Title: Effects of Short-Lived Climate Forcers on Future Warming and Human Health

Presenter/First Author: Antti-Ilari Partanen, Finnish Meteorological Institute, Helsinki,

Presenter/First Author Email: antti-ilari.partanen@concordia.ca

Co-authors: Damon Matthews, Concordia University, Montreal, QC, Canada

Abstract Body: The peak global temperature is largely determined by cumulative emissions of long-lived greenhouse gases. However, anthropogenic emissions include also so-called short-lived climate forcers (SLCFs), which include aerosol particles and methane. Previous studies with simple models indicate that the timing of SLCF emission reductions have only a small effect on the rate of global warming and even less of an effect on global peak temperatures. However, these simple model analyses do not capture the spatial dynamics of SLCF-climate interactions, nor do they consider the additional effects of SLCF emissions on human health. There is therefore merit in assessing how the timing of SLCF emission reductions affects global temperature and premature mortality caused by aerosol emissions, using more comprehensive climate models.

Here, we use an aerosol-climate model ECHAM-HAMMOZ to simulate the direct and indirect climate forcing resulting from realistic aerosol emission scenarios based on the Representative Concentration Pathways (RCPs). From these simulations we produce the effective radiative forcing from aerosol emissions between 1850 and 2100, as well as aerosol concentrations which are used to estimate the premature mortality caused by particulate pollution. We then use the University of Victoria Earth System Climate Model to simulate the spatial and temporal pattern of climate response to these aerosol forcing scenarios, in combination with prescribed emissions of both short and long-lived greenhouse gases. In the RCP scenarios, global anthropogenic aerosol forcing declines during the 21st century from -1.3 W m^{-2} to -0.4 W m^{-2} (RCP8.5) and -0.2 W m^{-2} (RCP2.6). This relatively small difference suggests that within this range of aerosol emission scenarios, the timing of aerosol emission reductions would not have a large effect on global peak temperatures. However, there is the potential for substantially larger regional differences amongst scenarios, which would result important differences in both regional temperature changes, as well as human health impacts associated with aerosol-induced mortality.

Title: Measurements of urban, marine and Biogenic Air: VOC measurements during the MUMBA campaign

Presenter/First Author: Elise-Andree Guerette, , Fairy Meadow, NSW

Presenter/First Author Email: eag873@uowmail.edu.au

Co-authors: Clare Paton-Walsh, University of Wollongong, Wollongong, Australia; Ruhi S Humphries, University of Wollongong, Wollongong, Australia; Dagmar Kubistin, University of Wollongong, Wollongong, Australia; Stephen R Wilson, University of Wollongong, Wollongong, NSW, Australia; David W T Griffith, University of Wollongong, Wollongong, Australia; Rebecca R Buchholz, National Center for Atmospheric Research, Boulder, CO; Voltaire A Velazco, University of Wollongong, Wollongong, NSW, Australia; Xue Shi, , , ; Ian Galbally, CSIRO Marine and Atmospheric Research, Aspendale, Australia; Melita Keywood, CSIRO Marine and Atmospheric Research, Aspendale, Australia; Sarah J Lawson, , , ; Paul W Selleck, , , ; Min Cheng, , , ; Suzie Molloy, CSIRO Marine and Atmospheric Research, Aspendale, Australia; Mahendra Bhujel, , , ; Alan Griffiths, Australian Nuclear Science and Technology Organization, Kirrawee, Australia; Scott D. Chambers, Australian Nuclear Science and Technology Organization, Kirrawee, Australia; Perry Da

Published Material: Some of this work has been presented at Australian scientific meetings.

Abstract Body: The Measurements of Urban, Marine and Biogenic Air (MUMBA) campaign took place in Wollongong, NSW (a city approximately 80 km south of Sydney, Australia) from 21st December 2012 to 15th February 2013. Wollongong is nestled between a steep forested escarpment to the west and the Pacific Ocean to the east, providing an ideal setting for characterising the complex atmospheric environment at the ocean/forest/urban interface. Instruments were deployed to measure the gaseous and aerosol composition of the atmosphere, with the overarching aim of providing a detailed characterisation that could be used to test the skill of regional atmospheric models. Gases measured included ozone, oxides of nitrogen, carbon monoxide, carbon dioxide, methane and many of the most abundant volatile organic compounds. Aerosol characterisation included total particle counts above 3 nm, total cloud condensation nuclei counting; mass concentration, number concentration size distribution, aerosol chemical analyses and elemental analysis. A weather station, a LIDAR (for vertical profiles of aerosols and boundary height measurement) and a MAX-DOAS(for profiles of aerosols and trace gases) were also deployed. Total column amounts of trace gases from the University of Wollongong's ground-based solar remote sensing Fourier transform spectrometer are available for the campaign period.

As part of MUMBA, ambient mixing ratios of common biogenic and anthropogenic volatile organic compounds (VOCs) such as methanol, acetone, isoprene, monoterpenes, benzene and toluene were measured by Proton Transfer Reaction Mass Spectrometry (PTR-MS). A preliminary analysis of these VOC measurements is presented, highlighting the differences in the source regions sampled (marine, urban or biogenic) and the effects of weather patterns on the measurements.

Title: Spatial and Temporal Variability of Black Carbon and Particulate Matter in the Vaal Triangle and Highveld Priority Areas in South Africa

Presenter/First Author: Beverley Cindy Vertue, South African Weather Service, Pretoria,

Presenter/First Author Email: beverley.barnes@weathersa.co.za

Co-authors: Gregor T Feig, South African Weather Service, Pretoria, South Africa; Desmond Mabaso, South African Weather Service, Pretoria, South Africa; Seneca Naidoo, , , ; Nokulunga Ncgukana, , ,

Abstract Body: The presence of aerosols in the atmosphere is of significant concern with regard to climate, the hydrological cycle and human health. Particulate Matter, of which Black Carbon may comprise a considerable portion, is emitted from a large number of combustion and non-combustion sources. Combustion sources such as biomass burning, domestic fuel burning and various industrial processes are of great importance within the context of South African air quality management. The Vaal Triangle and Highveld Priority areas were

established as priority areas for air quality management in South Africa. Particulate Matter concentrations (PM_{10} and $PM_{2.5}$) have been measured at eleven sites in these priority areas since 2007; while Black Carbon concentrations have been measured since 2012 at three of these stations, and at the other five stations since August 2013. The concentrations of Particulate Matter measured during this time period are revealed to be significantly high, often exceeding yearly allowable exceedances within one month. As a result of the adverse effects of Black Carbon and Particulate Matter on human health and climate, this paper explores the spatial and temporal distribution of Particulate Matter in relation to Black Carbon; as well as the impact of meteorology and seasonality in these priority areas. The relationship which exists between Black Carbon and Particulate Matter within the South African context is explored. Trajectory analysis will reveal the impact which foreign airmasses may have on the Particulate Matter and Black Carbon concentrations over these two priority areas. Further, using the data available the potential sources of Black Carbon and Particulate Matter are discussed. Finally, this paper will explore whether the Particulate Matter concentrations over the two priority areas have improved since the onset of measurements.

Title: Using Multi-Model Ensembles in Climate Change Projections: Challenges and Opportunities

Presenter/First Author: Claudia Tebaldi, National Center for Atmospheric Research, Boulder, CO

Presenter/First Author Email: claudia.tebaldi@gmail.com

Published Material: I have presented similar types of talks at several meetings in the past. Some of the illustrations have been published in papers by me and co-authors like Reto Knutti and David Lobell.

Abstract Body: I will talk about approaches to characterizing uncertainties in future climate projections on the basis of MMEs, highlighting the hurdles and challenges in translating characterization into quantification. I will offer an example where some of those obstacles can be overcome, using some recent work that quantified the risk of significant impacts on crop yields from anthropogenic climate change.

My aim is to caution about the statistical oddities that make MMEs difficult to interpret and analyze, but also to highlight circumstances under which I believe those oddities may be less relevant and therefore could be discounted in the quest for probabilistic quantification of uncertainties in climate changes and their impacts.

Title: Development of a Bayesian Probabilistic Model for the NARCCAP Regional Climate Model Ensemble Using Information from the Driving GCMs to Formulate Priors and Application to Hydrology Impacts

Presenter/First Author: Linda O Mearns, NCAR, Boulder, CO

Presenter/First Author Email: lindam@ucar.edu

Co-authors: Stephan R Sain, NCAR, Boulder, CO; Seth A McGinnis, National Center for Atmospheric Research, Boulder, CO

Abstract Body: In this talk we will describe the development of a joint Bayesian Probabilistic Model for the climate change results of the North American Regional Climate Change Assessment Program (NARCCAP) that uses a unique prior in the model formulation. We use the climate change results (joint distribution of seasonal temperature and precipitation changes (future vs. current)) from the global climate models (GCMs) that provided boundary conditions for the six different regional climate models used in the program as informative priors for the bivariate Bayesian Model. The two variables involved are seasonal temperature and precipitation over sub-regions (i.e., Bukovsky Regions) of the full NARCCAP domain. The basic approach to the joint Bayesian hierarchical model follows the approach of Tebaldi and Sansó (2009). We will compare model results using informative (i.e., GCM information) as well as uninformative priors. These results will be used in the context of hydrologic model sensitivities to ranges of temperature and precipitation results to determine the likelihoods of future climate conditions that cannot be accommodated by possible adaptation options.

