Abstract Body: The Coldwell Alkaline Complex (CAC) is associated with the Midcontinent rift event. The eastern and northern margin of the CAC consists of numerous cross-cutting gabbroic to ultramafic intrusions that are associated with magma conduit style Cu-Pd deposits. A package of basalt flows that overlie syenite near the centre of the CAC is linked to the gabbroic bodies by common geochemical characteristics. This study presents a petrogenetic model for the mafic rocks based on a comprehensive geochemical and isotopic study of the basalt and gabbroic bodies.

Observations are centred on the highly unusual LREE abundances in the basalt, and on trend lines for La vs. Zr or La vs. Th variation diagrams that resemble effects due to contamination, but evidence suggests contamination did not occur by assimilation of crustal material, as follows: (a) there is a negligible increase in Th, Zr and SiO_2 with increasing La; (b) absolute abundances of HFSE in basalt are comparable to E-MORB; and (c) Nd and Sr isotopic signatures are near CHUR. The evidence suggests LREE enrichment occurred at the time of partial melting from a LREE enriched mantle source, and not by crustal contamination.

Excluding LREE abundances, the composition of the initial Coubran basalt magma is interpreted to be comparable to Mamainse Point volcanic group 1. This interpretation is supported by similar Th/Nb and Tb/Yb values, and similar abundances of LILE, HREE, HFSE, and major elements. However the extruded Coubran basalt magma must have undergone fractional crystallization at depth in order to explain the present low Ni and Mg Numbers.

A proposed geochemical model for fractional crystallization of various basalt magma compositions that lie along the La-Zr or La-Th trajectories can explain the trace element compositions of five prominent gabbroic bodies in the CAC (Two Duck Lake gabbro, layered troctolite sill, Geordie Lake gabbro, gabbroic anorthosite and layered olivine gabbro).

Title: Black Thor Intrusive Complex in the 2.7 Ga McFaulds Greenstone belt, Superior Province: a feeder system of an Archean Large Igneous Province?

Presenter/First Author: Heather J. E. Carson, Laurentian University, Sudbury, ON

Presenter/First Author Email: hcarson@laurentian.ca

Co-authors: C Michael Lesher, Laurentian University, Sudbury, ON, Canada; Michel G Houlé, Laurentian University, Sudbury, ON, Canada

Abstract Body: The Ring of Fire Intrusive Suite (RoFIS) encompasses coeval ultramafic- and mafic-dominated intrusions, interpreted to represent the subvolcanic parts of a large igneous province that has either eroded away or not yet been identified due to limited outcrop in the region. The RoFIS contains world-class chromite deposits (e.g., Black Thor, Big Daddy, Blackbird), significant Ni-Cu-(PGE) mineralization (e.g., Eagle's Nest), and potentially significant Fe-Ti-V mineralization (e.g., Thunderbird). The Black Thor Intrusive Complex (BTIC) of the RoFIS is dominated by olivine ± pyroxene-rich cumulate rocks, contains an aggregate thickness of 100m chromite mineralization (much more than in typical stratiform chromite deposits) and is derived from a komatiitic magma with 22-23 wt% MgO. Mass balance calculations indicate that the BTIC contains ~30% more Ol and ~6% more Chr than the parental magma (i.e., 12x more Chr than cotectic proportions), indicating that the BTIC represents a feeder system in which Ol and Chr accumulated. The BTIC is at least 15 km long x 1.5 km wide x 1 km deep (open at depth). Combined with abundant nearly contemporaneous mafic-dominated ferrogabbroic intrusions and the missing volume of evolved magma required to mass balance BTIC cumulates, the volume of the magmatic system is inferred to be greater than 32,000 km3. Ni-Cu-(PGE) ores occur within magmatic feeders and along basal contacts of the ultramafic-dominated intrusions and formed early in the magmatic history of the system, chromite ores occur in the middle parts of the ultramafic-dominated intrusions and formed at an intermediate stage, and Fe-Ti-V mineralization occurs in mafic-dominated intrusions, more evolved parts of the entire system. Together these imply the presence of both deeper fractionation chambers (to produce the ferrogabbros) and overlying evolved lavas (fractionates of BTIC cumulates).

Title: Mafic-Ultramafic Magmatism in the Bird River/Uchi/Oxford-Stull/La Grande-Eastmain Superdomain: Potential Remnants of Meso- and Neoarchean LIPs in the Northern Superior Province

Presenter/First Author: Michel G Houlé, Laurentian University, Sudbury, ON

Presenter/First Author Email: michel.houle@nrcan.gc.ca

Co-authors: C Michael Lesher, Laurentian University, Sudbury, ON, Canada; Vicki McNicoll, Geological Survey of Canada, Ottawa, Canada, ON, Canada; Riku T Metsaranta, Ontario Geological Survey, Sudbury, ON, Canada; Anne-Aurélie Sappin, Geological Survey of Canada, Québec, Canada; Jean Goutier, Géologie Québec, Rouyn-Noranda, QC, Canada; Valérie Bécu, Geological Survey of Canada, Québec, Canada; Paul Gilbert, , ,

Abstract Body: The discoveries of world-class Cr deposits, significant Ni-Cu-PGE deposits, and numerous Fe-Ti-V occurrences in the McFaulds Lake (a.k.a. "Ring of Fire") area of northern Ontario have greatly renewed interest in orthomagmatic mineralization associated with mafic-ultramafic intrusions in the Superior Province. Cr-(PGE) deposits and, to lesser extent, Fe-Ti-V and Ni-Cu-(PGE) deposits/occurrences, occur predominantly in the northern part of the Superior Province within Meso- to Neoarchean supracrustal successions along the margins and within the cores of the Bird River–Uchi–Oxford-Stull–La Grande–Eastmain domains (i.e., BUOGE "superdomain").

Ultramafic to mafic magmatism of various types (e.g., komatiitic, tholeiitic, alkalic) extended over a period of more than 200 Ma within the BUOGE superdomain, from ~2.88 to 2.66 Ga. However, only two main intervals (ca. 2810 Ma and ca. 2735 Ma) are recognized to have generated major magmatic events across the superdomain. Although limited in size, emplacement of large amounts of ultramafic to mafic magmas over a short period of time, locally combined with komatiite-tholeiite successions, argues in favor that these intrusions could represents remnants of Archean LIPs. The broader Neoarchean magmatic event that includes the intrusive suites of the Bird River in Manitoba (ca. 2743 Ma), the Ring of Fire in Ontario (ca. 2734 Ma), and several but more localized ultramafic intrusions within the La Grande domain in Québec (ca. 2754 Ma), is by far the best candidate to represent an Archean LIP that consist of at least three magmatic pulses over 20 My associated with the emplacement of Cr-PGE, Ni-Cu-PGE deposits, and significant Fe-Ti-V occurrences.

This superdomain defines a major Cr-Ni-Cu-PGE-V metallotect within the Superior Province that appears to be fundamentally different from other parts, such as the Abitibi greenstone belt or the apparently relatively unmineralized North Caribou core, Island Lake, and Goudalie domains. Ongoing work aims at establishing geological settings and characteristics of these orthomagmatic deposits in many of these areas, to help constrain the likelihood of discovering additional mineral resources in the BUOGE superdomain, but also in other frontier areas throughout the Canadian Shield.

Title: Hf Isotope Constraints on the Origin of the Bushveld Magmatic Province

Presenter/First Author: Nasser Alexander Zirakparvar, American Museum of Natural History, New York, NY

Presenter/First Author Email: nzirakparvar@amnh.org

Co-authors: Edmond A Mathez, American Museum Natural Histry, New York, NY

Abstract Body: The Bushveld Magmatic Province (BMP) contains >30 individual mafic-ulramafic to felsic bodies that were intruded into the northern half of the Kaapvaal craton of South Africa and Zimbabwe, between 2.05 and 2.06 Ga. The initial Hf isotope compositions of zircon from the Bushveld Igneous Complex (BIC) and Phalaborwa Carbonatite Complex (PCC), two large bodies in the BMP, are unradiogenic, internally homogeneous, and similar to one another ($\varepsilon Hf_{(2.06\ Ga)}$ = -8.6 ± 2.6 and -7.5 ± 2.4 for the BIC and PCC, respectively). We have previously interpreted this to mean that the BIC and PCC parent magmas were produced by melting of a geochemically enriched source within the ancient subcontinental lithospheric mantle (SCLM). We are now determining the Hf isotope compositions of zircon by LA-ICP-MS from related rocks in the region to constrain the geographic distribution of this SCLM source and the extent to which it was involved in the generation of other bodies in the BMP. The Marble Hall diorite, a small intrusion situated near the BIC's geographic center but whose structural relationship to the BIC remains unclear, yields a range of $\varepsilon Hf_{(2.06\ Ga)}$ from -1.3 ± 0.9 to -6.2 ± 1.9 (Avg. = -3.7 ± 2.8; n = 15). This more radiogenic composition relative to the BIC and PCC may indicate that the SCLM source of these intrusions is more heterogeneous than initially thought, or that the Marble Hall diorite was derived from a different source altogether. In the southeastern part of the BMP, the Schurwedraai alkali granite, a ~2.05 Ga peralkaline to peraluminous intrusion exposed in the northern collar of the Vredefort Dome, yields $\varepsilon Hf_{(2.06\ Ga)}$ from -18.6 ± 2.0 to -30.4 ± 3.0, (Avg. = -22.6 ± 6.4; n = 29). This unradiogenic composition is consistent with melting of Archean continental crust, suggesting that the heat source that induced melting of the SCLM to produce the BIC and PCC parent magmas also resulted in anatexis.

Title: Tapping of the Bushveld magma chamber: Experiments on the parental magma to the Upper Zone

Presenter/First Author: Bernard Charlier, Leibniz University of Hannover, Hannover,

Presenter/First Author Email: b.charlier@mineralogie.uni-hannover.de

Co-authors: Saskia Hövelmann, , , ; Olivier Namur, University of Hannover, Hannover, Germany; André Stechern, , , ; Francois Holtz, Leibniz University of Hannover, Hannover, Germany

Abstract Body: The Bushveld layered intrusion covers ca. 65.000 km² in South Africa and is made up of a 7-9 km thick cumulate sequence. The upper 2 km of the intrusion (upper part of the Main Zone and Upper Zone) is known for the abundance of Fe-Ti-V±P ore deposits. The bottom of this sequence is characterized by a 2-3 m thick layer of orthopyroxenite known as the 'Pyroxenite Marker'. It is considered as the last major influx of magma (ferrobasalt) in the Bushveld magma chamber. In this study, we have performed crystallization experiments and MELTS calculations on various estimates for parental magmas to the 'Upper Zone and Upper Main Zone' of the Bushveld Complex. Our experimental data constrain phase equilibria and the liquid line of descent during the evolution from evolved basalt to rhyolite. We also aim at constraining the composition of the parent magma after the Pyroxenite Marker by comparing experimental data and the continuous crystallization record in the Bellevue and Bierkraal drill-cores. Experiments were conducted at 200 MPa and 1160-1100°C in internally heated pressure vessels on selected compositions proposed in the literature, varying essentially in SiO_2 (50-55 wt%), CaO (7-11 wt%) and Mg-number (37-48). The stability fields of the pyroxenes and olivine are very sensitive to small compositional differences in the starting materials, producing a variety of pyroxenes from orthopyroxene, pigeonite, sub-calcic augite to augite. The formation of orthopyroxene at the base of the sequence requires a parental magma that corresponds to the bulk cumulate composition of the Upper zone to which 25-40% monzonite/rhyolite is added. Little evidence exists for the occurrence of this amount of evolved material in plutonic environment. It is more reasonable to consider open-system evolution of the Bushveld magma chamber that was regularly tapped during the crystallization of the Upper Zone, possibly erupted at the surface as the Rooiberg suite.

Title: Geochemistry of small differentiated intrusions and associated large igneous provinces: controls on the formation of magmatic sulfide ore deposits

Presenter/First Author: Peter C Lightfoot, Vale, Sudbury, ON

Presenter/First Author Email: peter.lightfoot@vale.com

Abstract Body: The formation of magmatic sulfide ore deposits is often considered to be the result of the saturation of mafic and ultramafic magmas in sulfur, and the formation of dense immiscible sulfide melts which segregate from the magma, concentrate metals, and form ore deposits. The triggers for saturation are widely considered to be contamination by the assimilation of S-rich crust, whereas the as important in the formation of world class ore deposits like Noril'sk. Several controls remain less well understood; viz: 1. Does the composition of the source and the depth of magma generation control mineral potential?; 2. Is the pathway of magma transportation an important control on ore formation?; 3. Are magmatic sulfides actually transported from the site of formation into the intrusions?; 4. What is the relationship of small differentiated intrusions to the large volumes of mafic magma that erupt in rift settings and as continental flood basalts?; 5. What relationships exist between ore formation and the stage of formation of large igneous provinces (LIPs)?

This presentation uses geochemical data for basaltic volcanic rocks and differentiated intrusions to look at process controls in the Siberian, Deccan, West Greenland, and Emeishan flood basalt provinces, the Keweenawan Mid-continent Rift (MCR), and the Nain Plutonic Suite (NPS). In the cases of the Deccan and NPS, composition of the source appears to control the availability of precious metals, nickel and copper. Mineralized differentiated intrusions in the Siberian Trap, MCR, and Emeishan occupy space created by trans-tension in strike-slip structural zones, and have geochemical and petrological features which support the emplacement of sulfide-laden magmas. The stage of formation of the mineralized intrusions often links to the early rifting and faulting of the crust in response to far-field tectonic events; this is illustrated by mineralized intrusions associated with the Siberian, West Greenland, and Emeishan LIPs. Although ore systems are genetically related to LIP events, the geochemical signatures of ore formation are found in discrete packages of comagmatic flood basalt erupted in depo-centers along the structural zones.

Title: Minor Ultramafic-mafic Intrusions of Devonian Altai-Sayan LIP (South Siberia): Petrogenesis and Ore Potential

Presenter/First Author: Andrey Vishnevskiy, V.S. Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk,

Presenter/First Author Email: vishnevsky@igm.nsc.ru

Co-authors: Andrey Izokh, , , ; Gleb Polyakov, , , ; Maria Cherdantseva, , ,

Published Material: Partly reported on IPS12 in Yekaterinburg last year and LIPs of Asia in Hanoi in 2013, under review in Mineralium Deposita special issue

Abstract Body: There are several hundred minor ultramafic-mafic and mafic bodies of Early Devonian age in the central part of the Altai-Sayan folded area (part of Central Asia Orogenic Belt). It is assumed that they are derived from one of the earliest and most primitive melts formed during the formation of the Altai-Sayan LIP. Altai-Sayan LIP formed simultaneously with Vilyui LIP (NE Siberia), the bulk of which are intracontinental rift basalts filled large depressions like Minusa and Tuva troughs. We have studied more than 20 minor intrusions of this age in the Tsagaan Shiveet Ridge in NW Mongolia. Rocks composition varies greatly and there are different types of intrusions: minor homogeneous, layered and minor differentiated. However, the geochemical characteristics of these rocks are relatively close to each other, and in this way are significantly different from the bodies of the Cambrian age also situated in the area, suggesting a common mantle source, but different ways of evolution of the initial melts. In one of the intrusions a small occurence of Cu-Ni ores with PGE mineralization was found. The total content of PGE in the samples is about 750 ppb, with 0.35 wt.% Cu and 0.5 wt.% Ni. Thus there is potential to find similar deposits in other intrusions of this age.

This works were funded by Russian Foundation for Basic Research (grants 12-05-00435, 13-05-01132, 13-05-00951 and 13-05-12056).

Title: Get Good Data: Establishing Optimal Measurement Precision and Practical Detection Limits for Portable XRF

Presenter/First Author: Pim van Geffen, REFLEX Geosciences, Vancouver, BC

Presenter/First Author Email: pim.vangeffen@imdexlimited.com

Co-authors: Cindy Collins, , ,

Abstract Body: The data quality of field-portable and handheld X-Ray Fluorescence devices has made huge leaps over the past decade, most notably in improved analytical precision. More sensitive detectors and higher count rates provide greater spectral resolution. Spectral interferences and other matrix effects aside, the technique provides reliable quantification of elemental compositions within the detectable energy range (Mg to U) and some elements can be confidently measured as low as single ppm. However, the ultimate data quality relies mostly on the instrument's operator. Decisions about sample collection, preparation, presentation and instrument settings are critical, as is observing a thorough QA/QC protocol to assess contamination, precision and accuracy. Most critical of these parameters is the precision. The accuracy can be adjusted by post-process calibration, provided the precision is acceptable and a sufficient number of appropriate certified reference materials have been included in the analytical sequence. Given the chemical complexity of typical geological samples, it is imperative to assess the actual measurement precision, from sampling error (field duplicates) to analytical error (detection). Because of aforementioned interferences and matrix effects, most elements may not have quite as low detection limits as could be achieved in clean, homogenous substances. Fortunately, we can derive practical detection limits for each element in an analytical sequence, based on the recorded measurement-error distributions.

Title: Combining pXRF Analysis with pXRD Data Provides Truly Quantitative and Qualitative Sample Characterisation

Presenter/First Author: Yulia Uvarova, CSIRO Australian Resources Research Center, Perth,

Presenter/First Author Email: yulia.uvarova@csiro.au

Co-authors: James Cleverley, REFLEX, Perth, Australia; Aaron Baensch, , ,

Published Material: Partially reported at the IMA 2014 meeting

Abstract Body: Portable X-ray fluorescence (pXRF) spectrometry has numerous applications in a wide range of studies, including: non-destructive analyses in the alloy metals industry, particularly scrap metal sorting and material identification; archaeometry; environmental sciences for conducting contamination characterization, removal, and remedial operations at hazardous waste sites; archaeology; non-invasive analysis of museum artefacts; rapid screening of toxic elements in various products, goods and media; and soil analysis and agriculture. In the last decade, pXRF analysis has emerged as an important analytical technique for exploration and mining. Portable XRF offers rapid and cost-effective analysis of geologic samples and provides data of high quality and accuracy where appropriate calibration and quality assurance/quality control protocols are followed. Conversely, until now powder X-ray Diffraction (XRD) has been a technique that is used mainly in research. With the advancement in hardware technology, namely X-ray tubes, detectors and processors, and more powerful and sophisticated software packages, X-ray diffraction has become a qualitative and quantitative tool for the identification of crystalline materials, and has tremendous potential applications in exploration and mining. With the current progress in development and implementation of automated algorithms for data processing, XRD has the potential to become a routine technique for analysis of geologic materials. Ultimately, combined portable XRF and XRD instrument analyses will allow rapid chemical and mineralogical characterisation of a sample. The current study illustrates that coupled pXRF-pXRD analysis can be performed on a large set of complex geological samples and the techniques complement each other. In this study we also give a few practical examples from various industrial applications.

Title: Assessing the Interpretability of Soil Geochemical Surveys from Site Duplicate Sampling: Measures and Metrics

Presenter/First Author: Charles Beaudry, Retired, Toronto,

Presenter/First Author Email: beaurycha@hotmail.com

Published Material: Parts of conference were presented at the AIGS Symposium https://www.appliedgeochemists.org/index.php/events/aag-events/2-uncategorised/115-26th-international-applied-geochemistry-symposium in Rotorua, NZ, in 2013.

Abstract Body: Strong evidence exists in the recent literature on partial and selective extraction soil geochemistry to show that these methods can detect blind mineral deposits covered by transported overburden that should normally preclude detection, at least according to any conventional understanding of how soil geochemical anomalies form. However in routine applications these methods tend to produce high proportions of false positive and false negative anomalies hindering interpretation of results and preventing their widespread adoption.