Title: On the Level of Agreement Between Climate-Change Projections from Same-Centre Models

Presenter/First Author: Martin Leduc, Concordia University, Montréal, QC

Presenter/First Author Email: leduc@sca.uqam.ca

Co-authors: René Laprise, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Ramón de Elía, Ouranos, Montreal, QC, Canada; Leo Separovic, Environment Canada, Dorval, QC, Canada

Published Material: Leduc M., R. Laprise and R. de Elia, 2014: Investigating structural dependencies between AOGCMs and their impact on regional-scale climate-change projections, 3rd Lund Regional-scale Climate Modelling Workshop: 21st Century Challenges in Regional Climate Modelling, Lund, Sweden, 16 - 19 June 2014.

Abstract Body: Climate models developed by a same research group are prone to share structural similarities. It is also known that such dependencies may induce resembling climatic features in the models' simulations. The "same-centre" hypothesis, which combines these two assertions into a single one, suggests that two models from a same centre should lead to climate-change projections that agree to some extent. We explore this idea throughout an analysis of climate-change projections by considering several groups of same-centre climate models.

With some exceptions, the same-centre hypothesis appears as an efficient rule to filter out non-informative agreements between models and thus clarify the message conveyed by an ensemble of opportunity. Minor modelling differences often lead to non-informative agreements while non-generalized structural differences (e.g. changing the ocean component) may reveal disagreements that are limited to specific regions (e.g. in surface air temperature over the Hudson Bay). However, there are also cases where the same-centre hypothesis fails. One typical example is that of slight iterative changes between two versions of a same model that lead to highly differing climate sensitivities. Maybe more interestingly, major changes in all of the model components may correspond to highly similar projections. The latter result suggests two outcomes. First, the two models may have reach an informative agreement, i.e. a robust result that deserves a high confidence. But conversely, this might also reflect some higher-level dependencies, such as in institutional decisions made in model development or through similar practices for model validation and tuning.

Title: Introducing Multi-Model Ensembles to Decision-Makers: The Perception Challenge

Presenter/First Author: David B Huard, David Huard Solutions, Quebec City, QC

Presenter/First Author Email: david.huard@gmail.com

Co-authors: Michael P.H. Vieira, , , ; Nathalie Thiémonge, , , ; René Roy, Ouranos, Montréal, QC, Canada

Published Material: I've just submitted another abstract discussing the same case studies to the 22nd Canadian Hydrotechnical Conference. The point-of-view and audience are however completely different. For the CHC, attended by engineers, I'll focus on the mechanics of the investment analysis and the decision-making tools, whereas here I'll address the perception of climate model ensembles by decision-makers and how to present scenarios to this particular crowd.

Abstract Body: Large infrastructure investments in the hydroelectric sector are planned decades in advance and their economic returns evaluated over periods ranging up to a century. Such long time spans and the sensitivity of hydroelectric productivity to climatic conditions make those investments especially sensitive to uncertainties in climate projections. However, there are very few known examples of hydroelectric investments from private investors using climate projections to assess their robustness to future climate conditions. One explanation may be that typical top-down climate scenarios prepared for impacts and adaptation studies do not give decision-makers a solid footing to evaluate the climate risks, or opportunities, of a given project. Indeed, the large uncertainties around climate projections from multi-model ensembles may either be perceived by non-climatologists as an obstacle to their use in investment planning or as an indication of climate science's immaturity. In collaboration with Hydro-Québec and Manitoba-Hydro, Ouranos is developing decision-making tools for two case studies in the hydroelectricity sector. The aim of these studies is to show-case how climate information from multi-model ensembles can be leveraged by decision-makers. The approach uses the “Robust Decision Making” framework and explores the sensitivity of different investment options to climate projection uncertainty. Of particular interest within this framework is the role played by climate projections, where instead of defining future conditions through top-down scenarios, they play the role of expert advice, weighing in on the likelihood of parameterized climate scenarios. This fundamental switch in the interpretation and perception of climate projections may ease their integration into decision-making process by explicitly acknowledging their conditional nature.

Title: APCC Multi-Model Ensemble Forecasting and an Empirical-Dynamical Approach for Summertime Temperature Prediction in South Korea

Presenter/First Author: Hyung Jin Kim, APEC Climate Center, Busan,

Presenter/First Author Email: hyungjin@apcc21.org

Co-authors: Young-Mi Min, APEC Climate Center, Busan, South Korea; Hae-Jeong Kim, APEC Climate Center, Busan, South Korea; Sang Myeong Oh, APEC Climate Center, Busan, South Korea

Published Material: Parts of this presentation were introduced in the session entitled “Multi-Model Ensembles Predictions for Intrasesonal-to-Interannual Timescales” at the 2014 AGU Fall Meeting.

Abstract Body: The APEC Climate Center (APCC) is a leading climate information service provider and research institute that serves the 21 APEC member economies as well as the broader international community. Currently, 16 operational centers and research institutes from around the world participate in the APCC operational multi-model ensemble (MME) prediction system by routinely providing ensembles of global forecast fields. Various MME methods implemented in APCC's MME system were compared with a simple averaged MME (with equal weightings) to assess one-month lead seasonal mean temperature and precipitation. The results showed that the simple averaged MME is generally superior to the empirically-weighted multiple regression MMEs if all aspects of the predictions were taken into account. On the other hand, the calibrated MME with a step-wise pattern projection resulted in reduced errors and improved forecast skills in a large proportion of cases. Two empirical models, a multivariate regression model and a simple empirical model, were established based on the tropical-extratropical teleconnection patterns and applied to the APCC MME prediction to investigate the predictability of summertime temperature in South Korea. The multivariate regression model outperformed the simple empirical model at all lead times ranging from one to six months. The notably different predictability arguably arose from the higher fidelity of the simulated tropical SST in the Central and Eastern Pacific than in the Western Pacific. In addition, the multivariate model outstripped the one-month lead MME prediction, suggesting that the reproducibility of tropical SST, despite the regional dependency, can pave a promising way for the use of an empirical-dynamical prediction for summertime temperature in South Korea.

Title: Bias-corrected Down-scaled Multi-Model Ensemble Prediction of the Indian Summer Monsoon Rainfall using Self-Organizing Map

Presenter/First Author: Nabanita Borah, Indian Institute of Tropical Meteorology, Pune,

Presenter/First Author Email: nita@tropmet.res.in

Co-authors: A. K. Sahai, Indian Institute of Tropical Meteorology, Pune, India; Rajib Chattopadhyay, Indian Institute of Tropical Meteorology, Pune, India; S. Abhilash, Indian Institute of Tropical Meteorology, Pune, India; Susmitha Joseph, Indian Institute of Tropical Meteorology, Pune, India

Abstract Body: The probabilistic large scale forecasts though useful for Extended Range Prediction (ERP) of the Indian Summer Monsoon Rainfall (ISMR) over larger regions of Indian subcontinent, it has been found that the regional forecast outlook misrepresents the amplitude of rainfall variability. This is a common problem in a large scale Global Circulation Model. E.g. the rainfall prediction over north-east India, south-peninsular India and the regions with elevated orography show large underestimation of rainfall amplitude and limited forecast skill at fourth pentad lead time.

Hence, bias correction of the large scale forecast and its downscaling to smallest possible regions need to be explored rigorously. In this study, Self-Organizing Map (SOM) has been used to bias-correct and downscale the CFS v2 generated ERP forecast of ISMR. SOM is used to identify the patterns from the low-resolution (1x1, IMD) observed data. Then dynamical model (CFSv2) generated data is projected onto these patterns to generate the bias-corrected forecast and reconstructed using a high resolution observed data (0.25x0.25, TRMM) so that we finally get the bias-corrected downscaled prediction of the ISMR.

Three versions of CFSv2 [T126, T382 and the bias corrected GFS (GFSbc) at T126] is used in this study to generate total 129 [(11 members of CFST126+11 members of CFST382+21 members of GFSbc) x3 different lattices] members. Mean of these are given as the deterministic forecast. The brier skill score and the pattern correlation shows significant improvement in the forecast skill.

Title: Improving Multimodel Medium Range Precipitation Forecasts over the Greater Horn of Africa Using the FSU Superensemble

Presenter/First Author: Oliver Kipkogei, IGAD Climate Prediction and Application Center, Nairobi,

Presenter/First Author Email: okipkogei@gmail.com

Co-authors: Amit Bhardwaj, Florida State University, Tallahassee, FL 32306, USA, Tallahassee, FL; T N Krishnamurti, Florida State Univ, Tallahassee, FL; Laban Ogallo, , , ; Vinay Kumar, , ,

Published Material: Currently under review by *Journal of Meteorology and Atmospheric Physics*

Abstract Body: Abstract

This study makes use of the WMO's multimodel data set called THORPEX Integrated Grand Global Ensemble (TIGGE) towards the construction of multimodel superensemble forecasts covering a period of 10 days. The goal of this study is to explore the forecast skill for precipitation forecasts over the Greater Horn of Africa (this is a consortium of 11 countries). The multimodels include forecast data set from a suite of models that include: the UK Met office model (UKMO), the US National weather model (NCEP), the European Model (ECMWF), and the Brazilian model (CPTEC). After performing a training phase for the superensemble weights covering the previous 450 days of October, November and December months of 2008 to 2012, forecasts of precipitation were prepared for the multimodel superensemble. These covered Day-1 to Day-10 of forecasts over the region. Various skill metrics were prepared to validate the forecast rainfall against the Tropical Rainfall Measuring Mission (TRMM) observed rainfall data. This study shows that the construction of the multimodel superensemble was a worthwhile effort since it provided the best overall skills for the RMS errors, the spatial correlations and the equitable threat scores and their bias errors for precipitation forecasts from day 1 to day 10 over all of the countries covered by the Greater Horn of Africa. The best among the member model was the UKMO model. This study strongly suggests the usefulness of a product such as the multimodel superensemble for improved precipitation forecasts over East Africa.