To understand why these methods are difficult to work with one must consider a soil geochemical survey from the perspective of a measurement system. The variance of results is a combination of the variance of the survey and the variance of the measurement system (which includes all sources of variance from the point of collection of the sample to the analysis itself and is cumulative). Conceptually this is the partitioning of variance between sources and can be measured in principal, albeit with difficulty, by collecting sample site duplicates. For an acceptable measurement system the variance of site duplicates should be less than 30% of the variance of the survey and the lower this number the better it will be able to detect variations in the survey results and hence able to detect reliable anomalies if present. As a comparison, surveys in residual soils based on aqua regia digestion typically give values below 10% but partial/selective extraction methods in Abitibi clay covered areas often have sampling variance exceeding 50% of the survey variance. This leads to excessively noisy data making interpretations very difficult. Methods exist to reduce the variance of sampling but unfortunately in some instances it is the variance itself that is anomalous and may be signaling the presence of mineralization.

The method presented here based on the Gage R&R analysis, available in any commercial statistical software package, allows us to calculate measures of fitness of any survey dataset containing a standardized set of site duplicates and metrics to measure performance of the survey including minimum anomaly thresholds for any analysed component.

This approach is probably even more essential when using field portable instrumentation such as XRF analysers.

Title: HH-XRF: A decision tool for exploration success, the example from Sirios' gold Cheechoo project

Presenter/First Author: Réjean Réjean, Geoscientists IOS Services Inc, Saguenay, QC

Presenter/First Author Email: rejeang@iosgeo.com

Co-authors: Dominique Doucet, Ressources Sirios Inc, Montréal, QC, Canada

Abstract Body: Hand held X-ray fluorescence analyzer (HHXRF) were made available to mineral exploration industry about 10 years ago, and then regarded as high-tech toy for gizmo lovers, trigging dreams ofexploration efficiency. However, when properly used, HH-XRF analysers are powerful decision making tools. As example, a HH-XRF has been used in the course of a humus geochemistry program where provided quick analyses, although of lesser quality, prior that sample being to submitted for conventional ICP-MS assaying. Although definitively less sensitive and accurate, HHXRF detected reliably the presence of the main pathfinder elements for gold, such as arsenic, tungsten and cobalt. Obtaining fast results enabled Sirios Resources to convey an effective prospecting program upon the detected anomaly within the same summer. HH-XRF lead to the discovery of the first gold bearing occurrence on their Cheechoo project located in James Bay, northern Québec. All the significant anomalies were subsequently confirmed by ICP-MS analysis after Na-pyrophosphate digestion.. Anomalies were related to minutely disseminated pyrite, arsenopyrite and scheelite in subjacent bedrock, barely distinguishable by the naked eyes, and grams per ton gold grades. Although HHXRF has not detected subtleties, it proved effective to detect the major signatures, and saved almost a year in the exploration cycle. A review of the analytical results and reliability, with inter-elements and inter-methods comparison will be presented. The Cheechoo project host a broad low-grade gold mineralization hosted within an Archean tonalite near Goldcorp's Eleonore mine, a context interpreted as a reduced intrusion hosted deposit. This type of mineralization is notorious for being difficult to detect.

Title: The Application of pXRF and benchtop SEM (bSEM) to Characterize the Igneous Stratigraphy and Cu-Pd Mineralization in the Eastern Gabbro, Coldwell Alkaline Complex

Presenter/First Author: Yonghua Cao, University of Western Ontario, London,

Presenter/First Author Email: ycao84@uwo.ca

Co-authors: Robert Linnen, University of Western Ontario, London, Canada; David John Good, University of Western Ontario, London, ON, Canada; Iain M. Samson, University of Windsor, Windsor, ON, Canada; Matthew Jacek Brzozowski, University of Windsor, Windsor, Canada

Abstract Body: The current study involves the application of pXRF and bSEM to characterize the igneous stratigraphy and Cu-Pd mineralization on the north edge of the Eastern Gabbro of the Coldwell Alkaline Complex. The Midcontinent Rift-related Coldwell complex intruded into the Schreiber-White River Archean greenstone belt, which consists of low-grade metamorphic volcanic and sedimentary rocks. The Eastern Gabbro occurs along the outer margin of the complex and consists of the Fine Grained, the Layered and the Marathon magmatic series. The Marathon Series hosts several Cu-Pd occurrences in the area, including the Geordie Lake and Marathon Cu-Pd deposits.

Comparisons between portable analyses and lab-based analyses were carried out first to confirm their data quality. For example, pXRF data and bSEM-EDS data were compared to traditional XRF and ICP data and electron microprobe data, respectively. Our results show that both portable techniques are comparable with their lab-based counterparts. In addition, the comparison among EDS measurements on unpolished blocks, polished blocks, and carbon-coated thin sections was conducted to evaluate the necessity of different amounts of sample preparation.

Distinguishing the different gabbro units is a key to Cu-Pd exploration, however, it is difficult to identify the different series of gabbros in the field, in particular for magnetite- and plagioclase-rich augite melatroctolite in the Layered Series, and the magnetite melatroctolite in the Marathon Series. The combination of pXRF and the bSEM successfully differentiated these units: The pXRF was used to differentiate the different igneous units using P_2O_5, Fe_2O_3, TiO_2, Ba, and V. The bSEM was applied to characterize different units using Mg# of olivine and clinopyroxene, and the An content of plagioclase. The combination of these two techniques demonstrates that field-portable methods can be used to map igneous stratigraphy, which is a key component of future Cu-Pd exploration.

Title: Comparison of portable XRF performance on unprepared drill cores and on powders for “whole rock” analysis

Presenter/First Author: Alexandre Bourke, INRS-ETE, Quebec City, QC

Presenter/First Author Email: alexandre.bourke@ete.inrs.ca

Co-authors: Pierre-Simon Ross, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, Canada

Published Material: The content of this presentation is found in an article submitted in november 2014 to the journal Geochemistry: Exploration, Environment, Analysis. It is still waiting for acceptance.

Abstract Body: Portable (including handheld) XRF devices (pXRF) are fast gaining in popularity in the mining and exploration industries. They can acquire quickly and *in situ* (a) concentrations of elements of economic interest and (b) “whole rock” analysis for major oxides and trace elements. But since pXRF is a relatively new and rapidly evolving technology, analytical protocols and instrumental performances are not yet well known. In particular, the question of whether a rock core sample should be crushed and pulverized or not prior to analysis has not been systematically studied. Considering that sample preparation is time-consuming and that it destroys the cores, is it worth it?

This presentation compares pXRF data quality on unprepared rock cores and on powders for “whole rock” analyses, examining the instrumental precision (relative standard deviation, RSD, of a series of measurements on the same spot), the sample precision (for unprepared samples, RSD of a series of measurements on different spots on the core) and the accuracy. We also test for instrumental drift.

Our tests use two Olympus Innov-X Delta Premium pXRF analyzers and samples of dense Precambrian volcanic and intrusive cores from the Abitibi Subprovince. In general, we find that: (1) sample preparation does not improve instrumental precision, and may even degrade it for some elements; (2) mineralogical heterogeneity effects can be attenuated, and even canceled for some elements, by averaging closely spaced *in situ* data taken during the same amount of time required for pulverizing a sample; (3) accuracy is much worse on powders for three oxides, namely Al_2O_3, MgO and SiO_2, it is improved for Cu and Zn on powders, and it is comparable on both media for the other elements. Finally, we find no significant instrumental drift within a day, or between different months.

Abstract Body: Gunbarrel magmas display similar geochemical characteristics to known economic LIPs of Canada, including a range of chalcophile element depleted magmas and (Cu/Zr)PM vs. (Th/Yb)PM trends towards crustal input which suggests possible S-saturation and sulphide immiscibility. This makes Gunbarrel intrusions a potential economic target for Ni-Cu-PGE exploration.

Title: Modelling the Structure and Composition of Layered Intrusions in Plume Center Regions using Potential Field Data

Presenter/First Author: Jennifer Blanchard, Carleton University, Ottawa,

Presenter/First Author Email: jennifer.blanchard3@carleton.ca

Co-authors: Claire Samson, Carleton University, Ottowa, ON, Canada; Richard E Ernst, Ernst Geosciences, Ottawa, ON, Canada; Alan Robert King, Geoscience North, Sudbury, ON, Canada

Abstract Body: Economic concentrations of Ni-Cu-PGEs are commonly emplaced in layered mafic-ultramafic intrusions. These intrusions can be linked with Large Igneous Provinces (LIPs), suggesting that LIPs should be primary exploration targets. Furthermore, it has been proposed that layered intrusions located within a few hundred kilometers of the plume center are the most prospective mining targets.

Intrusions are often associated with prominent gravity and magnetic anomalies, allowing for their detection using geophysical methods. We assessed the plume center regions of 17 LIPs and have catalogued possible layered intrusions in about half of these. At least two styles of geophysical anomalies are recognized. The first is the more common occurrence of a large gravity high adjacent to the plume center, typically associated with a magnetic anomaly (eg., 1270 Ma Mackenzie LIP, Canada) . The second type is a large magnetic anomaly coincident with a weak gravity signature (e.g., 130-80 Ma High Arctic LIP). These anomalies are being modelled to determine their source depth, shape and composition based on joint modelling of gravity and aeromagnetic data.

A prominent +700 nT sub-circular magnetic anomaly with a diameter of about 60 km, likely linked with the High Arctic LIP, is situated on Ellesmere Island, Arctic Canada. Preliminary modelling infers the presence of an intrusive body that extends to a depth of approximately 15 km and is composed of an upper felsic and a lower mafic component, with intermittent magnetite-rich horizons.

Systematic modelling of the catalogued anomalies associated with plume centers will help quantify the proportions of felsic, mafic and ultramafic components in each intrusion. This will be a guide to help better understand the magmatic plumbing system of LIPs as well as the economic potential of these intrusions.

Title: Evidence for the extension of the 180 Ma Karoo LIP of southern Africa northward into Zambia and Tanzania

Presenter/First Author: Richard E Ernst, Ernst Geosciences, Ottawa, ON

Presenter/First Author Email: Richard.Ernst@ErnstGeosciences.com

Co-authors: Abdul H Mruma, , , ; Ulf Söderlund, Lund University, Lund, Sweden; Henry C Halls, University of Toronto, Toronto, ON, Canada

Abstract Body: The Uvinza dyke of a N-trending mafic dyke swarm in Tanzania (Swarm III in Halls et al., 1987, Geol. Assoc. Canada SP 34) yields a 181 Ma U-Pb baddeleyite age. This is a match to the widespread Karoo Large Igneous Province (LIP) of southern Africa. A previous aeromagnetic interpretation by Halls et al. (1987) shows that Swarm III dykes extend south from Tanzania for 500-800 km, but can possibly be traced for another 500 km through Zambia. This new geochronology and age estimates based on the previous aeromagnetic study by Halls et al. (1987) suggest that a major arm of the Karoo LIP extends northward into Zambia and Tanzania.

Title: Forensic geochemistry of a basaltic flow and tabular intrusions of the High Arctic LIP: The case of South Fiord, Axel Heiberg Island, Nunavut

Presenter/First Author: Cole Kingsbury, Carleton University, Ottawa, ON

Presenter/First Author Email: Cole_Kingsbury@carleton.ca

Co-authors: Richard E Ernst, Ernst Geosciences, Ottawa, ON, Canada; Brian Cousens, Carleton University, Ottawa, ON, Canada; Marie-Claude Williamson, Geological Survey of Canada, Natural Resources Canada, Ottawa, ON, Canada

Abstract Body: The High Arctic Large Igneous Province (HALIP) consists of mafic dykes, sills and lava flows that were emplaced mainly during two major episodes of igneous activity (c.130-120 and c. 100-90 Ma). Near South Fiord on western Axel Heiberg Island, Nunavut Canada, two basalt flows (10 & 2 m thick) exists within the Isachsen formation (older episode). About 7 km east of the field area, a thick >100 m sequence of Strand Fiord formation flood basalts (younger episode) crops out.

In this contribution, geochemical signatures of a lava flow and intrusions sampled in the vicinity of South Fiord are used to discriminate between the two pulses of Cretaceous magmatism. New geochemical data on 40 samples from tabular intrusions and the 10 m thick basalt flow from South Fiord are compared with published data on Strand Fiord and Isachsen formation flows. On Nb/Y vs. Zr/Ti and AFM diagrams, all South Fiord samples are subalkaline tholeiitic basalts apart from one tholeiitic basaltic andesite. Chondrite-normalized REE data show consistent shallow slopes, signifying partial melting of spinel lherzolites in the shallow mantle. There are distinct chemical differences between the basalt flow and intrusions around South Fiord. The tabular intrusions are more enriched in Zr at given Zr/Y. In addition, the basalt flow displays lower Ce/Yb than many intrusions with similar Mg#. There are also distinct differences between the basalt flow and nearby Strand Fiord formation basalts. In Zr/4-2Nb-Y ternary space, the basalt flow plots within VAB whereas the Strand Fiord basalts plot in an elongate cluster straddling the VAB and E-MORB fields and the trajectory is nearly orthogonal to that of the basalt flow. In addition, the basalt flow along with previously described Isachsen data from Axel Heiberg and Ellesmere Islands show higher Zr/Y when compared with Strand Fiord formation basalts. Our new data indicate that the basalt flow at South Fiord is likely part of the older Isachsen Formation flows that are chemically distinct from intrusions exposed around South Fiord. The chemistry of these intrusions is identical to lavas and intrusions of the Strand Fiord formation, suggesting that they were feeders of the Strand Fiord formation flows and part of the younger episode of HALIP.

Title: A New Method to Quantify Sulfur Concentration in Basaltic Melts Based on Crystal/Melt Partition Coefficients

Presenter/First Author: Don R Baker, McGill University, Montreal, QC

Presenter/First Author Email: don.baker@mcgill.ca

Co-authors: Andrea Marzoli, University of Padova, Padova, Italy; Kalotina Geraki, Diamond Light Source, Didcot, United Kingdom; Angelo De Min, , ,

Abstract Body: Knowledge of the volatile concentrations in magmas provides insight into processes as the formation of magmatic sulfide ore deposits, the explosivity of eruptions, and the role of large igneous provinces (LIPs) on mass extinctions. Traditionally these concentrations have been determined through analysis of melt inclusions, but these are rare and formed under rapid crystal growth conditions that may not result in the capture of representative melt aliquots. An alternative method to constrain volatile concentatrations in magmas is to use the partition coefficients of volatiles between crystals and melts and then to measure the volatile concentration in natural crystals and combine that with the partition coefficients to calculate concentrations in the melt. We chose to investigate the partitioning of sulfur between crystals and melts because of its suggested role in mass extinctions caused by LIPs. We previously defined the partition coefficient of S between clinopyroxene and basaltic melt at low oxygen fugacity and applied it to rocks from three LIPs (Callegaro et al., 2014, Geology 42:895). Our previous measurements were made under the conditions appropriate for LIPs, but to constrain partition coefficients applicable to a broad spectrum of common igneous compositions we performed a new set of experiments to investigate the effect of oxygen fugacity, water concentration, and melt composition on

the partitioning of sulfur between magmatic melts and nominally anhydrous (and sulfur-free) minerals (NAMs). We performed piston cylinder experiments at 800 or 1000 MPa and temperatures from 1350° to 1000°C, using andesite and dacite glass powders doped with pyrrhotite, and a Mid Ocean Ridge Basalt (MORB) powder as starting materials. Experiments were performed at different oxygen fugacities, one low enough that all S was present in the melt as sulfide and the other high enough that all S in the melt was present as sulfate. Hydrous experiments at the different oxygen fugacities were also performed and contain approximately 5 wt.% H_2O in the system. Partition coefficients for augite, pigeonite, olivine, orthopyroxene and plagioclase have been measured and allow us to use these phases to calculate the sulfur concentrations in the coexisting melts.

Title: The Ste Sophie dyke swarm: A chemically distinct facies of the Grenville Swarm

Presenter/First Author: Michael Higgins, Univ Quebec a Chicoutimi, Chicoutimi, QC

Presenter/First Author Email: mhiggins@uqac.ca

Co-authors: Fatim Hankard, Univ Michigan, Ann Arbor, MI; Morgan Ganerod, Geological Survey of Norway, Trondheim, Norway; Rob Van Der Voo, Univ Michigan, Ann Arbor, MI

Abstract Body: About 20 diabase dykes up to 5 m wide occur in an area of ~100 sq kms about 50 km of Montreal near the village of Sainte-Sophie. Most are approximately vertical and E-W. Initially, it was thought that these dykes were part of the much more extensive Grenville dyke swarm which occurs just to the west. However, there are petrographic and geochemical differences: All dykes were vesicular, typically with 2-5% spherical vesicles 0.1-1 mm in diameter, and up to 10 mm for one dyke. Margins are always fine-grained and in one case glassy over 5 mm which suggest emplacement very close to the present surface. The most common phase is plagioclase (1-2 mm, exceptionally 10 mm), followed by olivine and, in one dyke, pyroxene. Alteration is extensive: plagioclase is partly sericitised, olivine is serpentinised, and zeolites and carbonate are developed in the vesicles and matrix. The bulk chemical compositions of the Ste Sophie dykes are also clearly distinct from those of the Grenville dykes: They have lower SiO_2 contents, 44-48%, and higher K2O contents, mostly around 1%, with two at about 6%. On a TAS diagram most of the dykes are subalkaline. Ar-Ar dating of plagioclase and whole-rock samples was not easy but indicated an age of 592±3 Ma, which is within the range of the Grenville dykes. The age, location and orientation of the dykes suggest that they may be a component of the much larger Grenville dyke swarm that was fed from a chemically distinct, somewhat enriched, source. This source may have been the same one that produced the alkali Monteregian intrusions some 470 million years later in the same region. If these dykes are part of the Grenville event then the use of chemical fingerprints to identify this swarm must be used with caution.

Title: New Data on Igneous Rocks in the Adriatic Sea: a Possible Indicator of the Pangea Supercontinent Disintegration

Presenter/First Author: Marko Kudrna Prašek, Self Employed, Chicoutimi,

Presenter/First Author Email: marko.prasek@gmail.com

Co-authors: Dražen Balen, , , ; Zorica Petrinec, , ,

Published Material: Preliminary data from this research was presented as a poster at EGU 2014 conference.

Abstract Body: Occurrences of igneous rocks (mainly gabbro to diorite) on the Adriatic Sea islands are few - this research focuses on two known igneous islands (Jabuka and Brusnik) and on a previously unknown underwater shoal locality (Brusnik Shoal). All three localities are part of the Adriatic microplate that hosts the Mesozoic Adriatic Dinaridic Carbonate Platform (ADCP) and is mostly comprised of carbonates.

Previously published ^{40}K-^{40}Ar (Balogh et al., 1994, Geologia (Bologna), 56, 13-25) and ^{40}Ar-^{39}Ar ages (Palinkaš et al., 2010, Acta Mineralogica-Petrographica, 8, 1-15) constrain the emplacement of gabbroitic rocks in ADCP to 276-200 Ma. The Central Atlantic Magmatic Province (CAMP) formed 200 Ma ago (Blackburn et al., 2013, Science, 340, 6135, 941-945) during the rifting of the supercontinent Pangea, whilst the Adriatic microplate migrated northward through the Tethys Ocean. Sedimentation on the ADCP continued and covered the igneous rocks with a thick succession of Mesozoic limestone. We determined that the major and trace element signature of the gabbros indicate a non-primitive parental magma in an active continental marginal setting with significant contribution from a recycled continental crust.

Considering the wide age data ranging from 276-200 Ma, question arises whether these occurrences of igneous rocks in the Adriatic Sea are connected to CAMP due to their past vicinity and could they be a remnant of the initial stages of disintegration of the supercontinent Pangea. If so, these rare localities within the Adriatic Sea could be the easternmost occurrences of CAMP-like rocks and possibly an important source of information about the initial processes that accompanied the disintegration of Pangea. Geochemical data from previously published work and the new geochemical data were compared to Moroccan gabbros related to CAMP (Bensalah et al., 2011, Comunicações Geológicas, 98, 15-27) indicating a plausible connection. Mineral chemistry of orthopyroxene, clinopyroxene, magnetite, ilmenite, amphibole, plagioclase and prehnite together with microstructural relations observed on BSE images reveal a complex set of syn- to post-kinematic reactions inside igneous body and preliminary constrain its temperature evolution and emplacement depth in accordance with scarce field observations.

Title: ^{187}Re- ^{187}Os Nuclear Geochronometry of Diamond Sulphide Inclusions: Constraining the Chemical Evolution of the SCLM

Presenter/First Author: Goetz Roller, Kompassbau, Munich,

Presenter/First Author Email: info@kompassbau.de

Abstract Body: Nuclear geochronometry [1-2] is a new research field constrained by other scientific fields like cosmology, cosmochemistry and nuclear theory. It connects geochronology with nuclear astrophysics. Based upon terrestrial signatures from at least two rapid (r) neutron-capture processes [3], so-called nucleogeochronometric TPI ages are calculated by means of two-point-isochrones (TPI). Because of identified Re/Os nuclear production ratios ≈ 1 and ultra-subchondritic initial $^{187}Os/^{188}Os$ ratios, it is argued that Earth's inner core (IC) contains isotopic signatures of a 13.78 Ga old component, as it can be found within the komatiitic basalt [5085 BasKom] (Onverwacht Group, South Africa) [4]. The other signatures are assigned to the Earth's outer core (OC), due to at least one gravitational collapse of the old component ≈ 3.48 Ga [2]. $^{187}Os/^{188}Os_i$ ratios of sulphide inclusions from eclogitic diamonds usually plot above an r-process chronometer evolution line in an $^{187}Os/^{188}Os$ evolution diagram, the eclogite field [5] showing a pronounced bulge contemporaneous with the Great Oxidation Event ≈ 2.22 Ga – 2.46 Ga. This coincides with an

$^{187}Re/^{188}Os$ fractionation event ≈ 2.3 ± 0.3 Ga, constrained by TPI ages for the Ellendale (Australia) peridotitic diamond sulphide inclusions EL50 and EL23 reported in the literature [6]. Contrary to eclogitic sulphide inclusions, $^{187}Os/^{188}Os$ ratios of most peridotitic sulphide inclusions [6] plot below the r-process chronometer evolution line, pointing to significant Re losses of the r-process reservoir. From the emerging pattern it may be concluded that $^{187}Os/^{188}Os_i$ ratios of eclogitic diamond sulphide inclusions between 3 Ga and 1 Ga are due to episodic mixing, mingling and fractionation of IC/OC isotopic signatures and redistribution of Re during the evolution of the SCLM. This could explain the difficulty to obtain reliable conventional model or isochrone ages for these inclusions, a problem which may be solved by means of nuclear geochronometry.

Title: Salty kimberlites, magmatic or contaminated? Insights from sulfur isotopes on the source of alkalies in kimberlite magmas

Presenter/First Author: Yumi C. Kitayama, CRPG Centre de Recherches Pétrographiques et Géochimiques, Nancy,

Presenter/First Author Email: yumi@crpg.cnrs-nancy.fr

Co-authors: Emilie Thomassot, CRPG-Nancy, Vandoeuvre-Les-Nancy, France; Elisabeth d'Eyrames, CRPG-Nancy, Vandoeuvre-Les-Nancy, France; Thomas Rigaudier, , , ; Alexander V. Golovin, V.S. Sobolev Institute of Geology and Mineralogy, Novosibirsk, Russia; Andrey V. Korsakov, V.S. Sobolev Institute of Geology and Mineralogy, Novosibirsk, Russia; Albert Galy, CRPG Centre de Recherches Pétrographiques et Géochimiques, Vandoeuvre-Les-Nancy, France

Abstract Body: Kimberlites are volatile-rich rocks of alkaline composition containing abundant olivine crystals. Rare but widespread, they carry diamonds and mantle xenoliths from great depths to the surface, thus providing information on the composition of the mantle underneath cratons. However, the strong hydrous alteration of most kimberlites, as reflected by the common serpentinization of olivine, raises questions over the pristine composition of kimberlite magmas. Indeed, common characteristics of kimberlites such as low Na and high water content may relate to post-magmatic alteration involving external meteoritic or hydrothermal waters. The Udachnaya East kimberlite pipe of the Siberian craton preserves a diversity of kimberlite types ranging from a hydrous and serpentinized breccia, to a unique occurence of serpentine-free kimberlite with unusually salty (Na_2O and Cl both up to 6 wt.%) and dry compositions (<1 wt.% H_2O) [1]. These kimberlites were emplaced through a portion of crust saturated with brines, and could thus have acquired their ususual Na, K, Cl and S-rich chemistry by contamination [2]. Alternatively, a magmatic origin for the salts is supported by the similar compositions of alkali carbonate and chloride minerals throughout the salty kimberlites, from minerals in the groundmass, melt inclusions in olivine, to chloride-carbonate "nodules" [1]. In the groundmass of the Udachnaya kimberlites, sulfates and sulfides are both present and were characterized by electron microprobe. In this contribution we will present the sulfur isotope compositions ($d^{34}S$) of sulfides and sulfates present in 3 types of kimberlites that coexist at the Udachnaya locality, including dry salty kimberlites containing fresh olivine (n=5), wet non-salty kimberlites containing fresh olivine (n=4), and brecciated kimberlite containing serpentinized olivine (n=1). We will compare these results to the canonic S-isotopic composition of the mantle [3], the surrounding hydrothermal deposits (n=4) and siberian cambrian carbonaceous sediments (e.g. Chukuck suite). In light of our S-isotope measurements, we will discuss the magmatic or contaminated origin of the kimberlites from the Udachnaya pipe.

Title: Diamond Resorption Morphology and Applications: a Review

Presenter/First Author: Yana Fedortchouk, Dalhousie University, Halifax, NS

Presenter/First Author Email: yana@dal.ca

Published Material: This review referes to some published or submitted experimental data. However, the content and findings of this presentation have not been published or submitted.

Abstract Body: Diamond resorption morphology reflects the conditions of diamond reaction with the host kimberlite magma and with metasomatic agents in the mantle. During the last decade experimental studies combined with application of new analytical method of atomic force microscopy (AFM) provided new quantitative data and notably extended our understanding of this process. I will discuss types of morphological transformations of diamond, what do we know from experiments and see on natural stones, and what can we learn about the conditions in natural diamond-hosting environments from diamond morphology. The study uses experimental data simulating three stages in diamond history: 5 – 7 GPa runs examine conditions during the mantle residence, 1- 3 GPa runs examine conditions during kimberlite emplacement, and runs at 0.1 MPa examine diamond resorption in near surface conditions after the emplacement. Diamond resorption causes transformation of crystal morphology and development of etch feature on the crystal surface. The type of morphological changes depends on the composition of the reacting media, whereas the degree of rounding depends on the pressure and gives an estimate of the depth of the fluid exsolution in different kimberlite magmas. The surface features include negative trigons, as well as positive trigons, tetragonal and circular pits, terraces, and cavities with surface graphitization. AFM based classification of the trigons reflects their evolution, the reaction conditions, and gives an estimate of H2O:CO2 ratio and the temperature of the reacting fluid. Positive trigons are a feature of near-surface resorption and occur only in limited number of diamond populations, and the circular pits can serve as indicators of low-pressure aqueous fluid. Morphology of natural diamonds is used to assess the importance of their reaction with carbonatitic melts, silicate aqueous melt / fluid, and CHO fluid (with variable H2O:CO2 ratio) on diamond road from the mantle to the surface.

Abstract Body: Natural diamonds develop resorption features due to partial dissolution in kimberlites and mantle metasomatism. Experimental data shows that diamond resorption features strongly depend on the presence and composition of kimberlitic fluid. Atomic force microscopy (AFM) can be used to quantitatively examine individual features on diamond to put robust constraints on their resorption conditions. Thus, diamond morphology can be a proxy of magmatic and mantle fluids and the emplacement conditions of kimberlite magma. This study examines dissolution features on diamonds from kimberlite localities with presumably different fluid and emplacement histories - Snap Lake kimberlite dyke and pipes with volcaniclastic and coherent kimberlite facies from Ekati Mine. The results are compared to the dissolution features produced in controlled experiments. Optical microscopy and SEM study of resorption on 251 micro-diamonds from Snap Lake and several hundred of micro-diamonds from six Ekati kimberlites, allowed dividing them into morphological groups. Selected crystals studied with AFM provided quantitative data on the geometry of diamond micro-features. The results were compared to the AFM data for diamonds after resorption in experiments at 0.1 MPa in H_2 – CO_2 gas mixture and at 1 – 3 GPa in CHO fluid with H_2O:CO_2 = 1, 0.5, 0.35, 0.1, 0. Snap Lake diamonds show widespread development of positive trigonal pits in addition to the common negative trigons, indicating severe etching at the near-surface conditions and evolved composition of the reacting fluid during the early (deep) and late (shallow) resorption. Ekati diamonds show only negative trigons implying deeper resorption. The AFM data show significant variation in H_2O:CO_2 ratio between the kimberlites. Application of the new AFM-based method to examine conditions during kimberlite emplacement using diamond resorption helps to better constraint of the nature of kimberlitic fluids and evaluating diamond preservation.

Title: An *in situ* Technique for U-Th-Pb-He Chronometry with Applications to Diamond Exploration

Presenter/First Author: Noreen Evans, Curtin University, Perth, WA

Presenter/First Author Email: noreen.evans@curtin.edu.au

Co-authors: Brent McInnes, Curtin University, Perth, Australia; Brad McDonald, , , ; Martin Danišík, , , ; Michael Shelley, , , ; Pieter Vermeesch, University College London, London, United Kingdom

Published Material: Submitted for publication in Geochimica et Cosmochimica Acta in December 2014. Under review.

Abstract Body: Zircon U-Pb and (U-Th-Sm)/He 'double dating' can distinguish deep mantle source lithologies from upper crustal source lithologies and can be used in geochemical exploration for diamonds (Evans et al., 2013). However, improved data production efficiency was required before it could be considered a practicable tool for industry. We present a new laser-based technique for rapid, quantitative and automated *in situ* microanalysis of U, Th, Sm, Pb and He for applications in geochronology, thermochronometry and geochemistry. This novel capability permits a detailed interrogation of the time-temperature history of rocks containing apatite, zircon and other accessory phases by providing both (U-Th-Sm)/He and U-Pb ages (+trace element analysis) on single crystals. *In situ*laser microanalysis offers several advantages over conventional bulk crystal methods in terms of safety, cost, productivity and spatial resolution.

We developed and integrated a suite of analytical instruments including a 193 nm ArF excimer laser system (RESOlution M-50A-LR), a quadrupole ICP-MS (Agilent 7700s), a quadrupole helium mass spectrometry system (ALPHAchron) and swappable flow-through and ultra-high vacuum analytical chambers. The analytical protocols for zircon require the following steps: mounting/polishing in PFA Teflon using methods similar to those adopted for fission track etching (e.g., Zaun and Wagner, 1985); laser He extraction and analysis using a 2 s ablation at 5 Hz and 2-3 J/cm^{2}fluence; He pit volume measurement using confocal laser scanning microscopy or atomic force microscopy, and U-Th-Sm-Pb (plus optional trace element) analysis using traditional laser ablation methods. A freeware application has been developed for determining (U-Th-Sm)/He ages from the raw analytical data and Iolite software was used for U-Pb age and trace element determination.

*In situ*double dating has successfully replicated conventional U-Pb and (U-Th)/He age variations in xenocrystic zircon from the diamondiferous Ellendale lamproite pipe, Western Australia and increased zircon analytical throughput by a factor of 50 over conventional methods.

Title: Compositional and Thermal Characterization of Basinal Fluids in the Athabasca Basin: Implications for Unconformity-related Uranium Deposits

Presenter/First Author: Haixia Chu, University of Regina, Regina,

Presenter/First Author Email: chu207@uregina.ca

Co-authors: Guoxiang Chi, University of Regina, Department of Geology, Regina, SK, Canada, Regina, SK, Canada; Ryan Scott, , ,

Published Material: Chu, H., Chi, G., Scott, R. 2014. Thermal Profiles Inferred from Fluid Inclusions and Illite Geothermometry - Implications for Fluid Flow Patterns in the Athabasca Basin. Saskatchewan Geological Survey Open House 2014 (Dec 1 – 3, 2014, Saskatoon). The results are being prepared for a scientific journal but not yet have been under review now.

Abstract Body: The Athabasca basin hosts the largest high-grade unconformity-related uranium deposits in the world. It is generally agreed that the mineralizing fluids were basinal brines of evaporitic origin, which became enriched in U and Ca through fluid-rock interactions. However, it remains controversial whether these metals were extracted from the basin or the basement, and what driving forces were responsible for fluid flow. In order to address these problems, fluid inclusions entrapped in quartz overgrowths as well as authigenic illite from four drill cores in the central part of the Athabasca basin (DV10-001, Rumpel Lake, WC-79-1 and BL-08-01), away from any known mineralization, were examined in this study.

Liquid-vapor inclusions have $T_{m\text{-}ice}$ from -17.0^o to -50.0^{o}C, with salinities from 20.2 to 31.0 wt.%; Halite-bearing inclusions have $T_{m\text{-}halite}$ from141^o to 218 ^{o}C, with salinities from 29.3 to 32.9 wt.%. Low $T_{m\text{-}ice}$ values suggest the potential existence of Ca^{2+} and this was confirmed by cryogenic Raman spectroscopy with clear Ca-hydrates peaks and calculated NaCl/ (NaCl+$CaCl_2$) molar ratios from 0.2 to 0.8. Homogenization temperatures for all the inclusions range from 50^o to 250^{o}C. Temperatures estimated from illite geothermometry were mostly from 200 ^{o} to 250 ^{o}C and documented the maximum burial temperatures. No systematic changes in temperature were observed vertically within individual cores or laterally from core to core.

These results suggest that basinal fluids in the Athabasca basin are characterized by high salinities and elevated Ca, which are similar to those found in the uranium deposits. The presence of Ca-rich brines in area away from the basement, which is common in many sedimentary basins, suggest that at least some Ca in the ore fluids may have been derived from the sediments within the basin.The absence of horizontal and vertical thermal gradients may be best explained by basin-scale dynamic thermal convection.

Title: The Effects of Basement Faults on Fluid Convection in the Athabasca Basin and Significance for Localization of Uranium Mineralization

Presenter/First Author: Zenghua Li, University of Regina, Regina, SK

Presenter/First Author Email: lizenghua@gmail.com

Co-authors: Guoxiang Chi, University of Regina, Department of Geology, Regina, SK, Canada, Regina, SK, Canada; Kathryn M Bethune, University of Regina, Regina, SK, Canada

Abstract Body: A common feature of the unconformity-type uranium deposits in the Athabasca Basin is their close spatial association with reactivated basement faults intersecting the unconformity surface. It has been proposed that the fluid flow related to uranium mineralization in this basin was driven by thermal convection; however, little is known regarding how basement faults influence fluid convection and how this may affect the localization of mineralization. These questions are addressed through simulations of thermal convection with various configurations of basement faults using the FLAC3D software. Our numerical modelling indicates that the location, spacing and networks of basement faults influence the size and location of thermally-driven fluid convection. In a model with a single, isolated fault, the fault coincides with an upwelling plume. When the fault is moved from the centre laterally, the upwelling plume shifts accordingly. In the case of two faults, the faults may coincide with upwelling flow or alternatively be centrally located below convection cells, depending on fault spacing. In the latter case, the size of the convection cells tends to get larger and fluid may flow into and out of individual fault zones. In contrast, for connected faults, either in a pop-up or imbricated pattern, fluid may flow into one fault zone and out of the other, correlating closely with real-world attributes of unconformity-type deposits (i.e., ‘ingress’ versus ‘egress’ deposits). Collectively, this exploration of the relationship between thermal convection and faults (position, spacing and network) will shed light on why some faults are more favourable for fluid flow than others, which will in turn help to evaluate whether a given structure has the potential to host mineralization.

Title: Principal Component Analysis and Mineralogical Studies of Sandstones Overlying the Phoenix U Deposits and REE-rich Maw Zone, Athabasca Basin, Saskatchewan

Presenter/First Author: Shishi Chen, University of Ottawa, Ottawa,

Presenter/First Author Email: schen162@uottawa.ca

Co-authors: Keiko Hattori, University of Ottawa, Ottawa, ON, Canada; Eric C Grunsky, Geological Survey of Canada, Ottawa, ON, Canada; Yongxing Liu, Denison Mines Corp., Saskatoon, SK, Canada

Published Material: Saskatchewan Geological Open House 2014, Dec, 2014

Abstract Body: The Denison Mines’ Phoenix deposits, with indicated resources of 70.2 M lbs U_3O_8, occur at the unconformity and along steeply dipping fault in the basement, at ~ 400 m depth. The Maw Zone, REE-rich breccia with surface exposure of 300 x 200 m, consists of highly silicified, hematitized, dravitic tourmaline-rich rocks with high REE (<8.1 wt% as total REE oxides). The Maw Zone is ~ 4 km SW from the south end of Phoenix uranium deposits, but rocks in the Maw Zone do not show significantly high U (< 7.8 ppm in most rocks). Elemental plots suggest that major alteration minerals in sandstones above the Phoenix and in Maw Zone are illite, sudoite, tourmaline and kaolin. The ratios of Mg/Fe above the Phoenix deposits are generally higher than those in the Maw Zone. At the Phoenix site, the ratios of Mg/Fe are higher in deeper sandstones closer to the deposits.

Principal Component Analysis (PCA) of sandstones overlying the Phoenix deposits shows that U is associated with Heavy REEs (HREE)+Y, Light REEs (LREE) and Pb, and inversely correlated with Ti, Zr, Al, and Th. The Maw Zone displays different element groupings: U is strongly correlated with V, Cr, Fe, Ni, Cu, Cd, Na, Li and Ba, but very weakly correlated with HREEs+Y, and inversely with LREEs and P. Relative enrichment of HREEs, Y, and P in the sedimentary units, MFb, MFc and MFd, suggesting that xenotime as the predominant host of the HREEs. The association of LREEs+Sr+Th+P suggests the occurrence of monazite and/or APS minerals. A mineralogical study confirmed xenotime and APS minerals as the major host of HREEs and LREEs, respectively. Xenotime rims zircon grains and forms fine dissemination with magesiofoitite. These REE minerals precipitated from hydrothermal fluids during the brecciation of hematitized sandstones. The positive association between U and Fe in the PCA plot in the Maw Zone suggests that U was transported by oxidized fluids. The absence of U mineralization in the Maw Zone is explained by low U in the oxidizing fluids. Alternatively, the oxidizing fluids did not encounter reduced fluids to precipitate U.