Title: Towards regional understanding and predictions of tropical cyclone activity and hydroclimate

Presenter/First Author: Gabriel Andres Vecchi, Geophysical Fluid Dynamics Laboratory, Princeton, NJ

Presenter/First Author Email: gabriel.a.vecchi@noaa.gov

Published Material: Some appeared in Vecchi, G.A., T. Delworth, R. Gudgel, S. Kapnick, A. Rosati, A.T. Wittenberg, F. Zeng, W. Anderson, V. Balaji, K. Dixon, L. Jia, H.-S. Kim, L. Krishnamurthy, R. Msadek, W.F. Stern, S.D. Underwood, G. Villarini, X. Yang, S. Zhang (2014): On the Seasonal Forecasting to Regional Tropical Cyclone Activity. J. Climate. doi:10.1175/JCLI-D-14-00158.1

Abstract Body: Seasonal to decadal prediction systems have demonstrated skill at predicting some aspects of large-scale climate, such as temperatures over the equatorial Pacific and North Atlantic, and even the statistics of some extremes aggregated over large regions, such as the basin-wide number of hurricanes in the Atlantic. However, information at smaller space scales and of more targeted quantities is a more desirable prediction target both for decision support and for testing our understanding of processes controlling regional hydroclimate. Prediction of regional climate depends on both correct simulation and prediction of large-scale climate drivers, as well as of regional processes.

Potential for skillful seasonal prediction at the regional scale is highlighted using two new high-resolution (with 50km and 25km atmospheric/land resolution) global coupled climate models, targeted to the understanding, intraseasonal-to-decadal prediction and near-term projection of regional and extreme climate. Initialized predictions of global hurricane activity show skill on regional scales, comparable to the skill on basin-wide scales, suggesting that regional seasonal TC predictions may be a feasible target. The variation and prediction of regional hydroclimate globally, with a focus on the Caribbean/Gulf of Mexico and surrounding land regions are explored, including methods for maximizing prediction skill. It is shown that mean-state errors are a key constraint on the simulation and prediction of variations of regional climate and extremes, and methodologies for overcoming model biases are explored. Improvements in predictions of regional climate are due both to improved representation of local processes, and to improvements in the large-scale climate and variability from improved process representation.

Title: Evaluation of the January-March 2015 Monthly Rainfall Predicted by Taiwan CWB Two-tier MME Forecast System

Presenter/First Author: Mong-ming Lu, Central Weather Bureau, Taiwan, Taipei,

Presenter/First Author Email: lu@rdc.cwb.gov.tw

Co-authors: Yun-Ching Lin, Central Weather Bureau, Taiwan, Taipei, Taiwan; Ching-Teng Lee, Central Weather Bureau, Taipei, Taiwan; Jyh-Wen Hwu, Central Weather Bureau, Taipei, Taiwan

Abstract Body: Taiwan faced a serious water shortage situation since the commencement of dry season in November 2014. The water shortage is a result of the less active typhoon activity during the preceding typhoon season. Thus, the rainfall prediction for January-March 2015 is of particular importance to the water resources management sector. In this paper, we will use the January-March 2015 monthly and seasonal rainfall prediction to introduce the forecast system, ensemble strategy, statistical downscaling procedure, forecast product, and related forecast tools

developed at the Central Weather Bureau (CWB) of Taiwan. The forecast system TCWB2T-2 is CWB's second version multi-model two-tier forecast system consisting of two atmospheric generation circulation models and two sets of forecast SST. The two AGCMs and two set of forecast SST form 4 suites of two-tier forecast models, namely, CWB-GFS/CWB-OPGSST, CWB-GFS/NCEP-SST, ECHAM5/CWB-OPGSST, and ECHAM5/NCEP-SST. Each suite has 30 members, differentiated by different initial conditions for the atmosphere and ocean occurring on 30 sequential days. Four suites of the models form 120 forecast members. A SVD-type statistical downscaling method applied to five large-scale variables is used to downscale the global forecast to 16 Taiwan stations. The individual and ensemble members can generate 620 monthly and seasonal prediction values at each station. The station rainfall prediction is generated from the difference of the real-time forecast probability distribution formed by 620 prediction values and the background forecast probability distribution formed by historical prediction of the training period from 1982 to the latest global forecast operational runs. The prediction skill of the downscaling method provided to the users is based on the evaluation results of the retrospective forecast of 1982-2011.

Title: Multi-Model Ensemble for Seasonal Forecasting at Environment Canada

Presenter/First Author: Bertrand Denis, Organization Not Listed, Dorval,

Presenter/First Author Email: bertrand.denis@ec.gc.ca

Co-authors: William J Merryfield, University of Victoria, Victoria, BC, Canada; Juan Sebastian Fontecilla, , ,

Abstract Body: Environment Canada has been in the business of producing seasonal forecasts using the Multi-Model Ensemble (MME) approach since 1995. Nowadays, the MME approach is widely spread but typically uses model contributions from different producing centres instead of only one center. Current examples of these multi-center MMEs for seasonal forecasting include the WMO, APCC, NMME and EUROSIP MMEs. During that 20 years period, successive versions of the EC's seasonal forecasting system have drawn upon "models of opportunity" that were developed for other purposes by EC's climate and meteorological modeling centers. This talk will describe the origins of this single-center/multi-model approach, and its evolution through configurations consisting of two and subsequently four 2-tier models in the 1990s and 2000s, to the current Canadian Seasonal to Interannual Prediction System (CanSIPS). The latter is based on two global climate models, CanCM3 and CanCM4, that employ common ocean, sea ice and land components coupled to two versions of CCCma's atmospheric model. Lessons learned concerning the efficacy of this multi-model approach will be discussed, focusing on the relative merits of adding more ensemble members versus adding more models, and on methods for combination and calibration.

Title: Probabilistic Forecasting in NMME

Presenter/First Author: Emily J Becker, Climate Prediction Center, College Park, MD

Presenter/First Author Email: ejbecker@gmail.com

Co-authors: Hugo M Van den Dool, Climate Prediction Center, College Park, MD

Published Material: A preliminary version of this material was presented at the 39th CDPW in October 2014. These findings are currently under review at J. Climate.

Abstract Body: The North American Multi-Model Ensemble (NMME) forecasting system has been continuously producing seasonal forecasts since August, 2011. The NMME, with its suite of diverse models, provides a valuable opportunity for characterizing forecast confidence using probabilistic forecasts. The current experimental probabilistic forecast product (in map format) presents the most likely tercile for the monthly mean value, chosen out of "above normal", "near normal", or "below normal", using a non-parametric counting method to determine the probability of each class. A first-order bias correction is applied when the hindcast based local model climatology is removed (for each model separately) and replaced with the climatology from observations. A 2nd order bias correction is applied when forecasts are expressed in terciles derived from model hindcast data.

The skill of the monthly-mean and three-month-mean probabilistic forecasts of 2 m surface temperature, precipitation rate, and sea-surface temperature is assessed using the 29-year (1982-2010) NMME hindcast database. Skill is assessed on the cross-validated hindcasts using the Brier skill score; forecast reliability and ROC diagrams are also assessed, and the anomaly correlation of deterministic forecasts is shown for comparison. Results of a probabilistic anomaly correlation correction are presented. For all of the fields and regions examined, forecasts for the above and below terciles from the NMME system result in substantially higher BSS than is found for the CFSv2 forecasts alone. NMME forecasts were also found to have greater reliability than those from the CFSv2. Skill relative to model diversity and ensemble size is assessed.

Title: Evaluating the Skill of NMME Seasonal Precipitation Ensemble Predictions for 17 Hydroclimatic Regions in Continental China

Presenter/First Author: Feng Ma, BNU Beijing Normal University, Beijing,

Presenter/First Author Email: fma@mail.bnu.edu.cn

Co-authors: Aizhong Ye, Beijing Normal University, Beijng, China; Xiaoxue Deng, Beijing Normal University, Beijing, China; Zheng Zhou, Beijing Normal University, Beijing, China; Qingyun Duan, Beijing Normal University, Beijing, China

Published Material: This results were submitted to *International Journal of Climatology* at 16-Oct-2014, and are under review.

Abstract Body: There is increasing focus on the usefulness of climate model–based seasonal precipitation forecasts as inputs for hydrological applications. This study reveals that most models from the North American Multi-Model Ensemble (NMME) have potential to forecast seasonal precipitation over 17 hydroclimatic regions in continental China. In this paper, we evaluated the NMME precipitation forecast against observations. The evaluation indices included the correlation coefficient (R), relative root-mean-square error (RRMSE), rank histogram (RH), and continuous ranked probability skill score (CRPSS). We presented the RRMSE-R diagram to distinguish differences between the performances of individual models. We find that the predictive skill is seasonally and regionally dependent, exhibiting higher values in autumn and spring and lower values in summer. Higher predictive skill is observed over most regions except the southeastern monsoon regions, which may be attributable to local climatology and variability. Among the 11 NMME models, CFS, especially CFSv2, exhibits the best predictive skill. The GFDL and NASA models, which are followed by CMC, perform worse than CFS.