Title: Organic Carbon-rich Sulfide-rich Metasediments from the Fraser Lakes Zone B Uranium-thorium-rare earth element (U-Th-REE) Deposit, northern Saskatchewan (Canada): Trace-metal Concentration Data, Paleoredox Environment, and Implications for the Metal Source of U/C-type Uranium Deposits

Presenter/First Author: Irvine R Annesley, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: jnrirvine@gmail.com

Co-authors: Julien Mercadier, CNRS, Vandoeuvre-lès-Nancy, France; Christine L. McKechnie, , , ; Michel M Cuney, Universite Henri Poincare, Vandoeuvre Les Nancy, France; Robert Millar, , ,

Abstract Body: The U-Th-REE mineralization at Fraser Lakes Zone B is hosted by ca. 1800 Ma granitic pegmatite/leucogranite sheets intruding the tectonic decollement between basal Paleoproterozoic Wollaston Group pelitic (+/-graphitic) gneisses and underlying Archean granitoid orthogneisses. These pelitic gneisses are inferred to be metamorphosed black shales deposited in a back-arc continental margin marine environment. The "Rossing-type" Zone B deposit and its host rocks are located ~20-25 km southeast of the Athabasca Basin (eastern Wollaston Domain, northern Saskatchewan), and provide evidence for being both

potential economic ore and a source rock for unconformity-type (U/C-type) uranium deposits. Although U/C-type uranium deposits have been studied extensively, questions still remain, including the origin of their transition metals (e.g. Cr, Co, Cu, Mo, Ni, V, and Zn). Using trace-metal geochemical data from the metamorphosed sulfide-rich black shales at Fraser Lakes, we present new insights into Paleoproterozoic shale formation and their metal potential for U/C-type deposits.

The graphite-sulfide-bearing pelitic gneisses are highly variable in composition, with C and S ranging from 0.5 to 7.5 and 0.2 to 16.0 wt%, respectively, with varied metal concentrations. However, the highest Ni (2600 ppm), Cu (1500 ppm), Mo (1740 ppm), Zn (943 ppm), and Co (137 ppm) are hosted in the most S-rich rocks; whereas the highest Cr (259 ppm) and V (815 ppm) occur in the most Fe-rich rocks. Uranium (up to 100 ppm) and Th (up to 557 ppm) are enriched relative to the North American Shale Composite (NASC) with values of 2.66 ppm U and 12.30 ppm Th. The abundances of Co, Cr, La, Mo, Ni, Th, U, V, and Zn are comparable to, but much higher than, those of post-Archean shale.

After assessing the degree of element mobility, we conclude the wide range of chemical variation in the fresh graphitic pelitic gneisses reflects original sedimentary facies variations of metal content and constrains original paleoredox conditions. This study documents that pre-Athabasca metal enrichments in the basal Wollaston Group represent the most likely metal source for U/C-type deposits.

Title: Petrographic and Raman spectroscopic study of graphite alteration in the Phoenix uranium deposit, southeastern Athabasca Basin, northern Saskatchewan

Presenter/First Author: Kewen Wang, University of Regina, Regina,

Presenter/First Author Email: karenwong521@gmail.com

Co-authors: Guoxiang Chi, University of Regina, Department of Geology, Regina, SK, Canada, Regina, SK, Canada; Kathryn M Bethune, University of Regina, Regina, SK, Canada; Zenghua Li, University of Regina, Regina, SK, Canada; Colin Card, , ,

Abstract Body: The Phoenix unconformity-type uranium (U) deposit, located in the southeastern Athabasca Basin, is associated with a NE-trending, moderately SE-dipping reverse fault crosscutting the unconformity between the Athabasca basin and the Archean – Paleoproterozoic basement. Graphite is well developed in metapelite and locally in pegmatitic rocks in the basement, and is spatially associated with U mineralization; however, as in most other unconformity-related U deposits, its role in mineralization is still unclear. It is uncertain whether graphite acted as a direct reductant to precipitate uraninite, or as the precursor of hydrocarbons that caused uraninite precipitation. It is also unclear whether fluid – graphite interactions left a signature in the graphite that may be used as a mineralization indicator. In this study, a series of graphitic metapelite samples were collected from the alteration zones hosting mineralization near the unconformity down to the unaltered basement. Petrographic study of the graphite was undertaken and followed by Raman spectroscopic analysis. Preliminary petrographic observations indicate that graphite flakes near the mineralization zone are relatively discontinuous and locally have a corroded crystal shape. The Raman spectra of all samples show a prominent G band (~1580 cm^{-1}) in the first-order region. However, graphite in samples closer to the mineralization has more obvious D1 and D2 bands (~1350cm^{-1} and 1620 cm^{-1}), attributed to defects in the graphite. The spectra in the second-order region are similar among the samples, but the samples closer to the U mineralization have stronger S2 bands than those farther away from it. These observations indicate that there is a gradual loss of the structural ordering of graphite toward the U mineralization zone, which may be related to increasing reactivity between fluids and graphite.

Title: Characterization of Fluids Associated with Uranium Mineralization in the Beaverlodge Uranium District, Northern Saskatchewan: Field, Petrographic, Fluid Inclusion and C-O Isotope Studies

Presenter/First Author: Rong Liang, University of Regina, Regina,

Presenter/First Author Email: liang23r@uregina.ca

Co-authors: Guoxiang Chi, University of Regina, Department of Geology, Regina, SK, Canada, Regina, SK, Canada; Ken Ashton, Saskatchewan Geological Survey, Regina, SK, Canada; Nigel Blamey, , ,

Published Material: This presentation was reported in Saskatchewan geological survey open house at 2nd. Dec. 2014 in Saskatoon. Findingd are not under review and accepted.

Abstract Body: The Beaverlodge uranium district north of Lake Athabasca in northern Saskatchewan is known for vein-type uranium mineralization in the pre-Athabasca basin basement. Most of the uranium deposits are distributed along major structures, and hosted by granitic rocks of various ages (and albitite derived from them) and by the ca. 2.33 Murmac Bay group amphibolite, both of which are unconformably overlain locally by deformed but unmetamorphosed redbeds of the ca. 1.82 Martin group. The uranium mineralization is mainly developed in breccias and carbonate±quartz veins. Three types of fluid inclusions were found in the veins, liquid-dominated biphase, vapour-dominated biphase, and vapour-only monophase, suggesting boiling or phase separation. The liquid-dominated fluid inclusions have homogenization temperatures from 57^o to 329 ^{o}C (mainly 150^o – 200 ^{o}C) and salinities from 0.2 to 31.4 wt% NaCl equivalent (clustered in two ranges, 0.2 – 7.0 and 20.0 – 31.4). Mass spectrometric analysis of bulk fluid inclusions shows that the volatiles are dominated by H_2O, with minor amounts of CO_2, CH_4 and H_2; the data plot in an area overlapping those of basinal brines and meteoric water. The $\delta^{18}O$ and $\delta^{13}C$ values of carbonates in the veins range from -22.5 to -6.6‰ (PDB) and from -10.1 to +1.1‰ (PDB), respectively. $\delta^{13}C$ values from the Martin group (-2.7 to +1.1‰) are among the highest, whereas those from some deposits are relatively low (-10.1 to -8.2‰). The calculated $\delta^{18}O$ values of the parent fluids mainly range from 0 to +5.0‰ (SMOW), lower than magmatic and metamorphic fluids. These data suggest that the uranium mineralization was formed in a relatively shallow environment, where brines from the Martin Lake basin and meteoric water may have been channelled along high permeability zones produced by structural deformation and albitization, and mixed with fluids from the basement containing Fe^{2+} and methane. Fluid mixing, fluid-rock interaction, and boiling may have caused precipitation of uraninite.

Title: The Potential of Rare Earth Elements for Revealing the Conditions of Uranium Deposit Formation and their Subsequent use for Exploration and Uranium Forensic Issues

Presenter/First Author: Julien Mercadier, CNRS, Vandoeuvre-lès-Nancy,

Presenter/First Author Email: julien.mercadier@univ-lorraine.fr

Abstract Body: Uranium deposits are known to be formed in a wide range of geological settings including deep metamorphic/magmatic to surficial

conditions and range in age from Archean to recent time. These temporal and spatial variations have given rise to an extreme diversity of U deposits. However, understanding their genesis and thereafter exploring for uranium deposits have remained challenging. In particular, very limited link between trace elements or isotopic composition of uranium oxide and the conditions for their accumulation to economic grades have been clearly established.

Natural uranium oxides (UO2) bear variable quantities of minor and traces elements (< 1 ppm and up to several pourcents) which have been more and more used to better understand the primary conditions of ore formation but also alteration processes which have potentially posteriorly affected them. Consequently, the quantification of trace elements in UO2 and the measurement of their isotopic ratio(s) have been a major research direction to better understand geologically the uranium deposits but also to fight against nuclear proliferation via forensic programs.

The present contribution aims to synthetize the recent developments in the use of Rare Earth Elements (REE) to uranium geological and forensic applications. The first part will emphasize on the last analytical developments to measure this group of elements by in-situ techniques (SIMS and LA-ICP-MS). The second part will present case studies of application of these techniques on several deposits to demonstrate that the REE contents of uranium oxides are very specific to each deposit type, regardless of the age or variations in local geological settings, and that the REE abundances reflect directly the mineralising processes specific to each deposit type. An evaluation of the first order parameters (T, REE sources and fluid composition) controlling the REE behaviour in each mineralized system is proposed. The last part will present some results and potential developments on the use of REE for forensic issues with comparison between some ore mineralization and the subsequent Yellow Cake to consider the limits of this technique in helping tracking the U production.

Title: Evidence of Middle Jurassic Magmatism within the Seychelles Microcontinent: A Possible Connection to the Initial Rifting between East Gondwana and Africa

Presenter/First Author: J Gregory Shellnutt, NTNU National Taiwan Normal University, Taipei,

Presenter/First Author Email: jgshelln@ntnu.edu.tw

Co-authors: Tung-Yi Lee, NTNU National Taiwan Normal University, Taipei, Taiwan; Yuan-Hsi Lee, CCU National Chung Cheng University, Chiayi County, Taiwan; Han-Yi Chiu, University of the Ryukyus, Nishihara, Japan

Abstract Body: From the Middle Mesozoic to Early Cenozoic numerous continental and microcontinental blocks of Gondwana have dispersed. East Gondwana, comprising Madagascar-Seychelles-India-East Antarctica, started to rift from eastern Africa during the Middle Jurassic with sea-floor spreading occurring by Late Jurassic to Early Cretaceous (i.e. ~140 Ma). Antarctica separated from Madagascar-Seychelles-India by ~120 Ma followed by the rifting of Madagascar by ~90 Ma and finally the rifting of Seychelles from India by ~64 Ma. New *in situ* LA-ICP-MS zircon U/Pb dating of a rhyolite from Silhouette Island, Seychelles, yielded a range of zircon $^{206}Pb/^{238}U$ ages from Neoproterozoic to Late Cretaceous. Thirteen zircons produced a mean age of 64.9 ± 1.6 Ma which is within error of reported ages of the neighbouring silicic plutonic rocks of Silhouette (i.e. 64.0 ± 0.6 Ma and 64.6 ± 0.8 Ma) and North Island (i.e. 63.8 ± 0.8 Ma and 63.6 ± 0.9 Ma) and is interpreted as the eruption age of the rock. A single Neoproterozoic inherited zircon yielded an age of 807 ± 20 which is contemporaneous with the bedrock geology and indicates that the Late Cretaceous magmas passed through the ancient basement of the Seychelles microcontinent. In addition to the Late Cretaceous and Neoproterozoic zircons, a set of 21 zircons produced a mean $^{206}Pb/^{238}U$ age of 163.8 ± 1.8 Ma and a smaller subset produced a mean age of 147.7 ± 4.5 Ma. The new Middle Jurassic ages reported from inherited zircons are contemporaneous with the opening of the Somali proto-ocean basin and the initial rifting between eastern Africa and East Gondwana whereas the Late Jurassic age may be correlative with mafic magmatism in Madagascar just prior to sea-floor spreading between East Gondwana and Africa. The Middle Jurassic zircons are the first evidence of rift magmatism in the Seychelles microcontinent attributed to the in the initial stages of plate separation between Africa and East Gondwana.

Title: Avalonia, The Missing Link between the Timarides (Baltica) and Arctic Alaska/Chukotka: Igneous T_{DM} Age and Detrital Zircon Constraints

Presenter/First Author: John Duncan Keppie, Universidad nacional Autonoma de Mexico, Mexico,

Presenter/First Author Email: keppie@eastlink.ca

Co-authors: Fraser Keppie, , , ; Jaroslav Dostal, , ,

Published Material: J. D. Keppie and D. F. Keppie, "Ediacaran-Middle Paleozoic oceanic voyage of Avalonia from Baltica via Gondwana to Laurentia: paleomagnetic, faunal and geological constraints," Geoscience Canada, vol. 41, no. 1, pp. 5–18, 2014.

Abstract Body: T_{DM} ages of igneous rocks represent a bulk average composition of the source and can be used as a tracer of the pre-Ediacaran basement of these regions, which is generally not exposed. The origin of Avalonia has been a puzzle for many years, with most opting for a peri-Gondwanan provenance of northwest Africa and Amazonia being favoured. Paleomagnetic data has been complicated by periods of true polar wander, whereas faunal provinciality has generally concentrated on affinities with major cratons. Reassessment of Ediacaran and Cambrian paleomagnetic data suggest that Greater Avalonia (Suwannee terrane in Florida, NW Avalonia, Ganderia, Iberia, Armorica, and Bohemia) is an island chain that lay at ca. 20°S, which is similar to the Bolshezemel block in the NE Timanides of northeastern Baltica. Greater Avalonia is characterized by a Neoproterozoic island arc (700-600/550 Ma) overlain by post-arc sedimentary and alkalic-tholeiitic, within plate, volcanic rocks. Ediacaran, Cambrian and Early Ordovician fauna in Avalonia are mainly endemic, which suggests that Greater Avalonia was an island chain. The higher degree of Ediacaran deformation in the Bolshezemel block is interpreted to be the result of continent-continent collision between Baltica and Arctida, and suggests that Greater Avalonia lay outside this collisional zone. Greater Avalonia and the Bolshezemal block have 840–1760 Ma T_{DM} model ages. Supporting evidence is provided by 1–2 Ga and 760–590 Ma detrital zircon grains in Greater Avalonia from Baltica and the Bolshezemel block. These ages are similar to those from the Arctic Alaska – Chukotka terrane, which evolved from an arc (700-600 Ma) to rifting (ca. 565-540 Ma). This suggests that, rather than originating on the southeastern side of Baltica as suggested by several authors, Greater Avalonia formed the missing link between the Bolshezemel block and Arctic Alaska – Chukotka terrane forming part of the same active plate margin.

Title: Archean to Phanerozoic Subcontinental Lithospheric Mantle and Relationships to the Mantle Components.

Presenter/First Author: John D. Greenough, University of British Columbia, Okanagan, Kelowna , BC, BC

Presenter/First Author Email: john.greenough@ubc.ca

Co-authors: Jordan McDivitt, Laurentian University, Sudbury, Canada

Abstract Body: Isotopes and trace element ratios identify three end-member types of mantle in oceanic island basalts (OIB). Trace-element-enriched (EM1 and EM2) and high U/Pb (HIMU) component types may reflect subducted sediment (enriched sources) or basaltic ocean floor (HIMU), in OIB sources, but recent work suggests they represent subcontinental lithospheric mantle (SLM) in the convecting oceanic mantle. Using > 3700 GEOROC whole-rock analyses from 10 continental flood basalt (CFB) provinces we test these hypotheses. Based on 65 similarly-incompatible element ratios (SIER; representative of mantle source ratios), exploratory statistics suggests that all CFB are distinct from OIB, and CFB associated with Archean lithosphere are distinct from those passing though Proterozoic/Phanerozoic lithosphere. Using transition metal (Fe, Mn, Sc, V, Cr, Ni, Co, Cu, Zn) concentrations in primitive (Mg#~0.72) CFBs extruded through Archean lithosphere resemble EM1 and EM2 OIB and those from Proterozoic/Phanerozoic lithosphere have HIMU-like compositions. Although the exploratory transition metal results appear different from those based on SIER, plots of individual SIER (e.g. Nb/Pb versus Ba/Nb) reveal a symmetry in compositions; values for CFB from Proterozoic lithosphere versus Archean lithosphere show relative values the same as the relative values for HIMU versus EM1. However, the CFB values are all more extreme. OIB component signatures may represent SLM signatures diluted by mixing with depleted mantle. It has been proposed that mafic intrusions bearing ore deposits (Ni, Pt, Cr etc.) may form from melting Archean EM1-like SLM. Our results do not suggest that Archean EM1-like sources have higher transition metal concentrations indicating that other factors (e.g. high % melting) make these magmas prone to forming deposits.

Title: Terrestrial Mantle Domains and Changing Tectonic Settings Through Time

Presenter/First Author: Kent C Condie, New Mexico Institute of Mining and Technology, Albuquerque, NM

Presenter/First Author Email: kcondie@nmt.edu

Abstract Body: Incompatible element distributions in modern oceanic basalts reflect three major mantle domains: enriched (EM), depleted (DM), and hydrated mantle (HM). As long as Earth was in a plate tectonic regime, these three domains can be traced into the geologic past and can be useful in constraining, but not unambiguously identifying, tectonic settings. Although there is overlap in the basalt populations, the three-fold division of mantle sources seems to remain in tack to at least 1 Ga and probably to 2.2 Ga. Although the earliest evidence for the three mantle domains appears in Archean basalts, it is not until after 2.2 Ga that basalts with these geochemical characteristics become widespread in the geologic record. The widespread appearance of DM and EM coincides with rapid propagation of plate tectonics between 3 and 2.5 Ga as shown by Hf and Nd isotopic models for continental growth. This suggests that mantle heterogeneity was increased at this time as crustal components were recycled into the mantle by widespread subduction.

So are EM, DM and HM mantle domains diagnostic of plate tectonics? No, because primitive crust (> 4 Ga) and residue of this crust with EM and DM signatures, respectively, may have been recycled into the deep mantle and rarely contribute to the sources of younger basalts. Although the HM geochemical signature (Nb-Ta-Ti depletion) is widely accepted in identifying ancient convergent margins, it also may have been produced in a stagnant lid regime by vertical recycling of lithosphere (for instance in heat-pipes), and hence even the HM geochemical signature is not sacred to plate tectonics. Because Earth is an evolving planet with changing tectonic regimes, extreme caution must be exercised in using incompatible element distributions to identify ancient tectonic settings and especially Archean and Hadean tectonic settings. It is only the convergence of evidence from greenstones that includes rock associations, stratigraphic variations, sediment types and provenances, information from syntectonic granitoids, and geochemistry of all rock types that we can make progress in understanding ancient tectonic settings.

Published Material: GAC-MAC 2014, FrederictonGSA Annual Meeting 2014, Vancouver

Abstract Body: The geology of SW England has long been interpreted to reflect Variscan collisional processes associated with the closure of the Rheic Ocean and the formation of Pangea. The Cornish peninsula is composed largely of Early Devonian to Late Carboniferous volcano-sedimentary successions that were deposited in pre- and syn-collisional basins and were subsequently metamorphosed and deformed during the Variscan orogeny. Voluminous Late Carboniferous granitic magmatism (Cornubian Batholith) is broadly coeval with the emplacement of ca. 290-300 Ma lamprophyric dykes and flows. Although these lamprophyres are well mapped and documented, the processes responsible for their genesis and their relationship with regional Variscan tectonic events are less understood.

Syn-rift basalts have intra-continental alkalic affinities, and have REE profiles consistent with derivation from the spinel-garnet lherzolite boundary. εNd values for the basalts range from +0.37 to +5.2 and T_{DM} ages from 595 Ma to 705 Ma. The lamprophyres are extremely enriched in LREE and LILE, and depleted in HREE suggesting a deep, garnet lherzolite source that was previously metasomatised. They display εNd values ranging from -1.4 to +1.4, I_{Sr} values of 0.706, and T_{DM} ages… from 671 Ma to 1031 Ma, suggesting that metasomatism occurred in the Neoproterozoic.