The performances of IRI and CCSM3 are relatively worse than that of the other models. The forecast skills are significantly improved in multi-model mean forecasts based on simple model averaging (SMA). The improvement is more obvious for Bayesian model averaging (BMA), which is employed to further improve the forecast skill and address model uncertainty using multiple model outputs, than individual model and SMA.

Title: Ensemble Hydrological Forecasts

Presenter/First Author: Dorothy A Durnford, Meteorlogical Service of Canada, Dorval, QC

Presenter/First Author Email: suttonplace@sympatico.ca

Co-authors: Vincent Fortin, Environment Canada Dorval, Dorval, QC, Canada; Etienne Gaborit, Environment Canada Dorval, Dorval, QC, Canada

Abstract Body: There is an increasing demand for sub-seasonal and seasonal hydrological forecasts. Long-range predictions would provide extremely useful guidance for water management practices, fisheries, and shipping companies. The Canadian Meteorological Centre (CMC) is currently developing a modelling system to produce monthly hydrological forecasts. Precipitation is the weakest component of extended range hydrological forecasts. No deterministic model can provide a reliable sub-seasonal forecast of precipitation. Therefore, an ensemble of month-long predictions of precipitation and other atmospheric variables will drive CMC's hydrological modelling system. The variation of key parameters in the streamflow routing model will further increase the number of ensemble members. An ensemble hydrological reforecast of the past 20 years will be combined with the ensemble monthly hydrological forecasts to yield predictions of anomalies of streamflow and water levels. Guidance issued to users will be a probabilistic forecast of the magnitude of the streamflow and water level anomalies over the coming month. The magnitudes will be presented as an index.

Title: Developing Operational MME Forecasts for Subseasonal Timescales.

Presenter/First Author: Dan C Collins, Climate Prediction Center College Park, College Park, MD

Presenter/First Author Email: dan.collins@noaa.gov

Published Material: A fraction of the material was presented at the Climate Diagnostics and Prediction Workshop in October 2014.

Abstract Body: A number of recent international research and operational prediction development projects have focused on bridging the gap between weather and climate forecasts; for example the WMO WCRP/WWRP Subseasonal to Seasonal Prediction Project (S2S). The NOAA Climate Prediction Center (CPC) has a milestone to provide operational subseasonal forecasts before the end of 2015. Environment Canada and U.S. National Centers for Environmental Prediction (NCEP) ensembles from the North American Ensemble Forecast System (NAEFS), currently used in weather forecasts out to two weeks lead time, have been extended to more than four weeks lead time. In addition to the NAEFS models, CPC is evaluating retrospective and real-time ensemble prediction system (EPS) subseasonal forecasts from the European Centre for Medium-range Weather Forecasts (ECMWF) and Japan Meteorological Agency (JMA). The ensemble models of the North American Multi-Model Ensemble (NMME) including the U.S. NCEP Climate Forecast System (CFS) and the Canadian Seasonal to Inter-annual Prediction System (CanSIPS), used in CPC operational seasonal forecasts with one to five months lead time, are now providing data at daily resolution for research on subseasonal prediction. The ensemble models available for subseasonal forecasts are varied in several respects. The NAEFS and JMA EPS are currently uncoupled atmosphere dynamical models, while the ECMWF EPS and NMME models are all coupled to ocean models. Extended weather models also differ from the seasonal forecast systems of the NMME in that they have generally higher spatial resolution and more advanced data assimilation and initialization schemes.

This talk will present preliminary evaluations of the multitude of ensemble model forecasts individually and combined as multi-model ensemble forecasts, compare subseasonal modeling systems, and discuss the prospects for provision of skillful subseasonal forecasts with three to four weeks lead time.

Title: Uncertainties on atmospheric aerosol particle emission and deposition fluxes: observation and needs to improve quantification

Presenter/First Author: Philippe Laguionie, IRSN Institut de Radioprotection et de Sûreté Nucléaire, Cherbourg-Octeville,

Presenter/First Author Email: philippe.laguionie@irsn.fr

Co-authors: Denis Maro, , , ; Olivier Connan, , , ; Didier Hébert, , , ; Geoffrey Pellerin, , , ; Luc Solier, , , ; Marianne Rozet, , , ; Mehdi Morillon, , ,

Abstract Body: Assessing, understanding and predicting the impact of accidental or chronic releases of particulate pollutants (chemical, radioactive, biologic) in ecosystems is a major issue in the context of risk management for the population. In addition, aerosol particles play an important role in global warming by reducing the action of greenhouse gas emissions. Particle concentrations in the atmosphere depend on the particle sources (primary and secondary), particle evolution (coagulation), and the dry and wet deposition processes. Predictive emission, transfer and deposition models, developed and improved from in situ flux measurements, are important tools to better protect population and to understand dynamics of aerosol in the surface layer. For now, experimental data are scarce and gaps between measurements and model results, and between model predictions, are usually huge. For examples, there is several orders of magnitude discrepancy between scavenging coefficients or dry deposition velocities. These uncertainties are due to the lack of accurate experimental data in function of specific parameters such as particle size and atmospheric turbulence. Although there have been recent important progresses in experimental and numerical studies, there remains many challenges before achieving this goal. For example, systematic high frequency measurements of particle concentrations combined with spectral corrections, or use of appropriate surrogates in deposition particle tracing methods, would allow a better quantification of the dry deposition fluxes. It is proposed here to review experimental and data processing techniques used in the environment to estimate aerosol particles fluxes and to discuss some improvements to methodologies for a better quantification. This topic is also being addressed by an international working group whose common goal is to publish recommendations for environmental particle fluxes quantification.

Title: Mechanisms Responsible for the Size-dependence of, and Bi-directionality of, Ultrafine Particle Fluxes Over Forest

Presenter/First Author: Sara C Pryor, Cornell University, Ithaca, NY

Presenter/First Author Email: sp2279@cornell.edu

Co-authors: Rebecca J Barthelmie, Cornell University, Ithaca, NY; Ryan Sullivan, Cornell University, Ithaca, NY

Published Material: I presented some very preliminary results in a poster at AGU Fall 2013 meeting

Abstract Body: Given the global importance of forests, there is a specific need to understand aerosol particle removal to, and formation in/above, forests. We present 18 months of size-resolved and total ultrafine particle fluxes (i.e. diameters < 100 nm) over (at 46 m) and in (at 7 m) a deciduous forest and use them to quantify controls on particle uptake. The flux data presented derive from 3 Gill 3-D WindMaster Pro sonic anemometers (deployed at 46 m, in the canopy at 20 m and below the canopy at 7 m), along with data from, an Ultrafine Condensation Particle Counter (UCPC) operated at 10 Hz and a Fast Mobility Particle Sizer (FMPS) operated at 1 Hz. Size-resolved particle profiles during the same period are measured using a separate FMPS scanning at three measurement heights across the canopy (top, middle and bottom). The results are integrated with fluxes of sensible heat, momentum and carbon dioxide derived using a Licor LI-7200. Results for the total number flux concentrations and the size-resolved concentrations derived using micrometeorological flux approaches show a high degree of accord, but relatively high uncertainty. Other results will be described in detail and include the following:

a) Selecting only deposition fluxes, above/below canopy fluxes indicate a median flux ratio of 3 (i.e. total number fluxes above canopy are 3× below canopy) and above versus below canopy deposition velocities implies a median interception fraction of 60%.

b) The net flux of both the total number of ultrafine particles and all size classes in the ultrafine modes are downwards, but a considerable number of the sampling periods are characterized by upward fluxes. Heat fluxes during large magnitude upward particle fluxes do not exhibit different quadrant partitioning than during large downward fluxes. But particle fluxes exhibit an increased role of both ejections and sweeps in upward fluxes that are differentially important in terms of leaf on versus leaf off and phenological stage.

c) Distinctly different flux diurnal profiles for the nucleation versus Aitken mode particles, and a clear link to nucleation events. This indicates differential control mechanisms on fluxes of particles of different sizes and a key role for aerosol dynamics.

Title: Variation in Seasonal Deposition of Indoor Carbon, Ionic, Toxic Metalloids and Metal Species in Different Anthropogenic Zones- CMB study

Presenter/First Author: Balakrishna Gurugubelli, Pt.Ravishankar Shukla University, Raipur,

Presenter/First Author Email: balakrishna2729@gmail.com

Abstract Body: Abstract

Different approaches of source apportionment of dust fractions have been reported world-over. Prediction of source categories within receptor chemical profiles using regression and factor analysis using PCA has been reported to evaluate possible source/routes of air pollution mass significantly. The present study is focused on application of all three (regression analysis, PCA and CMB) approaches to investigate higher degree of significance in source apportionment of indoor seasonal deposition of different species in different anthropogenic atmospheric zones. Modeled source categories obtained from regression and factor analysis (using PCA) has shown potential support in the selection of source profiles in CMB. About 75-88% agreement has been obtained between results of source signatures of indoor deposition obtained from three approaches. The application of combined approach has been extended to respirable fine particulates measured indoors. Both fractions have shown different dominance of selected source of emissions.

Practical implications: Major approaches of source signatures has been investigated in combination with the hypothesis that prediction and modeled source profiles will support the selection and inclusion of field based source profiles in source apportionment of indoor dust fractions using CMB. A stratified random sampling plan using longitudinal study design has been adopted for dust fallout source apportionment.

Key words: CMB, regression analysis, PCA, indoor air, anthropogenic zones

Title: Evaluating impact of surface ozone on mortality and crop yields over South Asia

Presenter/First Author: Chinmay Kumar Jena, Indian Institute of Tropical Meteorology, Pune,

Presenter/First Author Email: chinmay@tropmet.res.in

Co-authors: Sachin D Ghude, IITM, Pune, India; Dilip Chate, , , ; Gufran Beig, Indian Inst of Tropical Meteor, Pune, India

Published Material: One paper was publised and another one under review

Abstract Body: Climate change has been shown to increase surface O_3 in many regions of the world and have raised concerns about the O_3 impact on mortality and the magnitude of yield reductions, primarily occurring in the developing nations. Demographically agriculture is the broadest economic sector, rank worldwide second in farm output and principle source of livelihood for more than 58% of 1.2 billion populations which plays an important role in the overall socio-economic fabric of India. For the potential impact of ozone on district-wise cotton, soybeans, rice, and wheat crops in India for the first decade of the 21st century. Wheat is the most impacted crop with losses of 3.5±0.8 million tons (Mt), followed by rice at 2.1±0.8 Mt, with the losses concentrated in central and north India. On the national scale, this loss is about 9.2% of the cereals required every year (61.2 Mt) under the provision of the recently implemented National Food Security Bill by the Government of India. The nationally aggregated yield loss is sufficient to feed about 94 million people living below poverty line in India. Significant portion of human population in India is believed to be regularly exposed to higher surface ozone (O_3) levels. Here, we have also evaluate total, cardiovascular and respiratory mortalities and hospitalizations (COPD) caused by population exposure to surface O_3. Attributable mortalities are quantified using health impact function of long-term relative risk estimates (population attributable-risk proportion) for O_3 from epidemiology literature. We calculated total mortality of about 1125 thousands, 404 thousands by cardiovascular deceases and 176 thousands by respiratory deceases, and COPD cases of about 175 thousands caused by O_3 exposure to population of India in 2005. The highest number of total, cardiovascular and respiratory mortalities and

COPD cases are found in the highly populated Indo-Gangetic region followed by metro-cities and sub-urban and industrial areas.

Title: Temporal Trends in Mercury Wet Deposition Across the U.S. and Canada

Presenter/First Author: David Allen Gay, University of Illinois, Champaign, IL

Presenter/First Author Email: dgay@illinois.edu

Co-authors: Mark E Brigham, , Anoka, MN; Matthew Parsons, , , ; Arnout ter Schure, EPRI, PALO Alto, CA

Published Material: some of these early results were reported at the National Atmospheric Deposition Meeting 2014 October, but we have moved well beyond these reported results.

Abstract Body: To assess whether reductions in mercury (Hg) emissions from electrical generation units and other sources in the United States and Canada have translated into changes in Hg concentrations in precipitation, we assessed spatial gradients and temporal trends in mercury (Hg) wet deposition and Hg air concentration data. We obtained wet deposition Hg data from 185 National Atmospheric Deposition Program (NADP) sites across the U.S. and Canada, 128 of which have records of at least 5 years, and 27 of which have complete records from 1998-2013.

Annual rates of change in Hg concentration and Hg deposition rates were calculated using two different methods; (1) the Seasonal Kendall-Mann non-parametric method, and (2) a Fourier transform linear regression parametric method using precipitation depth as an input variable. For this presentation, we will also show results from both methods, where they agree, where they disagree, and potential reasons for this disagreement.

The results from both methods agreed in showing widespread decreasing Hg concentration trends ($p<0.05$) across most regions in the eastern half of the continent (-0.5 to < -3 %/yr) and significant increasing Hg concentration trends (+1.5 to > +3 %/yr), primarily located in the U.S. Great Plains and Rocky Mountain/Desert regions. Some trends are consistent region-wide, while other regions show significant between–site and –season variation. The downward trend in precipitation Hg concentrations observed at many sites with data beginning before 1998 is becoming significantly less steep in recent years. Finally, best estimates of trends over North America will be provided for use by others.

Title: A Synthesis of Global Observations on the Air-Surface Exchange of Elemental Mercury Vapor

Presenter/First Author: Che-Jen Lin, Lamar University, Beaumont, TX

Presenter/First Author Email: Jerry.Lin@lamar.edu

Co-authors: Wei Zhu, Institute of Geochemistry, Guiyang, China; Jonas Sommar, Institute of Geochemistry, Guiyang, China; Xinbin Feng, GIG Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, China

Abstract Body: Both the atmosphere and earth surface are transient reservoirs of mercury (Hg) in the environment. Reliable quantification of the air-surface exchange of elemental mercury vapor (Hg^0) is crucial for understanding the global biogeochemical cycling of Hg. There have been extensive measurement and modeling efforts made to estimate the exchange fluxes between the atmosphere and various surfaces (e.g., soil, canopy, water, snow, etc.). However, large uncertainty remains in these estimates due to the complexity of Hg^0 bi-directional exchange, the limitations of flux quantification techniques and the challenges in model parameterization. Due to the semi-volatile nature of Hg^0 and poorly understood redox transformation of Hg in different environmental media, the flux of deposition and re-volatilization of previously deposited Hg exhibits distinct characteristics subject to the influence of environmental variables such as natural surface types, temperature, light, moisture, atmospheric turbulence, presence of reactants that facilitate Hg redox chemistry, and relative levels of Hg in the media where Hg^0 exchange occurs. In this study, we provide an integrated synthesis on the current state of scientific understanding in the air-surface exchange of Hg^0. Specifically, the development of advancement of flux quantification methods, existing field observational data of Hg^0 flux, environmental factors driving the exchange process, and modeling efforts to scale up the measured flux for global assessment are presented. The existing knowledge gap and the associated research need to further understand the air-surface exchange of Hg^0 are discussed.

Title: Preliminary Evaluation of Methylmercury Concentrations for Wet Deposition Samples Collected in North America, 2003-2013

Presenter/First Author: Gregory Alan Wetherbee, USGS, Baltimore, MD

Presenter/First Author Email: wetherbe@usgs.gov

Co-authors: Mark F. Rhodes, , , ; David Allen Gay, University of Illinois, Champaign, IL; Robert C. Brunette, , , ; Eric M. Prestbo, Tekran Instruments Corporation, Toronto, ON, Canada; Martin R. Risch, , ,

Abstract Body: The National Atmospheric Deposition Program /Mercury Deposition Network (NADP/MDN) recently released data for methylmercury (MeHg) concentrations in 5,375 non-filtered samples of wet-only deposition. Samples were collected at 74 locations in the USA and Canada during 2003-2013.

Concentrations are censored at a mass-based RL=0.050 ng in samples collected before April 18, 2007 and at RL=0.0025 ng on or after that date, relevant for samples with a minimum volume of 45 mL. Mean MeHg concentrations for samples pre- and post-April 18, 2007 are statistically different per the Peto-Prentice test. The mean MeHg concentration is 71 percent lower for samples collected after April 18, 2007 due to an increased percentage of low-concentration samples above the RL. Approximately 66% of the MeHg determinations are less than the RLs.

Assigned quality rating codes classify 92.8 percent of the samples as "valid". Associated notes codes qualify the data based on various sample characteristics, including visible debris type (bird, insect/animal, plant, ash/soot, and cloudiness). Consideration of these codes is crucial to proper use of the data. Approximately 63% of valid samples with MeHg concentrations above the RL contained visible debris, indicating a highly significant relation ($p<.001$) between debris presence and quantifiable MeHg as measured by a chi-squared contingency analysis. The mean MeHg concentration in samples noted as containing debris is 1.7 times the mean for samples with no debris per the maximum likelihood estimator comparison test ($p<0.001$) .

A mean MeHg concentration of 0.122 + 0.450 ng/L and median of 0.050 ng/L is calculated by Regression on Ordered Statistics (ROS) for the complete dataset. Exclusion of both samples considered invalid and samples with visible debris shifted the mean concentration to 0.078 + 0.254 ng/L and median of 0.019 ng/L per ROS. Concentrations in the range 0.1 – 1.0 ng/L follow a log-normal distribution on a normal quantile plot, with higher concentrations departing from this distribution at 1 ng/L. Interestingly, 67 percent of MeHg concentrations greater than 1 ng/L were not coded as having observable debris.

Preliminary analysis indicates network-wide temporal variation in concentrations along with regional (spatial) patterns.

Title: Dry Deposition of Polycyclic Aromatic Compounds to Various Land Covers in the Athabasca Oil Sands Region

Presenter/First Author: Leiming Zhang, Environment Canada Toronto, Toronto, ON

Presenter/First Author Email: Leiming.Zhang@ec.gc.ca

Co-authors: Irene Cheng, , , ; Zhiyong Wu, Hohai University, Nanjing, China; Tom Harner, , , ; Jasmin Schuster, , , ; Jean-Pierre Charland, Environment Canada, Ottawa, ON, Canada; Derek Muir, Environment Canada, Burlington, ON, Canada

Abstract Body: Dry deposition is an important pathway inputting pollutants to various ecosystems. The present study provides the estimation of dry deposition of polycyclic aromatic compounds (PACs), including polycyclic aromatic hydrocarbons (PAHs), alkylated PAHs, dibenzothiophenes (DBTs) to various land covers in the Athabasca oil sands region. A framework was first developed to estimate dry deposition of individual PAC species making use of monitored ambient concentrations of 18 PAHs species, 20 alkylated PAHs and 5 DBTs at three sites. The gaseous dry deposition scheme of Zhang et al. (2003) was modified to handle gas-phase PACs and the particle dry deposition scheme of Zhang and He (2014) was applied to particulate-phase PACs. Henry's law constant and octanol-air partition coefficient of PACs were used as the basis for choosing model parameters needed in the gaseous dry deposition scheme. Modelled dry deposition velocities for various gaseous PACs and over various land covers were in the range of 0.01-0.1 cm s^{-1}, comparable with literature values obtained from field studies. Annual dry deposition of the sum of PAHs was estimated to range from 610 to 1150 µg m^{-2} over forested canopies surrounding the three sites and from 580 to 670 µg m^{-2} over agricultural lands, grass and shrubs. The corresponding numbers are 1500 to 4200 and 1900 to 2800 for the sum of 20 alkylated PAHs, and are 130 to 1100 and 370 to 690 for the sum of 5 DBTs. The three monitoring sites are situated nearby the Athabasca River, and the direct atmospheric dry deposition to water surface was estimated to range from 830 to 1000, 2200 to 4100, and 160 to 880 µg m^{-2} for PAHs, alkylated PAHs, and DBTs, respectively. In most cases the estimated annual dry deposition is two to four times the measured annual wet deposition. Alkylated PAHs contributed more than the sum of PAHs and DBTs in both dry and wet deposition budget, suggesting the importance of including this parent group of pollutants in atmospheric deposition budget estimation for subsequent ecosystem impact studies.