Lamprophyres and coeval granite batholiths of similar chemistry to those in Cornwall occur in other regions of the Variscan orogen, including Iberia and Bohemia. By constraining the evolution of the mantle beneath SW England and the processes associated with the formation of these post-collisional rocks, we may be able to gain a more complete understanding of mantle processes during the waning stages of supercontinent formation.

Title: Neoproterozoic and Paleozoic igneous events in the Ossa Morena Zone (SW Iberia): A record of Gondwana amalgamation, Gondwana breakup and Pangea amalgamation

Presenter/First Author: Cecilio Quesada, Universidad Complutense, Madrid,

Presenter/First Author Email: quesada.cecilio@gmail.com

Co-authors: Teresa Sánchez-García, , , ; Félix Bellido, , ,

Abstract Body: Neoproterozoic and Paleozoic igneous rocks are widespread in the Ossa Morena Zone (OMZ) of the Iberian Massif (W European Variscan orogen). They cluster in three main periods corresponding to rather distinct geodynamic scenarios. Plutonic, subvolcanic and volcanic rocks exist in all three periods of igneous activity.

- Neoproterozoic-Lowermost Cambrian (ca. 630-535 Ma) rocks are dominated by subduction-related calcalkaline types and record an initial period of continental (West-African affinity) arc growth followed by post-collisional types during arc accretion to Gondwana mainland (Cadomian orogeny).
- A second emplacement of igneous rocks in the OMZ took place soon after, from ca. 530-470 Ma (Cambrian-Lower Ordovician), and was related to a rift event. An *early* (ca. 530-525 Ma*) event,* dominated by crust-derived peraluminous rocks associated to mid/upper crust anatexis, was succeeded by a *main (*bimodal) *event*, in which tholeiitic, alkaline (peralkaline) mantle-derived rocks coexisted with minor crust-derived calcalkaline rocks. This rifting is thought to have culminated in opening the Rheic Ocean, leaving the OMZ at the outer margin of N-Gondwana.
- Finally, a third period of igneous activity affected the OMZ from mid-Devonian through early Permian times. Three main peaks of activity with distinct characteristics may be distinguished: 1) subduction-related rocks at the southern OMZ characterizing growth of a modest arc during N-directed subduction of the remaining Rheic Ocean (ca. 385-345 Ma); 2) a bimodal set of tholeiitic and calcalkaline rocks coeval to extension and HT-LP metamorphism in the southern OMZ (ca. 340-335 Ma); 3) a set of post-collisional felsic rocks (ca. 320-290 Ma). These sets of igneous rocks characterize various events and environments during Rheic Ocean closure (set 1), an event of thermal doming and extension, probably related to development of a slab window beneath the OMZ (set 2), and finally the collision of this part of Gondwana with Laurussia and its subsequent orogenic collapse (set 3). All together these three events characterize the Variscan orogeny in this part of the belt that culminated the amalgamation of Pangea.

Title: Ancient mantle lithosphere beneath the Khanka massif in Russian Far East: Re-Os evidence for the Siberia affinity

Presenter/First Author: Kuo-Lung Wang, Academia Sinica, Taipei,

Presenter/First Author Email: kwang@earth.sinica.edu.tw

Co-authors: Vladimir Prikhodko, , , ; Suzanne Yvette O'Reilly, Macquarie University, Sydney, NSW, Australia; William L Griffin, Macquarie University, Sydney, Australia; Norman Pearson, Macquarie University, Sydney, Australia; Victor P Kovach, Institute of Precambrian Geology and Geochronology, Russian Academy of Sciences, St-Petersburg, Russia; Yoshiyuki Iizuka, Academia Sinica, Taipei, Taiwan

Published Material: Under review (major revisin) by the journal Terra Nova

Abstract Body: The Os isotope compositions of sulfides in mantle xenoliths from the Sviyaginsky volcano, Russian Far East, reveal the presence of Proterozoic subcontinental lithospheric mantle (SCLM) beneath the Khanka massif. In this study, we document the Os-isotopic compositions of mantle sulfides in peridotite xenoliths to (1) date thermal/tectonic events recorded in the SCLM beneath the region; (2) confirm the existence of a Precambrian microcontinent within the eastern CAOB complex and (3) clarify that origin of the Khanka massif might have tectonic affinity to the Siberia Craton. Both their T_{MA} and T_{RD} model ages reveal similar peaks at 1.1 and 0.8 Ga suggesting later thermotectonic events in the SCLM, whereas T_{RD} model ages give the oldest age of 2.8 ± 0.5 (2s) Ga,. The events recognized in the SCLM are consistent with those recorded in crust of the Khanka massif. The sulfide Os-isotope data show that the SCLM beneath the the Khanka massif had formed at least by the Mesoproterozoic, and was subsequently metasomatised by juvenile crustal-growth events related to the evolution of the Altaids.

Title: Discovering a Polar Transform Zone in the Geological Record of the Mesozoic Mediterranean

Presenter/First Author: Duncan F Keppie, Fraser Keppie, Halifax, NS

Presenter/First Author Email: keppiedf@gov.ns.ca

Published Material: Keppie, D. Fraser (almost accepted in Geology) How the closure of Paleo-Tethys and Tethys oceans controlled the early breakup of Pangaea

Abstract Body: Tuzo Wilson noted in 1966 that transform deformation is an essential feature of plate tectonics on Earth. In theory, Wilson noted two ways transform deformation could occur in plate tectonics: (1) by linking complementary rift and subduction zones along a strike-slip fault: i.e., a transform fault, or (2) by connecting complementary rift and subduction zones across a tectonic rotation pole: i.e., a polar transform. In application, however, reported examples of polar transforms have been rare in interpretations of the terrestrial rock record when compared with the relatively ubiquity of transform faults. One can ask whether this discrepancy reflects a fundamental property of plate tectonics on Earth or whether key markers of polar transforms in the geological record have been systematically misinterpreted. Reconciliation of this question is critical to understanding how systems of complementary rift zones and subduction zones evolve through time. In this study, I consider the example of Mediterranean tectonics during the Jurassic and early Cretaceous periods. Global boundary conditions indicate that the Mediterranean region hosted a polar transform zone or a near-pole transform fault system during this time. However, classic interpretations of the regional rock record are inconsistent with this requirement. The Mesozoic Mediterranean may represent a key area where the geological record has been misinterpreted and a polar or near-polar transform zone awaits discovery.

Title: Chemical Variations in Uraninites from Various Types of Uranium Deposits

Presenter/First Author: Yulia Uvarova, CSIRO Australian Resources Research Center, Perth,

Presenter/First Author Email: yulia.uvarova@csiro.au

Co-authors: T Kurtis Kyser, Queen's University, Kingston, ON, Canada

Abstract Body: Uraninite, with an ideal formula UO_2, is the most common uranium mineral. It has been shown that natural uraninite contains such elements as Pb, Th, Zr, rare earth elements (REE), Y, Ca, Fe, and Si. Moreover, uranium in uraninite can be in U^{4+} and U^{6+} oxidation states, which makes its formula not so simple: $(U^{4+}_{1-x-y-z}U^{6+}_{x}REE^{3+}_{y}M^{2+}_{z})O_{2+x-y-z}$ (Janeczek and Ewing 1992, Finch and Murakami 1999). Conventional electron-microprobe analysis (EMPA) and laser-ablation inductively-conducted plasma mass spectrometry (LA-ICP-MS) studies show that natural uraninite is chemically heterogeneous at the micrometer scale in regard to major elements, but (1) it has not been established in what form 'impurity' elements occur in uraninite and where they reside, *i.e*. which elements substitute for U in the crystal structure of uraninite and which ones form micro-inclusions of other minerals such as zircon, thorite, thorianite, or galena, nor (2) has the variability of trace elements been well studied. Additionally, the U^{6+}/U^{4+} ratio in uranium minerals has been overlooked despite the fact that this ratio is a superb tracer of redox conditions. Combining results of electron microprobe analysis (EMPA) with element mapping, performed with the use of field emission gun scanning electron microscopy (FEG SEM) and synchrotron X-ray fluorescence microscopy (SXRF), allows to document rare micron-scale features and the distribution of trace elements in heterogeneous natural uraninites, and provides important information in which mineral phases elements reside and with which other trace elements they are associated. This in turn, aids in understanding the element mobility and constraining fluid chemistry and genesis of uraninites from various types of uranium deposits.

Title: Sulfur Isotope Fractionation in Bacterially and Chemically Controlled Roll-Front Deposits

Presenter/First Author: Gretchen Ann Hough, University of Wyoming, Laramie,

Presenter/First Author Email: ghough@uwyo.edu

Co-authors: Susan Swapp, University of Wyoming, Laramie; Carol D Frost, University of Wyoming, Laramie, WY

Abstract Body: Redox mechanisms driving uranium precipitation in roll-front deposits have been debated for decades with minimal evidence confirming either bacterial or chemical models. In order to resolve the issue, naturally occurring deposits that represent each endmember need to be identified and compared. Two deposits in Wyoming have been selected as likely redox endmembers. One deposit contains abundant organic material; the other has almost none. Organic material is essential to host a sulfur reducing bacteria colony, and its presence would favor bacterial redox. However, without organic material present, the environment would be inhospitable to bacteria and chemical redox would be favored. Several other distinctions between the two deposits are also striking: associated with abundant organic material is abundant pyrite precipitation and locally uranium vanadates; in deposits lacking appreciable organic material only minor pyrite is present and the predominant uranium mineralogy is uraninite and coffinite. Distinguishing between redox mechanisms may therefore be key in understanding the wide variations in uranium mineralogy.

Sulfur isotope fractionation in ore-zone pyrite should vary with redox mechanism. Chemical redox should produce lower $\delta^{34}S$ than biogenic redox processes. Because of the constant addition of sulfate to the system, bacterial redox may produce high $\delta^{34}S$ values. In contrast, oxidation of pyrite as it is cycled across the roll-front continuously produces ^{34}S-enriched sulfate that is removed from the system, leaving ore zone pyrite with low $\delta^{34}S$. Further, fractionation in a chemical deposit would show a trend of decreasing $\delta^{34}S$ across the ore zone from unaltered to altered sandstone. Cores from the Wyoming deposits have been collected that span the ore horizon. Sulfur isotope values will be analyzed across the roll-front for each deposit using SIMS to confirm redox drivers and expected trends to positively differentiate between bacterial and chemical redox.

Title: Examining three oxygen isotope mass-dependent fractionation in Uraninite

Presenter/First Author: Mostafa Fayek, University of Manitoba, Winnipeg, MB

Presenter/First Author Email: fayek@cc.umanitoba.ca

Co-authors: Julien Mercadier, CNRS, Vandoeuvre-lès-Nancy, France; Etienne Deloule, CRPG-Nancy, Vandoeuvre-Les-Nancy, France

Abstract Body: On a plot of $\delta^{17}O$ vs. $\delta^{18}O$ values for terrestrial samples define a line with slope of ~0.52 because equilibrium isotope theory predicts that variations in $\delta^{18}O$ caused by nearly any process on Earth (physical, chemical or biological) are approximately twice as large as variations in $\delta^{17}O$. This is known as mass-dependent fractionation. The ratios of logarithms of partition function ratios for oxygen compounds thus fall in a narrow range from about 0.520 to 0.530 over a range of temperatures. Kinetic processes can be examined in the same way as equilibrium processes to determine the proportionality between $^{18}O/^{16}O$ variations and $^{17}O/^{16}O$ variations for diffusion, in which the relative rates of isotopic species are inversely proportional to the square-root of the mass of the diffusing species. For example, the mass-dependent fractionation for oxygen atoms will define a line with a slope of 0.5232 whereas for SO_2 molecules the slope is 0.5087. It is evident that the fractionation ratio depends on the molecular weight of the diffusing species. Since the fractionation ratios both for equilibrium and for kinetic processes depend on the particular molecules, it is expected that terrestrial minerals, which form by various processes and reactions will yield a slope on a graph of $\delta^{17}O$ vs. $\delta^{18}O$, which is an average of the many individual slopes for individual processes. A value of 0.520 is generally chosen for mass-dependent fractionation in terrestrial samples. Here we suggest that the slope of the line that defines mass-dependent fractionation in uraninite (UO_2) significantly deviates from a slope of 0.52 because U-O molecules are significantly heavier than Si-O or Al-O molecules. We will compare the calculated value for the slope for UO_2 (0.5019) to the measured slope defined by uraninite that was overprinted by meteoric water and a synthetic uraninite.

Title: *Evaluation of the application of Diffusive Gradients in Thin Films (DGT) technique in water, soils and sediments as a monitoring tool in uranium mining environments*

Presenter/First Author: Jagoda Drozdzak, Vrije Universiteit Brussels, Brussels,

Presenter/First Author Email: jdrozdza@vub.ac.be

Co-authors: Martine Leermakers, Vrije Universiteit Brussel VUB, Brussels, Belgium; Vannapha Phrommavanh, AREVA, BG Mines, Paris, France; Michaël Descostes, AREVA, BG Mines, Paris, France

Abstract Body: In France, uranium mining activities in 1945-2001 led to the production of 76,000 t of uranium. To date, all these sites have been rehabilitated and a site-specific survey is performed by AREVA, local and public authorities. AREVA has undertaken R&D studies to perform hydro-geochemical modelling of these storage sites. Although the radiological impact of uranium is determined by the total concentration; the aquatic chemistry, its toxicity and bioavailability are determined by chemical speciation. The technique of Diffusive Gradients in Thin Films (DGT) is an *in situ* monitoring tool for the bioavailable fraction, as it provides the time-averaged concentrations of labile metal species in solution. The technique is also applied to soils and sediments, revealing high resolution porewater profiles and remobilization rates from the solid phase. The evaluation of the technique was performed in laboratory and in field conditions. The mining sites in France with different geochemical characteristics and water treatment technologies were investigated. DGTs were deployed in stream water upstream and downstream of the mining sites; within the various stages of the water treatment, in a wetland and in lake sediments. A device displayed high resolution profiles in sediments and soils up to a 1.5 m depth. The DGT technique was compared to filtration/ultrafiltration techniques and geochemical speciation. In the laboratory, different binding phase for U (Chelex®-100, Metsorb™, Diphonix®) in the DGT devices were evaluated. The different resins were compared across a wide pH (3-9) and ionic strength (0.001-0.7 M $NaNO_3$) range. Possible interferences with Ca^{2+} (up to 12.5 mM), PO_4^{3-} (up to 0.05 mM), SO_4^{2-} (up to 2.1 mM) and HCO_3^- (up to 8.2 mM) on U-DGT uptake were investigated. The laboratory and field studies along with speciation modelling allows better understanding of the applicability of DGT as a monitoring and speciation tool in mining environments.

Title: Trapping Processes of Uranium at Low Temperature

Presenter/First Author: Georges Calas, IMPMC Institut de Minéralogie et de Physique des Milieux Condensés, Paris Cedex 05,

Presenter/First Author Email: Georges.Calas@impmc.upmc.fr

Co-authors: Thierry Allard, CNRS, Paris, France; Martine Gérard, Institut de Minéralogie, de Physique des Matériaux, et de Cosmochimie (IMPMC), Sorbonne Universités - UPMC Univ. Paris 06, UMR CNRS 7590, Muséum National d'Histoire Naturelle, UR 206, 4 Place Jussieu, F-75005 Paris, France; Laurence Galoisy, University Pierre and Marie Curie Paris VI, Paris, France; Mostafa Fayek, University of Manitoba, Winnipeg, MB, Canada; Michaël Descostes, AREVA, BG Mines, Paris, France

Published Material: These data were partly published (Mineralium Depposita, ES&T, American Mineralogist)

Abstract Body: There is a growing interest in uranium geochemistry and mineralogy at low temperature, in order to get an accurate picture of the processes that can act on the mobility of this important element. This may be relevant to the modeling of uranium migration in the environment, in the perspective of remediation strategies, as well as to increasing our knowledge on U-concentration under low-temperature conditions. We will review some recent results concerning the behavior of uranium in epithermal volcanic deposits of the Sierra Peña Blanca (Mexico) as well as in mine tailings from Gunnar (Saskatchewan) and in granitic waste rocks around a former U-mine from Massif Central (France). These examples illustrate the diversity of the trapping processes, encompassing (i) biological activity, indicated by a geochemical signature of biogenic reducing conditions favoring uranium mineralization in an epithermal deposit, (ii) metastable, nanoscale uranate crystals that enlarge the diversity of low-temperature U-phases, (iii) pH-sensitive inner-sphere surface complexes bound to ferrihydrite and associated clay minerals and (iv) precipitation of secondary U-phases, e.g. (nano-) uranyl phosphates, under subsurface conditions. Unique information on the timescale characteristic of uranium mobilization and migration/trapping is provided by environmentally relevant sites such as mine tailings and mine wastes.

Title: Isotopic and Chemical Tracing of Uranium Ores Through Processing to Nuclear Fuels

Presenter/First Author: T Kurtis Kyser, Queen's University, Kingston, ON

Presenter/First Author Email: kyser@geol.queensu.ca

Co-authors: Don Chipley, Queen's University, Kingston, ON, Canada; George Healey, , , ; Peter Button, , ,

Abstract Body: Oxygen, Sr, Pb and U isotopic and chemical compositions of uranium ore concentrates (UOC) and resulting processed materials are examined where UOC is converted to UO_3 and subsequently to UF_6. There are significant variations in the U, Sr, Pb and O isotopic compositions of UOC samples, although each source tends to a distinct isotopic composition. Digestion of the UOC in nitric acid results in a significant increase in the $^{207}Pb/^{206}Pb$ ratio from 0.1538 to 0.4015 and a slight decrease in the $^{87}Sr/^{86}Sr$ ratio from 0.71314 to 0.71274 as a result of contamination. The resulting UO_3 product has lower Pb contents and much less radiogenic $^{207}Pb/^{206}Pb$ ratios than the UOC and much higher $^{238}U/^{235}U$ ratios because of loss of ^{235}U during the boildown and oxygen isotopes are also affected because of the preferential loss of ^{16}O . The contents of most elements are diminished in the UO_3 product, although B, Pb, Cr and Co levels are similar to those in the original UOC and thus behave "conservatively". Reduction of the UO_3 to UO_2 does not appreciably affect Pb or U isotopic compositions, but does affaect the oxygen isotopes. Conversion to UF_6 results in a decrease of most element contents, but also a change in the isotopic composition of uranium whereby ^{235}U is lost.

Title: Spectroscopic Investigation of Actinides (U, Np) and Zr in Nuclear Glasses

Presenter/First Author: Laurence Galoisy, University Pierre and Marie Curie Paris VI, Paris,

Presenter/First Author Email: laurence.galoisy@upmc.fr

Co-authors: Georges Calas, IMPMC Institut de Minéralogie et de Physique des Milieux Condensés, Paris Cedex 05, France; Patrick Jollivet, , ,

Abstract Body: Vitrification of high-level radioactive waste in borosilicate glasses is currently used on an industrial scale in several countries. The fundamental properties of the waste forms are their chemical and mechanical durability against the forcing conditions represented by chemical alteration or internal/external irradiation. The waste immobilized in glass is composed of over 30 different nuclear fission and activation products, as well as minor actinides. The oxidation state and local coordination of long-lived radionuclides are important parameters during glass elaboration but also help model the actinide behavior during glass alteration or irradiation. We will present a short overview of the local structure around actinides and Zr in the inactive analog of the French nuclear glass SON68. X-Ray absorption spectroscopy has been used to probe the local environment around uranium and neptunium in these glasses. The surrounding of Zr, a waste directly inherited from zircalloy claddings, has been also investigated for comparison in these glasses. Together with UV-visible spectroscopy used to get information on the different oxidation states of U in glasses, our spectroscopic data show that these elements occur in glasses in a peculiar surrounding, with significant differences with those encountered in crystalline compounds, as well as in the alteration gels. Element speciation is then an important parameter to follow the evolution of structural properties during long–term aging of nuclear glasses.