Title: Use of process tendencies to assess regional climate models

Presenter/First Author: Kamel Chikhar, Centre ESCER, Université du Québec à Montréal, Montreal, QC

Presenter/First Author Email: chikhar@sca.uqam.ca

Co-authors: Pierre Gauthier, University of Quebec at Montreal UQAM, Montreal, QC, Canada

Published Material: This presentation will summarize findings reported in two scientific papers. The first paper entitled "Impact of analyses on the dynamical balance of global and limited-area atmospheric models" by Chikhar and Gauthier, first published online on 25 FEB 2014 in Quarterly Journal of the Royal Meteorological Society. The second paper entitled "On the effect of boundary conditions on the Canadian Regional Climate Model: Use of process tendencies" by Chikhar and Gauthier, accepted in Climate Dynamics journal. Chikhar, K. and Gauthier, P. (2014), Impact of analyses on the dynamical balance of global and limited-area atmospheric models. Q.J.R. Meteorol. Soc., 140: 2535–2545. doi: 10.1002/qj.2319Chikhar K, Gauthier P (2015) On the effect of boundary conditions on the Canadian Regional Climate Model: Use of process tendencies (accepted in Climate Dynamics)

Abstract Body: Dynamical imbalances can induce spurious variability which can be diagnosed from the physical and dynamical tendencies observed in the first moments of short-term forecasts using as initial conditions analyses obtained from an assimilation system using this model.

This approach is first used to investigate differences in the balance observed in the Global Environmental Multiscale (GEM) model and its limited area version, the Canadian Regional Climate Model (CRCM) when these models are initialized and driven (lam version) with different data (4D-Var analyses from the the forecast–assimilation system of the Meteorological Service of Canada (MSC) and ERA-Interim reanalyses at low and full resolution). Results showed that GEM is best balanced when initialized with MSC 4D-Var analyses and is better balanced when using the higher-resolution reanalyses. Similar results are obtained for the CRCM initially. Moreover, after a few days of integration, we observe imbalances appearing gradually in the interior of the regional domain.

We also used process tendencies to investigate the lateral boundary effects on the CRCM balance for a much longer simulation. The different boundary conditions provided are outputs from the second-generation Canadian Earth System Model (CanESM2) and the Max Planck Institute for Meteorology's Earth System Model (MPI-ESM-LR) and also from ERA-Interim reanalysis. The tendencies are analysed when the regional model is well spun up and is sufficiently affected by the lateral forcing data. The results indicate that the model is very sensitive to those imposed lateral conditions.

Title: Assessment of Trend in Drought Propensity across the Globe Using GCM Projections

Presenter/First Author: Kironmala Chanda, Indian Institute of Technology Kharagpur, Kharagpur,

Presenter/First Author Email: kironmala.iitkgp@gmail.com

Co-authors: Rajib Maity, Indian Institute of Technology Kharagpur, Kharagpur, India

Abstract Body: This study aims to assess the global response of soil moisture drought propensity to climate change in the 21st century. The

projected monthly soil moisture data from two Global Circulation Models (GCMs) - Canada's new Earth System Model i.e, CanESM2 and Geophysical Fluid Dynamics Laboratory (GFDL) are obtained for Representative Concentration Pathways 8.5 (RCP8.5) scenario, which represents a scenario of high greenhouse gas emissions in absence of climate change policies. Each of the individual datasets as well as the model averaged data is bias corrected through an appropriate technique using past data from Climate Prediction Centre (CPC) as a reference. In order to capture the slowly-varying changes in soil moisture drought propensity, Drought Management Index (DMI), which is a newly developed probabilistic index for characterization of multi-year droughts, is applied. The intermediate measures – resilience and vulnerability of the soil moisture data are computed at a 2.5° x 2.5° global grid using the local (grid specific) long term monthly mean soil moisture data as thresholds. Subsequently, the DMI series is computed at each grid intersection at the aforementioned spatial resolution for overlapping 5-year periods from 1961 to 2100. The spatio-temporal variation in global drought propensity over 140 years is inspected from temporal snapshots of DMI contour maps. While there are some conflicts in the continent wise trends of drought propensity for the two GCM datasets, statistical analyses of the DMI series using the model averaged data indicate progressive drying over Africa, South America, eastern Australia and most of Asia towards the end of the 21st century. The status remains relatively unchanged in North America and the western part of Australia, while the high latitude regions of Europe tend to become wetter. These findings may be incorporated for global long term water resources planning and timely adoption of drought mitigation strategies.

Title: The statistic-dynamical joint approach can predict the decadal hiatus of East Asian Surface Air Temperatures

Presenter/First Author: Shuanglin Li, IAP Insititute of Atmospheric Physics, Chinese Academy of Sciences, Beijing,

Presenter/First Author Email: shuanglin.li@mail.iap.ac.cn

Co-authors: Feifei Luo, IAP Insititute of Atmospheric Physics, Chinese Academy of Sciences, Beijing, China

Published Material: The primary content was published by a scientific journal, Science China-Earth Sciences, in the December 2014 issue.

Abstract Body: A statistic-dynamical joint method considering both the internal decadal variability and the effect of anthropogenic forcing is developed to hindcast/predict the decadal components of East Asian Surface Air Temperatures (EATs). Since previous studies have revealed that the internal variability of EATs (EATs_int) is mainly influenced by oceanic modes, we first analyzed the lead-lag connections between EATs_int and the three SST multidecadal modes as well as the explained variance rates of EATs_int by the modes. Based on the lead-lag connections, we constructed a multiple linear regression with the three SST modes as predictors. The hindcast for the years from 2000 to 2005 indicated the regression model had a high skill in hindcasting the observational EATs_int. Therefore, the prediction for the EATs_int (Re_EATs_int) was obtained by the regression model based on quasi-periods of the decadal oceanic modes.The external forcing from greenhouse gases is likely to associate with global warming, and ensembles of monthly global land surface air temperature in the experiments with multiple CMIP5 models on historical and projected experiments under RCP4.5 are used to predict the curve of EATs (EATs_trend) by a second-order fit. Then, EATs_int and EATs_trend were combined to the reconstructed or predicted EATs (Re_EATs). Re_EATs shows a fluctuation during 2010-2040 with hiatus or a slight decrease from 2015-2030, and then an gradual increase. Compared with the decadal prediction in CMIP5 models, Re_EATs is in agreement qualitatively with the predictions of most of models and the MME.

Title: Spatio-temporal Variability of Rainfall over Central Himalaya, Uttarakhand

Presenter/First Author: Sneh Joshi, , Almora,

Presenter/First Author Email: snehjoshi31@gmail.com

Co-authors: Krushna Chandra Gouda, CSIR CENTRE FOR MATHEMATICAL MODELLING AND COMPUTER SIMULATION, Bangalore, India; Kireet Kumar, G.B. Pant Institute of Himalayan Environment and Development Kosi-Katarmal, Almora, India; Bimal Pande, Kumaun University, Nainital, Nainital, India; Prashant Goswami, CSIR CENTRE FOR MATHEMATICAL MODELLING AND COMPUTER SIMULATION, Bangalore, India

Abstract Body: Simulation and forecasting of the Indian Summer Monsoon (ISM) has remained a major scientific challenge, especially at smaller (regional) scale like Central Himalaya, Uttarakhand region which is situated at a very high altitude. While climate models have gained incomplexity, and hence, scope of the accuracy and reliability have not necessarily increased; this is particularly true at regional scales. An important issue is the appropriate model configuration for regional seasonal forecasting of rainfall simulations. An atmospheric GCM, without interannual variability of SST, can reproduce the important characteristics of the Himalayan regional climate. In the present study, the results show that considerable skill in seasonal forecasting over the central Himalayan region can be achieved with an appropriate model configuration. The
Correlation between the interannual variability (IAV) in multi-source observation and ensemble simulation is significant above 99% level and the phase synchronization (PS) is also about 75%. Together with earlier

results on skill on seasonal forecasting of ISM with the VR GCM (Goswami and Gouda 2009, 2010), the present work provides a forecast configuration with considerable skill over the central Himalaya; an important point is that the skill is considerably higher than that for all-India scale.

Although the seasonal cycles at station scale are generally under predicted over five out of six stations, the seasonal cycles from ensemble simulation and composite observations are significantly (99%) correlated. Thus, even at station scale, the skill in seasonal forecasting is non-trivial. It may be noted that this skill at station scale is somewhat less when considered against station scale observations. We believe that this is because unlike in the case of composite observation, gridded simulation does not correspond well to point (station observation).

Title: Skillful seasonal prediction of temperature and precipitation over land in a new GFDL high resolution climate model

Presenter/First Author: Liwei Jia, Princeton University, Princeton, NJ

Presenter/First Author Email: Liwei.Jia@noaa.gov

Co-authors: Xiaosong Yang, UCAR, Princeton, NJ; Gabriel Andres Vecchi, Geophysical Fluid Dynamics Laboratory, Princeton, NJ; Rich Gudgel, , , ; Thomas L Delworth, NOAA, Boulder, CO

Published Material: Part of these findings were accepted by Journal of Climate, and were presented as a poster in WMO S2S conference, in Maryland, USA, 2014.

Abstract Body: This study demonstrates skillful seasonal prediction of 2m air temperature and precipitation over land in a new high-resolution climate model developed by Geophysical Fluid Dynamics Laboratory, and explores the possible sources of the skill. The impact of atmosphere and land initialization on seasonal predictions is also investigated.

First, we show considerable skill improvement of the high-resolution model over the previous lower-resolution model in seasonal prediction of NINO3.4 index and other aspects of interest. Then, we employ a new statistical optimization approach to identify the most predictable components of seasonal mean temperature and precipitation over land in the high resolution model, and measure the skill of these components for boreal winter and summer, and further diagnose the sources of the skill. Predictions using a few most predictable components are then reconstructed to yield more skillful predictions than the raw model predictions.We find that the two most predictable components of temperature are characterized by a component that is likely due to changes in external radiative forcing in boreal winter and summer, and an ENSO-related pattern in boreal winter. The most predictable components of precipitation in both seasons are very likely ENSO-related. These components of temperature and precipitation can be predicted with significant correlation skill at least 9 months in advance. The reconstructed predictions using only the first few predictable components from the model show considerably better skill relative to observations than raw model predictions. Lastly, we show that by initializing atmosphere and land conditions, the high-resolution model is able to predict NAO with significant correlation skill, which consequently improves predictions of seasonal temperature and precipitation over North America and Europe compared to the predictions without initialization.

This study shows that the use of refined statistical analysis, a high-resolution dynamical model and initialization of atmosphere and land conditions leads to significant skill in seasonal predictions of temperature and precipitation over land.

Title: Studies on the Global Morphology of Middle and Upper Atmospheric Fluctuation

Presenter/First Author: Cunying Xiao, Center for Space Science and Applied Research, Chinese Academy of Sciences, Beijing,

Presenter/First Author Email: xiaocy@nssc.ac.cn

Co-authors: Xiong Hu, , , ; Bo Wang, , , ; Junfeng Yang, , ,

Abstract Body: Current analysis about the middle and upper atmospheric fluctuation often focuses on some certain waves or modes in certain area with observations. Little is known about the global distribution characteristics of the atmospheric fluctuation as a whole. In this paper, a method of global gridding and mathematical statistics in the grids has been developed in order to circumvent the difficulty of characterizing the global atmospheric fluctuation quantitatively. Based on a total of 11 years of TIMED/SABER temperature data from January 2002 to January 2013, temperature means and standard deviations are obtained, which extend 50 ° S ~ 50 ° N latitude, 0 ° ~ 360 °E longitude, 20~100 km altitude on each month from January to December. Quantitative results are derived by analysis on the distribution of the temperature standard deviations, which can be used to characterize the activity of the atmosphere fluctuation. In the lower altitude between 20 km and 70 km, temperature standard deviations are generally 1-10 K. The temperature standard deviations are larger in winter than those in summer and larger in austral winter than in boreal winter. There are some changes with the longitude, showing the structure of the wave 1 or wave 2. In the upper altitude between 70 km and 100 km, the temperature standard deviations are always strong, with typically values of 10-30 K. There are small differences in the winter/summer. The standard deviations are higher in the low-latitude regions than those in high latitudes. Their longitudinal distributions are quite complex, presenting many of small local structures. These statistic results can be used to fulfill the blank of MSIS models in describing the atmospheric fluctuation. They are valuable in modeling the middle and upper atmospheric fluctuation globally. Moreover, some physical processes related to these features are discussed in this paper.

Abstract Body: Previous studies have shown the importance of choosing appropriate domain size for dynamical downscaling with nested Regional Climate Models (RCM). The domain should not be too large to avoid large departures from the original driving data, and should not be too small to provide sufficient distance from the lateral inflow to allow the

development of the small-scale features permitted by the increased resolution. This latter point has repercussions on the computational cost, and becomes an issue with large jump in resolution between the driving data and the RCM mesh. The use of multiple nesting reduces the spatial spin-up compared to direct nesting, thus allows shrinking the domain size and reducing computational cost.

Our investigation compares direct and double nesting to achieve a grid mesh of 0.15° from driving data at 1.8°, using the perfect-prognostic approach of the Big-Brother protocol. The direct and double nesting appear to produce similar level of accuracy for the stationary components. The large-scale transient components however exhibit some reduction in time correlation. Overall this investigation suggests that multiple nesting may offer benefits compared to the one-step nesting for climate dynamical downscaling.

Title: Technical Support for Climate Assessment Data Services

Presenter: Andrew Buddenberg, The Cooperative Institute for Climate and Satellites/NC State University, Asheville, NC

Presenter Email: andrew.buddenberg@noaa.gov

First Author: Paula A Hennon, NOAA Asheville, Asheville, NC

First Author Email: paula.hennon@noaa.gov

First Author Student?: No

Abstract Body: NOAA's Climate Assessment Technical Support Unit provides critical climate science input and technical coordination support to the National Climate Assessment (NCA), a premier activity of the U.S. Global Change Research Program. The United States Global Change Research Act of 1990, calls for a report to the US President and Congress that evaluates, integrates, and interprets the findings of the federal research program on global change every four years. Seeking to establish an ongoing, sustainable assessment process, as well as deliver a timely interim and quadrennial reports, NOAA's Technical Support Unit provides coordination of the scientific input from more than 250 authors and technical expertise to a wide network of interagency and external groups and individuals.

To meet NOAA Information Quality Act requirements and manage the complexity of a large, distributed effort, the TSU adopted a number of technologies and best practices. With so many contributors to the NCA and iterations of code to process scientific datasets and produce figures, version control has been a great asset. Git Annex simplified the problem of versioning large datasets by providing a single common repository of the most up-to-date files with the ability to roll back at will. In addition, Gitlab provided a way to locate code see at-a-glance what program created a given figure. Automated testing verified the configuration of and prevented regressions in data processing code. Traceability and reproducibility of climate analyses were ensured through a massive metadata collection effort and integration with the United States GLobal Change Research Program's Global Change Information System.

These technologies and practices served the TSU well, though none are particularly novel in the greater context of software development. Techincal issues persist:

- Most scientific code is still specific to a particular dataset/analysis. How can we reduce "one-off" analyses and increase code reusability?
- Climate dataset description and metadata collection efforts are largely manual and very time-consuming especially after-the-fact. How can we improve the scientific workflow?
- Version control of the hundreds of submitted figures was difficult. How can the graphical asset management improve?

Title: A Modified Micrometeorological Gradient Method for Estimating O_3 Dry Deposition over a Forest Canopy

Presenter/First Author: Zhiyong Wu, Hohai University, Nanjing,

Presenter/First Author Email: zhiyong.wu@ec.gc.ca

Co-authors: Leiming Zhang, Environment Canada Toronto, Toronto, ON, Canada; Xuemei Wang, Sun Yat-Sen University, Guangzhou, China; J William Munger, Harvard University, Cambridge, MA

Published Material: published in *Atmospheric Chemistry and Physics Disccusion*, under review for *Atmospheric Chemistry and Physics*.

Abstract Body: Small pollutant concentration gradients between levels above a plant canopy result in large uncertainties in estimated air-surface exchange fluxes when using existing micrometeorological gradient methods, including the aerodynamic gradient method (AGM) and the modified Bowen-Ratio method (MBR). A modified micrometeorological gradient method (MGM) is proposed in this study for estimating O_3 dry deposition fluxes over a forest canopy using concentration gradients between a level above and a level below the canopy top, taking advantage of relatively large gradients between these levels due to significant pollutant uptake at top layers of the canopy. The new method is compared with the AGM and MBR methods and is also evaluated using eddy-

covariance (EC) flux measurements collected at the Harvard Forest Environmental Measurement Site, Massachusetts during 1993-2000. All the three gradient methods (AGM, MBR and MGM) produced similar diurnal cycles of O_3 dry deposition velocity ($V_d(O_3)$) to the EC measurements, with the MGM method being the closest in magnitude to the EC measurements. The multi-year average $V_d(O_3)$ differed significantly between these methods, with the AGM, MBR and MGM method being 2.28, 1.45 and 1.18 times of that of the EC. Sensitivity experiments identified several input parameters for the MGM method as first-order parameters that affect the estimated $V_d(O_3)$. A 10% uncertainty in the wind speed attenuation coefficient or canopy displacement height can cause about 10% uncertainty in the estimated $V_d(O_3)$. An unrealistic leaf area density vertical profile can cause an uncertainty of a factor of 2.0 in the estimated $V_d(O_3)$. Other input parameters or formulas for stability functions only caused an uncertainly of a few percent. The new method provides an alternative approach in monitoring/estimating long-term deposition fluxes of similar pollutants over tall canopies.