Title: Insights into ore-forming process through integration of evaporate mound chemistry with traditional microthermometry: Methodology and applications

Presenter/First Author: Daniel Kontak, Mineral Exploration Research Centre, Sudbury, ON

Presenter/First Author Email: dkontak@laurentian.ca

Published Material: Part of this has been presented at the PACROFI 2014 meeting, but this presentation presents new research data and it is presented to a very different audience.

Abstract Body: The composition of ore fluids is an important and integral part of understanding ore-forming processes. Traditionally the use of Tm(ice), inconjunction with the liquidus surface in the H_2O-NaCl binary, is used to estimate to bulk salinity (i.e., wt. % equiv. NaCl) of fluid inclusions (FI). That ore fluids are more complex mixtures of solutes is appreciated, but calculating bulk compositions using the apparent temperatures for eutectics (e.g., H_2O-$CaCl_2$)and hydrate melting (e.g., hydrohalite) can be challenging, hence this is not widely applied in FI studies where material and FI are challenging. Although newer analytical methods, such as LA ICP-MS, can fully characterize solute chemistry to low detection limits, the method is time intensive, costly and such facilities not widely accessbile. An alteranaitve method, which is relatively faster, less costly, and more accessible, is the evaporate mound technique. The method overheats FI such that the homogenizaed fluids released upon FI rupture generate evaporate salt mounds on the surface of the waffer hosting the FI. These mounds are subsequently imaged and analyzed with a coupled SEM-EDS system using conventional protocol. Integration of mound chemistry with salinity data (i.e., using salinity as an internal standard) also permits the quantification of solute abundance. The analysis of groups of mounds (i.e., mound fields), similar to the FI assemblage approach used for microthermometry, provides a means to document and characterize discrete compositional fluid events (e.g., Na-K vs. Na-Ca). In addition, where metastability is an issue, fluid composition can still be determnined.Widespread application of this method to a variety of ore systems (e.g., pegmatites, carbonatites, porphyry Cu-Mo, vein Sn-W, orogenic gold, epithermal, MVT) will illustrate how such elemental data, both cation (Na, K, Ca, Fe, Mg, Ba, Sr) and anion (Cl, F, S), that is not readily available with other methods provides a more robust interpretation of the fluid evolution in ore systems.

Co-authors: Hendrik Falck, Northwest Territories Geoscience Office, Yellowknife, NT, Canada; Robert J Bodnar, Virginia Tech, Blacksburg, VA; Luca Fedele, , , ; Mostafa Fayek, University of Manitoba, Winnipeg, MB, Canada; Ryan Sharpe, , ,

Abstract Body: The Caribou Lake Gabbro (CLG) comprises the western intrusive suite of the Early Proterozoic Blachford Lake Intrusive Complex, which intrudes sedimentary rocks of the Archean Yellowknife supergroup, the Morose granite, and the Defeat granodiorite. The CLG is located approximately 90km southeast of Yellowknife, NT. Magmatic Ni-Cu-PGE mineralization consists of disseminated to massive pyrrhotite+chalcopyrite+pentlandite+pyrite with minor sulfarsenide and telluride phases. Metal grades within the CLG are subeconomic, with the highest Ni and Cu values at 1.7 and 1.4 wt%, respectively.

Trails of small (≤30µm) secondary sulfide melt inclusions (SI) occur in plagioclase and apatite and in olivine and ilmenite as larger (≤500µm) secondary inclusions. The SI are polyphase, consisting of pyrrhotite (90-99 volume %), chalcopyrite (≤8%), and Co–pentlandite (≤5%). In apatite, SI co-exists with silicate melt, indicating that a sulfide and silicate liquid coexisted. LA-ICP-MS analyses of SI hosted in plagioclase and apatite indicate that they have low PGE and Au contents and base metal concentrations of 1840 ppm Co (n=50), 1900 ppm Ni (n=36) and, 7260 ppm Cu (n=49). Sulfur isotope analysis of the pyrrhotite phase in SI trapped in olivine and ilmenite ($\delta^{34}S=0.2\pm0.5$‰; n=15), have compositions consistent with a mantle S source, but we cannot rule out S contamination from the Yellowknife supergroup ($\delta^{34}S=0.2\pm0.4$‰; n=10). Primary silicate melt inclusions (SMI) are preserved within cumulus apatite in a medium-grained gabbro. Minimum trapping temperatures of 1120-1230°C were determined by measuring the final melting temperature of solid phases in the inclusions. LA-ICP-MS analyses of SMI indicate that they trapped a Fe-tholeiite melt with Ni and Cu generally below detection limits (<60; ≤40 ppm). SMI have base metal tenor well below MORB, which could indicate that the silicate melt was initially metal depleted, or a sulfide liquid had already separated at the time of melt entrapment.

Title: Tin-Tungsten Mineralizing Processes in Tungsten Vein Deposits: Panasqueira, Portugal

Presenter/First Author: Pilar Lecumberri Sanchez, Virginia Polytechnic Institute and State University, Blacksburg, VA

Presenter/First Author Email: pilar@vt.edu

Co-authors: Christoph A Heinrich, ETH Zurich, Zurich, Switzerland; Markus Wälle, , , ; Romeu Vieira, , , ; Filipe Pinto, , ,

Published Material: Goldschmidt 2014

Abstract Body: Tungsten has a high heat resistance, density and hardness (tungsten carbides), which makes it widely applied in industry (e.g. steel). Tungsten deposits are typically magmatic-hydrothermal systems. Despite the economic significance of tungsten, there are no modern quantitative analytical studies of the fluids responsible for the formation of its highest-grade deposit type (tungsten vein deposits). Panasqueira (Portugal) is a

tungsten vein deposit, one of the leading tungsten producers in Europe and one of the best geologically characterized tungsten vein deposits.

In this study, compositions of the mineralizing fluids at Panasqueira have been determined through combination of detailed petrography, microthermometric measurements and LA-ICPMS analyses, and geochemical modeling has been used to determine the processes that lead to tungsten mineralization. We characterized the fluids related to the various mineralizing stages in the system: the oxide stage (tin and tungsten mineralization), the sulfide stage (chalcopyrite and sphalerite mineralization) and the carbonate stage. Thus, our results provide information on the properties of fluids related with specific paragenetic stages. Furthermore we used those fluid compositions in combination with host rock mineralogy and chemistry to evaluate which are the controlling factors in the mineralizing process.

This study provides the first quantitative analytical data on fluid composition for tungsten vein deposits and evaluates the controlling mineralization processes helping to determine the mechanisms of formation of the Panasqueira tin-tungsten deposit and providing additional geochemical constraints on the local distribution of mineralization.

Title: Re-evaluation of the Raman densimeter for determining CO_2 density based on splitting of the Fermi diad

Presenter/First Author: Hector Lamadrid, Virginia Tech, Blacksburg, VA

Presenter/First Author Email: lamadrid@vt.edu

Co-authors: Robert J Bodnar, Virginia Tech, Blacksburg, VA; Lowell Moore, Virginia Polytech State University, Blacksburg, VA; Daniel Moncada, Universidad de Chile, Santiago, Chile

Abstract Body: During the last 20 years several groups have presented equations relating splitting of the Raman Fermi diad as a function of the density of CO_2. The results have been used to estimate the concentration of CO_2 in fluids trapped in different geological settings, including the CO_2 content of melt inclusions. In some settings in which the relative amount of CO_2 in the fluids is small, such as epithermal precious metal deposits, oceanic vents and some melt inclusions, the density of CO_2 in the vapor bubble is low. Moreover, these densities are lower than those used to develop most of the various published densimeters, resulting in relatively large errors in estimating CO_2 densities and concentrations of CO_2in the fluid calculated from these densities.

To address this problem, we measured the splitting of the Raman Fermi diad at 22±1°C and pressures ranging from 9 psi (0.062 MPa) to the pressure on the CO_2 liquid-vapor curve (~880 psi, or 6.07 MPa) using a High Pressure Optic Cell (HPOC). These data were used to develop a dependent equation relating the splitting of the Fermi diad to CO_2 density and pressure. The resulting equation was compared to other published equations for the Raman densimeter. At 22°C, our revised densimeter predicts CO_2densities that are in general agreement with results from Fall et al. (2011), Song et al. (2009) and Rosso and Bodnar (1995). Densities predicted by the equation of Kawakami et al. (2003) are significantly higher than those predicted by our revised equation, whereas those from Wang et al. (2011) are slightly lower.

Fall et al. (2011), GCA, 75, 951-964; Kawakami et al. (2003), Appl. Spectrosc., 57, 1333-1339; Ross and Bodnar (1995), GCA, 59, 3961-3975; Song et al. (2009), Acta Geol Sin, 83, 932-938; Wang et al. (2011), GCA, 75, 4080-4093.

Title: Deciphering Compositions of Saline, Multicomponent Fluid Inclusions from Combined Microthermometric and Microanalytical Data: Approaches for Interpreting Fluids Containing Multiple Major Salts

Presenter/First Author: Matthew J Steele-MacInnis, ETH Zurich, Zurich,

Presenter/First Author Email: mjmaci@vt.edu

Co-authors: Tobias U Schlegel, , , ; John Ridley, Colorado State University, Fort Collins, CO; Christoph A Heinrich, ETH Zurich, Zurich, Switzerland

Abstract Body: Fluid inclusions (FI) commonly provide the best available information on the compositions of geologic fluids. FI compositions are estimated based on the dissolution temperatures of one or more solid phases during heating from subsolidus temperatures. Such microthermometric data are commonly interpreted using model chemical systems such as H_2O-NaCl, H_2O-NaCl-KCl or H_2O-NaCl-$CaCl_2$. The advent of microanalytical techniques applied to individual FI, particularly laser ablation ICP-MS analysis, has permitted unprecedented new insights into the diversity of cation budgets in geologic fluids, demonstrating that Fe, Mn and other cation chloride concentrations sometimes approach or exceed those of Na, K or Ca chlorides. Nevertheless, challenges remain for rigorous coupling of microthermometric measurements with microanalytical data to quantitatively constrain concentrations of numerous salts simultaneously for inclusions with complex compositions. On the one hand, concentrations of some major cations such as Ca and Fe exhibit relatively large uncertainties by chemical microanalysis, and may be more precisely estimated by microthermometric measurements. On the other hand, the solid-liquid phase relations of complex fluids containing high concentrations of several salts (e.g., NaCl+KCl+$CaCl_2$+$FeCl_2$) remain poorly known, hindering the interpretation of thermometric data. Effects of additional anions are virtually unexplored.

Here, we describe approaches to overcome some of the challenges in deciphering complex, multicomponent fluid compositions. Microthermometric measurements including the dissolution temperatures of both the last and second-to-last solid phases are interpreted simultaneously with cation ratios derived from microanalytical data. Thermodynamic formalisms for electrolyte solutions are adapted to link microthermometric and microanalytical observations according to the activity of water, ion activity relations and solubility products of relevant solid phases. These methods allow us to uniquely and rigorously pinpoint the concentrations of multiple salts simultaneously, providing a basis for quantifying minor and trace element (e.g., ore metal) concentrations. We describe applications of these methods to interpreting FI from hydrothermal mineral deposits.

Title: Estimating Ore-fluid Conditions in the Cortaderas Ag-Zn-Sn-In Deposit, NW Argentina: Integrated Fluid Inclusion Thermometry, Sulfosalt Assemblages, and Tetrahedrite Chemistry

Presenter/First Author: Evan Slater, Laurentian University, Toronto,

Presenter/First Author Email: eslater@laurentian.ca

Co-authors: Daniel Kontak, Mineral Exploration Research Centre, Sudbury, ON, Canada; Andy McDonald, Mineral Exploration Research Centre, Sudbury, ON, Canada

Abstract Body: The nature of ore-forming processes is preserved in the mineralogy and textures of ore samples. In this study of the Cortaderas Ag-Zn-Sn-In-rich deposit, which is part of the larger Miocene epithermal system at the Pirquitas Mine of NW Argentina, such information is integrated with fluid inclusion (FI) thermometry to provide a record of the PTX conditions of ore formation. Colloform sphalerite in high-grade ore samples contains two populations of aqueous FIs: Type I are equant-shaped and L-rich with consistent V:L ratios of 0.1-0.2, whereas Type II are irregular-shaped and V-rich. Fluid inclusion assemblages (FIAs) of Type I inclusions, which cross-cut primary growth zones and are thus secondary or pseudosecondary in origin, have salinities of 0.18-4.80 wt. % eq. NaCl and T_h values of 207°-227°C. These data are consistent with dilution of a magmatic fluid with heated meteoric water. The FIAs of Type II inclusions may be primary and record the instantaneous boiling of the ore-fluid during transient fluctuations from lithostatic to hydrostatic conditions (i.e., flashing). The Ag-mineralization occurs as a variety of sulfosalts with Sb, As, Pb, Cu, Sn, Zn, Fe, and Bi that are intergrown with the colloform sphalerite. Sulfosalts with cuspate interfaces are interpreted to have unmixed from a heterogeneous phase, as minerals equilibrated with cooler thermal conditions after initial deposition. For example, kesterite exsolution lamellae are common in the stannite-like mineral pirquitasite; the two phases were deposited as a solid solution and exsolution resulted from structural differences at lower temperature. Re-heating of these sulfosalts, using a calibrated thermometric stage, until they have homogenized provides minimum temperature estimates for their initial deposition, which is inferred to be at least 300°C. These conditions are consistent with temperatures estimated from Ag-rich tetrahedrite used as a mineral thermometer to constrain formation to ~250°-300°C.

Title: Dependence of the Calculated CO_2 Content of Silicate Melt Inclusions on the Choice of Raman Densimeter Used to Estimate CO_2 Density

Presenter/First Author: Lowell Moore, Virginia Polytech State University, Blacksburg, VA

Presenter/First Author Email: moorelr@vt.edu

Co-authors: Hector Lamadrid, Virginia Tech, Blacksburg, VA; Daniel Moncada, Universidad de Chile, Santiago, Chile; Robert J Bodnar, Virginia Tech, Blacksburg, VA

Abstract Body: When a melt inclusion (MI) cools, the melt inside contracts, depressurizes and forms a bubble. Sometimes, CO_2 contained in the vapor bubble was originally dissolved in the melt, and exsolved from the melt as the bubble formed. In recent years, Raman spectroscopy has been used to estimate the density of CO_2 contained in vapor bubbles in silicate melt inclusions and mass balance calculations indicate that 50 to 90 percent of the CO_2 in the MI is often contained in the bubble. If the CO_2 contained in vapor bubbles is not taken into account when estimating the total CO_2 content of the melt inclusion, the pre-eruptive CO_2 concentration may be under-estimated by 1000s of ppm CO_2, corresponding to under-estimates in trapping pressures of hundreds to thousands of bars. The implications affect not only our understanding of the volcanic “plumbing” system, but also our understanding of the Earth’s global carbon cycle as related to volcanic degassing. Several different Raman densimeters have been proposed in recent years to estimate the CO_2 density based on splitting of the Fermi diad in the Raman spectrum. These various densimeters often predict significantly different densities for the same measured Fermi diad splitting, resulting in different calculated CO_2 concentrations in the reconstructed melt. To emphasize this point, we have compared the results of Raman analyses of MI vapor bubbles collected at two different labs on MI from several tectonic settings (Central America, Alaska, Hawaii, and Iceland). Raman spectral data were used to determine CO_2 densities of the vapor bubbles using the various densimeters, and these densities were then used to estimate pre-eruptive CO_2 contents of the melts and pressures of trapping. For the same measured Fermi diad splitting, the CO_2 densities can vary by as much as a factor of 2 depending on which densimeter is used. As a result, the choice of densimeter can result in differences in estimated trapping pressures ranging from 0-2 kbar.

Title: Sulfide Melt Inclusions in Magmatic-Hydrothermal Ore-Forming Systems

Presenter/First Author: Jacob J Hanley, Saint Mary's University, Halifax, NS

Presenter/First Author Email: jacob.hanley@smu.ca

Published Material: The results presented here constitute a review of studies conducted by my group over the past 7 years. Specific aspects of the presentation have been delivered at other conferences when those studies were in their preliminary stages. This presentation, intended as a keynote contribution, concludes those studies and importantly, links the findings from each study together into a general classification and interpretive scheme for sulfide melts as they occur in the inclusion record of magmatic-hydrothermal ore systems.

Abstract Body: Inclusions containing crystallized sulfide liquids are infrequently reported in magmatic-hydrothermal ore deposit settings. Some key conclusions are presented from recent studies of intrusion-related Au-Sn-W-Mo, porphyry Cu-Au-Pd, and mafic-ultramafic Ni-Cu-PGE deposits. Textural and compositional criteria for discriminating sulfide melt inclusions from sulfide mineral inclusions, and best approaches for microanalysis (LA-ICPMS, SEM, EMP, microthermometry) are also discussed.

Three classifications of sulfide melt inclusions are presented: (i) inclusions trapped in phenocrysts synchronous to magma mixing that resulted in a transient stage of sulfide saturation; (ii) inclusions trapped in intercumulus minerals synchronous to magma differentiation as sulfide liquids were migrating through crystal mush; and (iii) inclusions trapped in xenocryst phases that, on the basis of thermobarometry, were entrained during magma emplacement from mid-lower crustal cumulates or staging chambers. Type (ii) and (iii) sulfide melt populations are commonly observed coentrapped with immiscible silicate melt in non-cotectic proportions and show widely variable compositions ranging from relatively undifferentiated Fe-Ni-Cu-S to highly fractionated Cu-rich liquids enriched in Au and PGE, whereas type (i) inclusions typically show homogeneous compositions throughout large magma volumes. In several examples, sulfide melt inclusions preserve metal ratios consistent with bulk ore ratios. This is surprising as it demonstrates negligible fractionation of ore metals during any processes subsequent to sulfide melt resorption/destabilization.

Recognition of sulfide melts included in mineral phases and subsequent study of the timing of their entrapment and their compositional features can be shown to have great potential to address key first order problems in ore genesis. They aid in constraining the original metal budget and differentiation systematics of sulfide liquids, in particular in systems that have undergone extensive post-crystallization deformation and alteration, compromising bulk rock geochemical analysis of ore metals. They may also be used to predict metal tenor and metal ratios in undiscovered deposits if dispersed through magmatic host rocks in robust mineral host phases.

Title: Gas chromatographic investigation of the light hydrocarbon compositions of fluids associated with various geological environments and regimes: A first comparison

Presenter/First Author: Mitchell Kerr, Saint Mary's University, Halifax,

Presenter/First Author Email: mitchjkerr@gmail.com

Co-authors: Jacob J Hanley, Saint Mary's University, Halifax, NS, Canada

Abstract Body: The light, saturated hydrocarbon signatures (C1-C4 saturated species) of volatile fluids hosted in a variety of distinct geological environments (trapped in fluid inclusions and/or as occluded gas) have been analyzed. Fluid composition data was acquired directly by in-line gas chromatographic (GC) analysis, and from a number of published literature sources. The geological environments investigated include a variety of sedimentary, metamorphic and igneous terranes, both ore-bearing and non-ore-bearing. Although studies using bulk GC analysis to investigate the hydrocarbon signatures of trapped fluids from certain environments have been performed previously, a study comparing the hydrocarbon signatures from a diversity of geological environments has yet to be compiled and may offer insight into the influence of non-aqueous fluid constituents in these systems. Hydrocarbon-bearing fluids of known biogenic/thermogenic origin (i.e., from oil and gas fields and gas hydrates) are markedly richer in C3-C4 hydrocarbons and possess elevated C4/C3 and C3/C2 hydrocarbon ratios relative to hydrocarbon-bearing fluids of suspected abiogenic origin. Fluids from various igneous environments (e.g., mantle, porphyry-epithermal, alkali-agpaitic, mafic-ultramafic-associated Ni-Cu-PGE sulfide deposits, and rare metal pegmatitic environments) share very similar hydrocarbon signatures and consistently display a log linear decrease in hydrocarbon abundance with increasing carbon number (Shultz-Flory distribution). This suggests that light hydrocarbons hosted in these igneous terranes may share similar origins and genetic controls, likely abiogenic in nature, due to their magmatic, organic-poor setting of entrapment. These processes may include, but are not limited to, catalytic Fischer-Tropsch synthesis and reductive coupling reactions, which generate higher order hydrocarbon via step-wise homologation reactions. Understanding the non-aqueous fluid chemistry associated with various geological environments will help elucidate the complex physicochemical controls responsible for hydrocarbon generation under geologically relevant conditions (T, P, fO_2, pH, etc.) and the potential for ore metal remobilization by these non-aqueous compounds.

Title: Deep Degassing of CO_2-rich Basanite Magma at El Hierro, Canary Islands: Insights from Melt and Fluid Inclusions

Presenter/First Author: Marc-Antoine Longpre, CUNY Queens College, Flushing, NY

Presenter/First Author Email: mlongpre@qc.cuny.edu

Co-authors: John Stix, McGill University, Montreal, QC, Canada; Andreas Kluegel, University of Bremen, Bremen, Germany; Nobumichi Shimizu, WHOI, Woods Hole, MA

Abstract Body: Basaltic magmas erupted at mid-ocean ridges, subduction zones and intraplate hotspots transfer matter from the mantle to the surface of the Earth. In recent years, increasing research efforts have focused on constraining CO_2 degassing from the mantle, which is a critical, yet poorly resolved input into the carbon cycle. Such estimates of carbon flux rely partly on knowledge of the CO_2 content of primary magmas, the best archive of which is provided by melt inclusions. Here we report on detailed analyses of quenched basanite lava balloon samples from the recent submarine eruption at El Hierro (Canaries), an intraplate ocean island. Laser ablation ICP-MS and ion microprobe analyses of matrix glasses and melt inclusions reveal high concentrations of incompatible trace elements and dissolved volatiles in this magma, with 100 ppm Nb and up to 1.2 wt% CO_2, 3.0 wt% H_2O and 0.5 wt% S. Recent models (e.g., Shishkina et al., 2014) accounting for the effect of alkalinity on CO_2 solubility predict saturation pressures in excess of 200 MPa for most melt inclusions extending up to 1300 MPa. As most melt inclusions contain bubbles, which may have sequestered part of the originally dissolved CO_2 (e.g., Hartley et al., 2014), measured CO_2 concentrations, and hence calculated pressures, are considered minima. In addition, microthermometry on CO_2-rich fluid inclusions from the same basanite samples yield fluid densities between 590 and 860 kg/m^3, corresponding to equilibration pressures of 280-580 MPa at 1150 **°**C. The El Hierro basanite thus had a particularly high volatile-carrying capacity, began exsolving a CO_2-rich fluid at a depth of at least 20 km (but likely as deep as 40 km) in the upper mantle and may have released 4-6 Tg CO_2. These results have further implications for understanding the eruptive behavior at El Hierro and similar volcanoes elsewhere and the volumetrically small but potentially significant contribution of alkaline magmas to volatile fluxes from the mantle.

Title: Secondary Gold Precipitation Involving Immiscible Methane-Nitrogen-Carbon Dioxide and Aqueous Fluids, Lupin Gold Deposit, Nunavut

Presenter/First Author: Jacob J Hanley, Saint Mary's University, Halifax, NS

Presenter/First Author Email: jacob.hanley@smu.ca

Co-authors: Steven Crowell, Saint Mary's University, Halifax, NS, Canada; Daniel Kontak, Mineral Exploration Research Centre, Sudbury, ON, Canada

Published Material: The results of this study were recently presented as a poster contribution at the NWT Geoscience Forum in November of 2014

Abstract Body: Fluid inclusions in gold-rich, late-stage “ladder” quartz veins in sulfidic BIF of the Lupin Deposit, Nunavut, preserve CH_4-N_2-CO_2-H_2O fluids responsible for secondary gold transport and deposition.

Three inclusion types are identified in the mineralized vein quartz: (i) gas-rich inclusions containing single phase (at room T) CH_4-N_2-CO_2 homogenizing to liquid between -113º and -19^{o}C (but exhibiting similar T_h in inclusion assemblages), consistent with a wide inter-assemblage range in CH_4:N_2:CO_2 ratios and/or variable $P_{trapping}$; (ii) liquid-rich inclusions containing a vapour bubble and a saline aqueous fluid that exhibit clathrate melting (Tm_{clath}) between -0.3º and 1.8^{o}C (2s range; mean of 0.6 ^{o}C; n=64), corresponding to salinities of 15.9-13.6 wt.% eq. NaCl, and homogenize ($Th_{L-V>L}$) between 254º and 308^{o}C; and (iii) mixed CH_4-N_2-CO_2-H_2O inclusions that decrepitate on heating above ~300^{o}C rather than homogenize and which occur in groups with type (i) and (ii) inclusions. Petrographic and microthermometric characteristics of type (iii) trails are consistent with entrapment of only locally immiscible (coeval) CH_4-N_2-CO_2-rich and aqueous-rich fluid “end-members”. These end-member fluids were derived from separate sources and later interacted at the point of type iii inclusion entrapment. Entrapment conditions for end-member

fluids are estimated between 1-3 kbar and 350-550°C, with localized immiscibility occurring at <2 kbar and 400°C, well below conditions of peak metamorphism and late pluton emplacement associated with primary gold deposition in the Lupin BIF.

The results of this study introduce possible mechanisms for localized gold enrichment at Lupin and may explain the lack of gold enrichment associated with quartz veining in shallow parts of the deposit where immiscible fluids entering structures from depth had already precipitated gold. Importantly, cumulative gold deposition at Lupin was protracted and continued to much lower conditions than previously thought, requiring structural ponding of residual Au-bearing metamorphic fluids prior to secondary gold deposition.

Title: Sulphur Isotope Fractionation During Degassing of Canary Island Magmas

Presenter/First Author: Patrick Beaudry, CUNY Queens College, Flushing, NY

Presenter/First Author Email: pat.beaudry7@gmail.com

Co-authors: Marc-Antoine Longpre, CUNY Queens College, Flushing, NY; Rita C Economos, Southern Methodist University, Dallas, TX; Boswell A Wing, McGill University, Montreal, QC, Canada; Thi Hao Bui, McGill University, Montreal, QC, Canada; John Stix, McGill University, Montreal, QC, Canada

Abstract Body: Isotopic fractionation of sulphur in volcanic systems is controlled by the speciation of sulphur in the silicate melt, degassing of sulphur-rich volatiles, and saturation with sulphur-rich melts or minerals. These factors are in turn tightly linked to the oxidation state of the melt, as well as temperature and pressure. The complexity of such multi parameter systems results in a wide array of sulphur behaviours in magmas, the understanding of which is still limited. In this work, we present triple S-isotope ion microprobe measurements of crystal-hosted melt and sulphide inclusions as well as matrix glasses from the 2011-2012 submarine eruption at El Hierro, Canary Islands, which involved volatile-rich basanite magma. Comparison of $\delta^{34}S$ measurements on matrix glasses (457 ± 80 ppm S) and S-rich melt inclusions (up to 5000 ppm S) indicate that degassing results in the preferential loss of heavy sulphur isotopes (up to 10 permil relative). This can only occur in a narrow oxygen fugacity range. Isotopic and compositional differences among olivine-, pyroxene- and magnetite-hosted inclusions appear to describe the evolution of the oxidation state of the magmatic system, with consideration to the order of appearance of phenocryst phases. The isotopic characteristics of El Hierro products are consistent with bulk rock multiple S isotope compositions from nearly all other historical eruptions of the Canary Archipelago, measured in both sulphide and sulphate fractions by gas-source isotope-ratio mass spectrometry. Variations between and within islands are highlighted in view of their other compositional particularities and lateral configuration. This analysis further provides insight into the degassing history of the notable 1730-36 basaltic fissure eruption of Lanzarote. Our work implies that volatile-rich magmas in the Canary Islands are subject to open-system degassing processes that effectively fractionate sulphur isotopes.

Title: Using Petrographic Observations and Evaporate Mound Chemistry of Fluid Inclusions to Assess Metal Fertility and Fluid:Rock Interaction in a Large Peraluminous Batholith: A Case Study of the Mineralized (Sn-W-U-Cu-Zn-Ag) South Mountain Batholith, Nova Scotia, Canada .

Presenter/First Author: Fergus Michael Tweedale, Saint Mary's University, Halifax,

Presenter/First Author Email: fergus.tweedale@gmail.com

Co-authors: Jacob J Hanley, Saint Mary's University, Halifax, NS, Canada; Daniel Kontak, Mineral Exploration Research Centre, Sudbury, ON, Canada; Neil Rogers, , ,

Abstract Body: The Devonian South Mountain Batholith of Nova Scotia is a large (~7300 km^2), contiguous granitoid intrusion that consists of 13 coalesced plutons of granodiorite to leucomonzogranitic composition which host a variety of mineralized zones (e.g., Sn-Zn-Cu-Ag, Mo, Mn-Fe-P, U, Cu-Ag). Given the hydrothermal nature of this mineralization, it is expected that the mineralizing fluids might manifest itself both petrographically, as alteration assemblages, and by the chemistry of secondary fluid inclusions in the granites on a scale equal to or larger than the mineralized centres. This study assesses the potential of using such information as a vector for mineral exploration. The research protocol includes: (1) detailed petrography of hundreds of archived samples that focuses on: (i) abundance and type of perthite, (ii) degree of chloritization of biotite, (iii) abundance of sericite, (iv) degree of saussuritization of plagioclase, (v) abundance of white mica, and (vi) abundance of secondary fluid inclusions in quartz; and (2) the chemistry of quartz-hosted fluid inclusions, based on SEM/EDS mound analysis from a sample suite representative of the entire batholith. The petrographic data and fluid chemistry was used to map the extent of alteration across the batholith, which indicates that fluid:rock interaction was batholith-wide and that its interaction generated Na-K-Ca-Cl-F rich fluids in addition to primary enrichment of Fe, Zn and Cu. Specifically, two distinct fluid types are present, one Na-K-Cl and the other Na-Cl-F; this enrichment of F in one of the fluid populations is the first recognition of this phenomenon in granitic bodies on such a large scale. The occurrence of this F-rich fluid across the SMB, including its most primitive rocks (i.e., granodiorites), suggests its generation is part of the natural evolution of the system and consistent with the presence of topaz in both the most evolved phases and as an integral part mineralized greisens.

Title: Arc Magmatic Evolution: The Central American Example

Presenter/First Author: Scott Andrew Whattam, Korea University, Seoul,

Presenter/First Author Email: sawhatta@gmail.com

Co-authors: Robert J Stern, Univ Texas Dallas, Richardson, TX

Abstract Body: Geochemical and isotopic data compiled for >1000 samples of lavas and intrusives from the ~1000 km long segment of the Central American Volcanic Arc system (oceanic CAVAS: Panama, Costa Rica, and Nicaragua) allow us to demonstrate how it evolved chemically and isotopically over its 75 Ma lifespan. We used available age constraints to subdivide the data into six magmatic phases: 75-39 Ma (Phase I or PI); 35-16 Ma (PII); 16-6 Ma (PIII); 6 -3 Ma (PIV); 5.9-0.01 Ma (PVa arc alkaline and PVb adakitic); and 2.6-0 Ma (PVI, Quaternary to modern magmatism, mostly much younger than 1 Ma). To correct for magmatic fractionation, selected element abundances were linearly regressed to 55 wt. % SiO_2. The most striking observation is the collective chemotemporal evolution from early low-K tholeiitic to late high-K calc-alkaline and shoshonitic magmatism. Similarly, all $LILE_{55}$, $LREE_{55}$ ΣREE_{55} and $LREE_{55}$ fractionations systematically increase from either PI to PIII or to PIV. Compositions are collectively similar to bulk continental crust (BCC) by PIII in Panama and Costa Rica, however compositional trends between Costa Rica and

Nicaragua diverge after 6 Ma, with the former and latter evolving to more enriched and more depleted sources, respectively. Galapagos Plume contributions initially accelerated enrichment by providing an anomalously thick arc substrate which aided ultimately in the shrinking of melt columns after PI. We conclude that progressive crustal thickening and concomitant melt column shortening resulted in decreasing degrees of partial melting over time which allowed for collective enrichment of the CAVAS. This evolution was interrupted only when subduction ended, allowing adakite and alkali basalt formation or upper plate extension and melt column lengthening and production of more depleted magmas. Seamount-subduction interaction after 10 Ma as posited in recent models, accentuated enrichment processes which peaked during PIV and PV in Costa Rica and Panama.

Title: Mesozoic and Cenozoic reconstruction of magmatism and basin development within the South China Sea and their implications to regional tectonic evolution

Presenter/First Author: Hue Anh MAI, Department of Earth Sciences, National Taiwan Normal University, Taipei,

Presenter/First Author Email: hueanhdc@gmail.com

Co-authors: Yu Lu Chan, Department of Earth Sciences, National Taiwan Normal University, Taipei, Taiwan; Meng-Wan Yeh, Department of Earth Sciences, National Taiwan Normal University, Taipei, Taiwan; Tung-Yi Lee, NTNU National Taiwan Normal University, Taipei, Taiwan

Abstract Body: The South China Sea (SCS) is one of the most active exploration regions for oil and gas over the past decades. This marginal sea is situated within three major tectonic plates of the Eurasian, Indo-Australian and Philippine plates that exhibited various types of plate boundaries and complex tectonic evolutions. In order to decipher the evolution and their tectonic framework, correlation between the temporal and geographical distribution of Mesozoic and Cenozoic magmatisms, and the development histories of major basins within and surrounding the SCS were conducted. Firstly, three main collision processes formed the present shape of SE Asia are determined: The age of collision between South China and Indochina, is documented by age of the Song Ma ophiolite (230.5 Ma). Timing of collision of Sibumasu and East Malaysia (Indochina) (210 Ma) is based on the new U-Pb dating results of three main granite provinces of Malaysia. And when India collided with Asia, it only occurred the soft collision around 55 Ma and changed to the hard collision in 34 Ma because the age of metamorphic rocks in the region (<35Ma). And then, four major tectonic episodes, affecting the evolution of SCS, can be recognized. (1) The southeastward younging trend of A type granite and high-K calc-alkaline magmatic rock in SE Asia during Paleogen indicated the initiation of continent extension by eastward retreating of subduction of the Pacific plate to Asia. (2) The SCS began its spreading in the N-S direction (C11-7) around 30-25 Ma possibly response to southward slab pull during the subduction of proto-South China Sea oceanic crust, which is also marked by the break up unconformity within surrounding basins. (3) The left lateral shearing activity of the Red River Shear zone (23~16 Ma) due to collision of India into Eurasia trigger a southward ridge jump event (C6b~5c). (4) The SCS seized spreading around 15.5 Ma as the Pacific sea plate continued subducted westward.

Title: Trace element variation in plagioclase phenocrysts from ignimbrites from the Mogollon-Datil volcanic field, southern New Mexico, USA: Insights into the processes and timescales of magmatism

Presenter/First Author: Gary Michelfelder, Missouri State University, Springfield, MO

Presenter/First Author Email: garymichelfelder@missouristate.edu

Co-authors: Emily E. Salings, Missouri State University, Springfield, MO; Eric R. Sikes, , ,

Published Material: The ages of the volcanic units were published in the Fall 2012 New Mexico Geological Society Field guide. Citation below:Michelfelder, G.S.; and McMillan, N.J.; 2012, Geochemistry, origin, and U-Pb zircon ages of the Sierra Cuchillo laccolith, Sierra County, New Mexico. New Mexico Geological Society Fall Field Conference Guidebook vol. 63 Geology of the Warm Springs Region, Lucas, S. G., McLemore, V. T., Lueth, V. W., Spielmann, J. A., and Krainer, K. [eds], 249-260.

Abstract Body: The Mogollon-Datil volcanic field in southern New Mexico represents the last volcanism associated with continental arc magmatism in the southwest United States. In the 13 m.y. history of the volcanic field as few as 15 calderas erupted homogeneous andesite to rhyolite ignimbrites and lava flows between 38 Ma and 25 Ma. Here we present bulk-rock major- and trace- element compositions, Sr isotopic ratios and single crystal major- and trace- element data from phenocrysts for two volcanic sequences near the Sierra Cuchillo Mountains in Sierra County.

The Dacite-Rhyolite sequence (36.5 Ma) is a crystal-rich, high-K, calc-alkaline rhyolite consisting of six tuffs and tuff-breccias. The basal member is a densely welded, tuff-breccia and the remaining members are vitric-crystal tuffs. Mineralogically, this sequence contains plagioclase>quartz>biotite>>hornblende and trace orthopyroxene. The youngest member also contains abundant sanidine.

The Latite-Andesite sequence (36.2 Ma) is a crystal-rich, high-K, calc-alkaline suite of four volcanic units. The basal member consists of a crystal-rich, trachy-andesite lava. The remaining members of the sequence contain blocks of the underlying lava and lithics from the Paleozoic sedimentary rocks. Mineralogically, the tuff-breccia's contains plagioclase>alkali feldspar>quartz> biotite>hornblende>orthopyroxene. The lava flow contains plagioclase>alkali feldspar> hornblende>biotite>>quartz.

Geochemically, the two volcanic sequences are distinct. Bulk-rock trace elements compositions for the Dacite-Rhyolite sequence exhibit large negative Eu anomalies (Eu/Eu*~0.538) and high HREE concentrations (Lu=0.91 ppm, Yb=5.84 ppm). The Latite-Andesite sequence exhibits only a small Eu anomaly (Eu/Eu*=0.998) and comparatively lower HREE concentrations (Lu=0.24-0.27 ppm, Yb=1.5-1.7 ppm) that are similar to intrusive granitites outcropping in the area.

Title: Overview of Appinites and their relationships with other enigmatic igneous rock suites

Presenter/First Author: J Brendan Murphy, St. Francis Xavier University, Antigonish, NS

Presenter/First Author Email: bmurphy@stfx.ca

Co-authors: R Damian Nance, Ohio Univ, Athens, OH

Published Material: About 25% at a symposium in memory of Ben Kennedy in Dublin in February 2014. The start of the talk may provide an overview that I published in Earth Science Reviews in January 2014

Abstract Body: The appinite suite of rocks offers a unique opportunity to study the effect of water on the generation, emplacement and crystallization history of mafic to felsic magma. The suite consists of a group of coeval plutonic and/or hypabyssal rocks, ranging from ultramafic to felsic in composition in which hornblende is the dominant mafic mineral, and typically occurs both as large prismatic phenocrysts and in the finer grained matrix. The suite is also characterized by abundant evidence for mixing and mingling between diverse magma types and variable degrees of contamination by host rock. Textures characteristic of appinites are consistent with rapid growth and with experimental evidence for the reduced viscosity of depolymerized melts allowing efficient migration of ions to the sites of mineral growth.

Appinite suites apparently range in age from Neo-Archean to Recent, and occur at all crustal levels, at depths of up to 40 km. Appinite suites share some similar geochemical features with shoshonites, lamprophyres, high-Mg andesites, sanukitoids and adakites and genetic relationships with voluminous granitoid bodies have been proposed. Melting may be triggered by asthenospheric upwelling caused either by slab breakoff (e.g. after terrane or continental collision) or by the generation of a slab window (e.g. where a ridge collides with a subduction zone). Some common tectonic traits include a tendency to form soon after the cessation of subduction, and the important role of deep crustal faults as conduits for magmas of various compositions to rise towards the surface. These conduits provide the setting for magmas of diverse composition to mix and mingle. Neo-Archean appinites, and their genetic relationship with abundant coeval sanukitoids, have been interpreted as evidence for the existence of some form of plate tectonics at that time.

Title: Building Continents and Keels: Implications from the Hf Isotopic Compositions of Archean-Hadean Zircons

Presenter/First Author: Paul A Mueller, Univ Florida-Geology Dept, Gainesville, FL

Presenter/First Author Email: pamueller@ufl.edu

Co-authors: Marion E Bickford, Syracuse University, Syracuse, NY; Joseph Wooden, Stanford University, Los Altos Hills, CA

Published Material: The data are a combination of new data and data from the literature (ours and others) as the basis for a model of intial continent formation. The model itself has not been presented previously.

Abstract Body: A major, unresolved problem in terrestrial geochemistry is: When did the first crust form with sufficient volume and density to nucleate a modern continent? Although model dependent, "ages" calculated for separation of crust from mantle in the Sm-Nd, U-Pb, and Lu-Hf systems consistently point to the Eoarchean-Hadean (>3.6 Ga) as the time of separation for many continental nuclei. Older nuclei may have formed, but were likely destroyed (e.g., by large impacts). Consequently, the most robust data repository for the >3.6 Ga Earth is dominated by zircons, both detrital and igneous, and their chemical and isotopic compositions. Focusing on Hf, data are typically interpreted in two ways: 1) calculation of model ages to estimate the time of formation of the original source rock and 2) plotting of initial εHf vs. age in order to outline an evolutionary path for a specific locale. Here we focus on the pattern of Hf isotopic compositions over time because it reveals more about crustal evolution and does not require assumptions about model reservoir compositions. Most data-sets describe one of two distinct evolutionary paths, both of which are diachronous. In the more common Type-PR paths the oldest Hf isotopic compositions fall near BSE (bulk silicate earth) and DM (depleted mantle) models (i.e., initial εHf values within error of 0). Subsequently, εHf values show a sequence of progressively more negative values interspersed with less negative, but not positive, values for several hundred million years. This pattern is seen in data from the Jack Hills, Wyoming Province, Slave Province, and Minnesota River Valley. In Type-SR patterns, the evolution paths suggest less recycling with continua of values over a given age-span that may be negative or positive and may or may not show significant age-concentration (e.g., Rae Province, SW Greenland). We suggest that Type-PR patterns correspond to dominantly plume-driven growth and Type-SR to subduction driven growth.

Title: The tectonic implication of temporal-spatial distribution of magmatism in northwestern Sibumasu terrane, the western Yunnan, China

Presenter/First Author: Yu-Ping Chiu, Department of Earth Sciences, National Taiwan Normal University, Taipei,

Presenter/First Author Email: pennyx15@yahoo.com.tw

Co-authors: Meng-Wan Yeh, Department of Earth Sciences, National Taiwan Normal University, Taipei, Taiwan; Tung-Yi Lee, NTNU National Taiwan Normal University, Taipei, Taiwan

Abstract Body: The closure of Neo-Tethys Ocean between India and Eurasia since the Cretaceous, resulted in multiple episodes of magmatism in Lhasa and Sibumasu terranes. Tengchong block, the northwestern Sibumasu, displays wedge geometry with its narrower part in the north linking to the eastern Himalaya syntaxis and its wider part in the south extending into Burma. Thus, Tengchong block might be the only part of Sibumasu that recorded the magmatic events induced by the Neo-Tethyan subduction. In this district, the S-type granitoids are dominated by biotite granites with metaluminous to peraluminous compositions (A/CNK = 0.98-1.11), high SiO_2 contents (65.2-79.2 wt.%), and subalkaline contents (K_2O + Na_2O = 5.00-8.28 wt.%). LA-ICP-MS zircon U-Pb age results indicate that the emplacement of these granitoids occurred during the early Cretaceous (~118 Ma), late Cretaceous (~78 Ma) and early Paleocene (~63 Ma) periods. The temporal-spatial distribution of granitoids in Tengchong block shows that the ages of the plutons decreased progressively from east to west since the late Cretaceous, which fits the hypothesis of rollback of the subducted Neo-Tethyan slab. Combining the structural reconstruction, the slab retreated southward beneath Sibumasu after the late Cretaceous as in southern Tibet, then was bended along with the rotation of Tengchong block due to the formation of eastern Himalaya syntaxis.

Abstract Body: The Gongcai and Qinganlin plutonic complexes in the Danba Domal Terrane, eastern Tibetan plateau, consists of the ca. 860 Ma adakitic tonalite and the 828±2 Ma high-K granite, respectively. Rocks of the Gongcai complex have variable SiO_2 (66-72 wt%), high Al_2O_3 (14.3-17.6 wt%), low alkalis (5.71-6.61 wt%), and high Sr (576-1309 ppm) and low Yb (2.2-10.4 ppm), similar to typical adakites. The Qinganlin pluton possesses higher SiO_2 (71-73 wt%) and lower Al_2O_3 (13.5-14.2 wt%), and variably higher K_2O contents (1.2-3.8 wt%) than the Gongcai complex. On the chondrite-normalized REE diagram, both plutons are enriched in LREEs, but the Gongcai complex display strongly fractionated patterns or concave patterns ($(La/Yb)_N$ =7-33; $(Gd/Yb)_N$ =1.5-4.4) with weak negative to slightly positive Eu-anomalies (δEu=0.89-1.25), while the rocks of the Gongcai complex exhibit relatively flat HREE fractionation patterns ($(La/Yb)_N$ =6-10; $(Gd/Yb)_N$ =1.3-1.6), with apparent negative Eu-anomaly (δEu=0.56-0.67). Their primitive-mantle normalized spidergrams are all characterized by negative Nb-Ta and Ti anomalies but positive Pb spikes. Both rocks of Gongcai and Qinganlin plutons have high positive zircon εHf(t) values (+3.2 to +8.5 and +5.5 to +12.2, respectively) with two-stage Hf-isotope modeal ages of 1.08 and 1.33 Ga and 0.89 to 1.07 Ga, respectively, which imply different petrogenesis and magma source. We suggest that the Gongcai adakites are indicative of partial melting of basaltic rocks modified by minor slab melt, and their relatively lower Mg# (37-53), Cr (3.9-5.4 ppm) and Ni (1.5-2.7 ppm) compared to the Cenozoic adakites indicate an distinctive source region where allows the subducting slab to be abnormally heated, melted and rapidly ascent through the thin lithospheric mantle. The parental magma of high-K Qinganlin granites is considered to be produced by low-degree partial melting of newly underplated basaltic rocks.

Therefore, the nature and petrogenesis of the closely associated Na-rich adakites and high-K granites provide effective perspective into the initial flat subduction system of the western Yangtze Block at ~860 Ma, and a later intracontinental extension occurred at ~830 Ma immediately after the assembly of the Yangtze and Cathaysia Blocks during the Neoproterozoic.

Title: Tourmaline in the Maw Zone, the Gryphon Uranium Deposit, and Sandstones above the Phoenix Uranium Deposits, Athabasca Basin, Saskatchewan, Canada

Presenter/First Author: Ian Thomas O'Connell, University of Ottawa, Ottawa,

Presenter/First Author Email: iantoconnell@gmail.com

Co-authors: Keiko Hattori, University of Ottawa, Ottawa, ON, Canada; Erin Adlakha, University of Ottawa, Ottawa, ON, Canada; Shishi Chen, University of Ottawa, Ottawa, Canada; Chad Sorba, , ,

Abstract Body: Various species of tourmaline have been reported from the Athabasca Basin, northern Saskatchewan. We examined the occurrence and mineral chemistry of tourmaline from three areas of the Denison Mine's Wheeler River property: the Gryphon zone, the Maw zone, and the Phoenix deposits. The newly discovered Gryphon zone is high-grade basement-hosted uranium deposit and samples for tourmaline analysis are collected from a graphitic pelite 17 m above the mineralization of the discovery hole, WR-556. The Maw zone is a REE-rich breccia pipe in highly hematitized sandstones with no significant uranium (mostly less than 8 ppm). Samples were collected from sandstones of MFd, MFc, MFb, and RD. The Phoenix uranium deposits (confirmed resources of 70.2 M lb U_3O_8; Roscoe, 2014) occur primarily along the unconformity between the Athabasca sandstones and the crystalline basement rocks. Samples were collected from upper most part of RD and MFb; both over 100 m above the deposits. Tourmaline in all three study areas occurs as fan-shaped aggregates of needles (up to 0.2 mm in length) together with illite, kaolin and sudoite in grain boundaries of quartz grains that have already been coated with overgrowth. Similar compositions of tourmaline and its mineral assemblages in three sites suggest that they are all contemporaneous.

EPMA analysis shows that all tourmaline grains belong to vacancy group and are identified as magnesiofoitite following the classification method of Hawthorne and Henry (1997). Tourmaline from the Gryphon zone show a higher X-site vacancy (0.7-0.8) and Mg-rich with Mg/Fe atomic ratios ranging from 0.98-0.99. The composition plots in the field of tourmaline associated with the McArthur River uranium deposit (Adlakha et al., 2014). Tourmaline in sandstones far from the uranium ore, such as those from the Maw Zone and MFb/RD sandstones above the Phoenix uranium deposits, shows lower vacancy < 72% in the X-site and a large range in Mg/Fe (0.88-0.96). The difference in H+/Na+ in the X-site and Mg/Fe in the Y-site likely reflect the composition of hydrothermal fluids.

Abstract Body: The P2 fault is a 13 km long, reverse displacement basement structure along graphitic metapelite in the eastern Athabasca Basin and hosts the world-class McArthur River uranium deposit. An assemblage of magnesiofoitite (alkali-deficient tourmaline) and LREE-rich aluminum sulfate-phosphate minerals (APS) occur along the entire P2 fault. These minerals are found in highest abundance in proximity to the McArthur River deposit. In the basement, magnesiofoitite was found only along the P2 fault. Magnesiofoitite forms aggregates of fine-grained (typically < 0.2 µm) needles that are intergrown with sudoite and/or illite, or form veinlets (< 2 mm). Magnesiofoitite is similar in composition along the entire P2 fault, independent of mineralization, and contains a high vacancy in its alkali site (0.70 – 0.85 apfu), suggesting low Na^+/H^+ in the fluids. Magnesio-foitite has an average chemical formulae of $(◊_{0.77}Na_{0.20}Ca_{0.02}K_{0.01})(Mg_{1.95}Fe^{3+}_{0.09}Al_{0.94})Al_6(Si_{6.02}O_{18})(BO_3)_3OH_3(F_{0.04}OH_{0.66}O_{0.30})$, where ◊ = vacancy. Proximal to mineralization, magnesiofoitite is slightly enriched in HREE relative to LREE ($[LREE]_N/[HREE]_N \approx 0.7$), and displays slightly greater variability in LREE distal to mineralization. APS occur within and outside the P2 fault, but the compositions vary depending on the locations. Along the fault, APS form zoned pseudo-cubes (> 20 µm), with Sr- Ca- and SO_4^{2-}-rich cores (svanbergite composition) and LREE- and P-rich rims (florencite composition). These APS contain up to 16 ppm U, suggesting that the fluids were uraniferous. Outside the fault, APS occur along the unconformity with kaolin and are svanbergitic in composition. Magnesiofoitite and florencite show complementary REE patterns implying that the two minerals are contemporaneous. APS cores contain high SO_4^{2-}, suggesting an earlier oxidized fluid, whereas SO_4^{2-}-poor rims, especially near the ore, indicate that the fluid became relatively reduced. Reducing conditions are further supported by the presence of sulfides associated with florencite. The data suggests that the uraniferous fluids passed along the entire P2 fault, but the mineralization took place only when the fluids were reduced.

Title: Petrographic study of albitization associated with uranium mineralization in the Beaverlodge district of northern Saskatchewan

Presenter/First Author: Jacklynn Adell Kennicott, University of Regina, Regina,

Presenter/First Author Email: kennicoj@uregina.ca

Co-authors: Guoxiang Chi, University of Regina, Department of Geology, Regina, SK, Canada, Regina, SK, Canada; Ken Ashton, Saskatchewan Geological Survey, Regina, SK, Canada

Published Material: Kennicott, Jacklynn, Dr. Chi, Guoxiang, Dr. Ashton, Kenneth 2014. Petrographic study of albitization in the Beaverlodge area of northern Saskatchewan. Presented December 1-3, 2014 at the 45th Saskatchewan Geological Open House. Findingd are not under review or accepted.

Abstract Body: The Beaverlodge district is located in the southwest Rae craton of the Churchill province in northern Saskatchewan and is well known for its vein-type U mineralization. The mineralization is structurally controlled by major faults (e.g. Black Bay and St. Louis faults), many of which have an early ductile mylonitic history, although U tends to be concentrated in brittle secondary structures such as breccias, veins and fractures. Mineralization is found in variably deformed granites of differing ages, and Murmac Bay group supracrustal rocks, particularly amphibolites. The Martin group redbeds unconformably overlie the Murmac Bay group and are spatially associated with several deposits, but host only minor occurrences. Albitization occurs extensively as a replacement alteration of granitic rocks spanning several tens of meters in width and as millimeter-scale veins in albitites, partially altered granitic rocks and supracrustal rocks. Albitization has long been noted as having a spatial association with U mineralization in this area and in districts worldwide; however, a genetic relationship between the two is unclear.

Replacement albitites commonly form by the alteration of granitic rocks where dissolution of quartz and replacement of primary feldspars by albite has occurred. Voids believed to be the result of quartz dissolution, are filled with rutile, specular hematite, carbonate and minor albite. Rutile and specular hematite, often associated with carbonate, are also found interstitially and in veinlets. A range of carbonate and quartz veins, including at least one generation of U-mineralized veinlets with hematized albite margins and calcite ± dolomite cores, are found in many rock types. Relating the many generations of albite, carbonate, and U mineralization is an ongoing challenge. Although, the replacement albitization predates the main mineralizing event, mineralized albite-carbonate veins appear younger and coeval with at least one stage of U mineralization.

Title: Geochemistry and Geochronology of the Andrew Lake Deposit, Thelon Basin, Nunavut, Canada

Presenter/First Author: Brandi Marie Shabaga, University of Manitoba, Winnipeg, MB

Presenter/First Author Email: umshabab@cc.umanitoba.ca

Co-authors: Mostafa Fayek, University of Manitoba, Winnipeg, MB, Canada; David Quirt, , , ; Bill Davis, Geological Survey of Canada, Ottawa, Canada; Tom Pestaj, , , ; Charlie Jefferson, , ,

Abstract Body: The Thelon Basin is an intracratonic Paleoproterozoic basin that shares many similarities with the U producing Athabasca Basin, Canada. However, there are striking geological differences that highlight the need to better characterize the Thelon U systems. The Kiggavik project area, located near the northeastern edge of the basin, comprises a series of deposits and showings along an ~18km long NE-SW structural trend. At present, the basement-hosted Andrew Lake deposit is the southernmost end-member along this trend, located near the intersection with the Scissons North fault. Mineralization is hosted within Neoarchean metasedimentary rocks informally termed the Woodburn Lake group. The objectives of this study are to: (a) characterize the deposit mineralogy, (b) determine the ages of U and alteration minerals, and (c) develop a genetic model for the Andrew Lake deposit for comparison to other deposits along the trend. Three generations of U minerals have been identified: (1) uraninite, (2) coffinite, and (3) boltwoodite. Stage 1 uraninite occurs as nodules, veins and fracture-filling grains interstitial to quartz, and as colloform uraninite. Stage 1 uraninite has relatively high and variable SiO_2 and CaO contents, ranging from 0.63 to 7.23 wt.% and 1.94 to 8.14 wt.%, respectively. Alteration of nodular and colloform uraninite formed stage 2 coffinite, which is characterized by elevated and variable SiO_2 contents ranging from 9.35 to 20.97 wt.%. Stage 3 boltwoodite occurs clusters and disseminated halos around coffinite. Apatite occurs in several units, but is not associated with U minerals. Based on major element chemistry and U-Pb isotopic analysis of U minerals, both U and Pb were remobilized by numerous hydrothermal fluid events. Therefore, the oldest age obtained for U minerals, 578 Ma, is clearly not primary. Further work is required to establish how these stages of U correlate with hydrothermal fluid events recorded in other deposits in the Kiggavik area.

Title: Long term geochemical evolution of U mine tailings from the Denison TMA-1 tailings management area, Elliot Lake, ON, Canada.

Presenter/First Author: Mariea K. Kartick, University of Toronto, Toronto,

Presenter/First Author Email: mariea.k.kartick@gmail.com

Co-authors: Julie L. Brown, , , ; F. Grant Ferris, , , ; James E. Mungall, University of Toronto, Toronto, ON, Canada

Abstract Body: Unexpected remobilization of ^{226}Ra within uranium mine tailings disposal facilities after extended periods of stability is a complex phenomenon currently occurring within historic tailings sites. There are 11 legacy uranium mine tailings sites in the Elliot Lake mining camp in Ontario, Canada. At some sites ^{226}Ra remobilization appears to have resulted from biogeochemical cycles during sulphate reduction, whereas at others, such as the Denison tailings management area, remobilization of ^{226}Ra appears to have been caused by the dissolution of iron-oxy-hydroxides. We seek a better understanding of the long-term evolution of U-mine tailings through geochemical analysis and reactive transport modeling based on field sampling of the water-covered Denison tailings management area (TMA-1) in October 2014. We performed reconnaissance sonde probing of bottom water throughout the tailings pond and selected several areas with anomalous values of redox potential, pH and conductivity for sediment coring and pore water extraction. We will characterize core samples by SEM, XRD, XRF, MLA and solution ICP-MS analysis. Analytical results and observations will be used in conjunction with sequential extraction experiments performed by the CNSC, enabling a more thorough understanding of ^{226}Ra behaviour within the tailings pond.

Pore waters showed conductivity values ranging from ~250 uS/cm to extreme values of 3100 uS/cm within areas having both neutral and low pH

values with some areas having high redox potential. There is a distinct difference in pH and redox conditions between exposed and deeply submerged tailings environments. A pH of 2 was obtained from an area of exposed tailings whereas pH values of 7-8 were obtained where tailings are fully submerged. Redox potential ranged from 95 mV in neutral pH areas to ~530 mV closer to the location of the exposed tailings. Dissolved ferric and ferrous iron concentrations in tailings porewaters range from ~-2.0 and 0.5 mg/L respectively in reduced, water-covered tailings, reaching a high of 2300 mg/L and 6000 mg/L respectively in the exposed areas. Sediment cores display a zone of intense bleaching under a layer of thick, black organic material, thought to result from the dissolution of iron oxy-hydroxide phases and perhaps responsible for the remobilization of ^{226}Ra.