Title: Assessment of Artificial Intelligence implementation in Delhi addressed to a diagnostic air quality modelling

Presenter/First Author: Dhirendra Mishra, Indian Inst of Technology, New Delhi,

Presenter/First Author Email: dhirendra.mishra@cas.iitd.ac.in

Co-authors: Pramila Goyal, , ,

Abstract Body: Air pollution forecasting is the most important environmental issue in urban areas as it is useful to assess the effects of air pollutants on human health. It has been observed that the air pollution has been increased above the standard level in the urbanized area of Delhi and will be a major problem in the coming years. Therefore, the main objective of the present study is to develop the models that can forecast daily concentrations of air pollutions in one-day advance through artificial intelligence based models. The concentrations of air pollutants have been forecasted using the available meteorological variables viz. temperature, pressure, relative humidity, wind speed and direction, visibility and the estimated concentrations through air quality dispersion model, AERMOD. The nitrogen dioxide (NO_2) pollutant is chosen for model development and analysis in the present study. The eight and two year's seasonal data are used for training and validation respectively. The evaluation of artificial intelligence based model has been made by comparing its results with observed values in different seasons through statistical parameters, which reveals that the artificial intelligence based model is performing well and can be use for operational use.

Title: A Novel Approach to Measurement of Atmospheric Ultrafine Silica Particulate Matter

Presenter/First Author: Sean Marcus Olson O'Connell, University of Wisconsin Eau Claire, Eau Claire, WI

Presenter/First Author Email: oconnesm@uwec.edu

Co-authors: James E Boulter, University of Wisconsin Eau Claire, Eau Claire, WI

Abstract Body: This project entails the establishment of a novel analytical method for quantifying respirable, airborne silicon oxide-containing particles and design of an instrument to perform such an analysis. Many previous studies exploit heteropoly acids via reduction to molybdenum blue, and subsequent visible absorbance analysis for a variety of quantitative environmental analyses, primarily in aqueous media. This approach substantially extends the sensitivity of the analytical procedure and also simplifies the analysis. Applying the molybdenum blue approach to respirable atmospheric silica, NIOSH estimates a limit of detection (LOD) of 10 mg SiO_2. We estimate that our proposed analytical instrument design will have an LOD on the order of 0.5 µg SiO_2, enabling sampling times of less than an hour to reach the newly-proposed OSHA personal exposure limit (PEL) of 0.10 mg/m_3. Potential applications of such a measurement include many environmental applications such as atmospheric monitoring in the vicinity of sand mining operations and other industrial settings ranging from shipbuilding to non-conventional petroleum extraction.

Title: Formation and near-field evolution of fine particles in a plume from a metallurgy plant: Results from the NANO-INDUS project

Presenter/First Author: Pascal Flament, Organization Not Listed, Dunkerque,

Presenter/First Author Email: pascal.flament@univ-littoral.fr

Co-authors: Ari Setyan, EMPA - Swiss Federal Laboratories for Materials Science & Technology, Dubendorf, Switzerland; Nadine Locoge, , , ; Karine Deboudt, , , ; Véronique Riffault, , , ; Laurent Alleman, , , ; Coralie Schoemaecker, , , ; Jovanna Arndt, , , ; Patrick Augustin, , , ; Alodie Blondel, , , ; Fabrice Cazier, , , ; Hervé Delbarre, , , ; Dorothée Dewaele, , , ; Pascale Dewalle, , , ; Sophie Eliet, , , ; Marc Fourmentin, , , ; Paul Genevray, , , ; Robert Michael Healy, University of Toronto, Toronto, ON, Canada; Thierry Leonardis, , , ; Saliou Mbengue, , , ; John Wenger, University College Cork, Cork, Ireland

Abstract Body: The aim of the NANO-INDUS project was to study the evolution of the physico-chemical properties of industrial fine particles over a short-range distance, after their release from the stacks. First, measurements were performed directly at the stacks of a plant manufacturing iron-manganese alloy near Dunkirk Port, France. Separately, an intensive field campaign was undertaken at a site located close (<1 km) to the stacks. We present results obtained during four specific days, during which the wind direction was favorable for the transport of plumes (detected by Light Detection and Ranging [LIDAR] monitoring), from the stacks to the near-field sampling site, which was under the direct influence of the metallurgy plant emissions, mainly during sea breeze periods. These phenomena promoted a fast vertical dispersion of the plumes, as well as a mixing of pollutants from different sources.

The physico-chemical properties of particles sampled at the stacks were compared to those determined at the near-field site during these four days. Particles sampled at the stacks were characterized by a high Mn/Fe ratio (in the range 2-3). However, the ratios measured at the sampling site were much lower, in the range 0.5-1. The difference was explained by rapid mixing with emissions from a large steelworks close to the metallurgy plant, with specific Mn/Fe ratios < 0.1, which was also confirmed by high concentrations of non-refractory chloride used in the neighboring plant process. Size distribution data showed the presence of a mode around 15 nm, much smaller than during other periods. This result suggests that new particle formation occurred within the few minutes it took for emissions to travel from the stacks to the receptor site. Given that aromatics were by far the most important class of volatile organic compounds (VOCs) emitted at the stacks (60% of the total VOCs), this class of compound is suspected to be involved in the nucleation events observed at the sampling site.

Title: Simulations of Pollutant Dispersal over Nairobi City,Kenya

Presenter/First Author: George Otieno, University of Nairobi, Nairobi,

Presenter/First Author Email: gotieno2000@gmail.com

Published Material: It is part of the work submitted for publication at journal of Environment and Agricultural Sciences, JEAS 2014, Volume 1, Article No. 10

Abstract Body: The current rapid deterioration of air quality in urban centres can be attributed to urbanization. Poor air quality has been associated with several negative effects on human health, climate and ecosystems. Most cities in developing countries, especially in Africa have poor or in some cases no air quality management systems in place despite having the fastest growing urban populations. City populations have high vulnerability to the impacts air pollution following high density of residents and economic activities as well.

Air pollution is evident in most cities; the case of Nairobi is an illustrative of this. The common air pollutants include carbon monoxide and total suspended particulates among others, the latter being the most widespread and the most serious for human health.

This study simulated air pollutant dispersal over the city using Hybrid Single Particle Lagrangian Integrated Trajectory (HYSPLIT), considering a case for emission of total suspended particles into the environment. The predominant wind speed over the city is 4-6 knots and the wind direction is easterly. The forward trajectory of a pollutant released in the city is generally observed to flow to the western side of the city. The pollutant is observed to be dispersed beyond 100 km from the city reducing the concentration of the same in the city.

The study thus recommends for a consultative planning process of the city that factors in the wind characteristics over the city; most industrial activities should be located to the extreme western side of the city to minimize concentration of pollutants over the city. The study further recommends studies that studies be carried out to ascertain the quality of rain water during the long rain season.

Title: Spheroidal carbonaceous particles (SCPs): Indicator of atmospherically deposited pollutants in Kongsfjorden, Ny-Ålesund, Arctic

Presenter/First Author: Neelu Singh, National Centre for Antarctic and Ocean Research, Vasco,

Presenter/First Author Email: neelu.singh0387@gmail.com

Abstract Body: Spheroidal carbonaceous particles (SCPs) are produced during the incomplete high temperature combustion of fossil fuels. Since these particles have no other known natural source, their presence in the snow and soil in such pristine areas as the Polar Regions can serve as proxy indicators for anthropogenic pollution. In this study we have carried out a morphological and chemical characterization of the SCPs extracted from the surface sediments of Kongsfjorden in Ny-Alesund, the Arctic. The characterization was carried out by scanning electron microscope coupled with X-ray spectrometer (SEM-EDX). The prevalent particle types in all the samples studied were granular-spherical, hollow- spherical and irregular shaped carbonaceous particles. Analysis of the elemental composition showed that the particles are mainly composed of C, O, NA, Si, Al, K, Cl, and Ti. Some particles contained heavy metals Fe, Al, Cu, Cr, Zn, Pb and Ni which indicate that the SCPs could have acted as the dominant carriers of the heavy metals deposited in the surface sediments.

Co-authors: Mirza M Hussain, NYSDOH/Empire State Plaza, Albany, NY; Fida Khatib, NYSDOH/Empire State Plaza, Albany, NY; Jahan Zeb, King Abdulaziz University, Jeddah, Saudi Arabia; Donald Ray Blake, University of California Irvine, Irvine, CA; Omar Siraj Aburizaiza, King Abdulaziz University, Jeddah, Saudi Arabia

Published Material: The preliminary results were presented in AGU fall meeting in a Press conference and poster

Abstract Body: Oil producing countries in Middle East is known to experience severe air pollution including many cities in Saudi Arabia. Each year this situation is intensified during the Hajj, the Holy Pilgrimage of Islam that draws millions of pilgrims to Mecca. Sharply deteriorated air quality during Hajj, exposing pilgrims to very high level of pollutants. Extremely high levels of air pollutants were observed during the intensive measuring periods. For example, the PM_7 , $PM_{2.5}$, O_3 , and BC concentrations of up to 9,433 μg/m³ , 484 μg/m³ , 444 ppb, and 468 μg/m³ , respectively, were observed. Results of this investigation revealed that most routers had on average exceeded the WHO standards for PM_{10} , $PM_{2.5}$, and . The reasons for the high air pollutants concentrations are most probably high volume traffic, fuel quality, poorly maintained vehicular fleets, re-suspension of particles, construction work, and geographical conditions (arid regions). The pilgrim's longer trip duration lead to their highest whole trip exposure to air pollutants, which indicate that they are subject to higher health risk.

Title: Characterization of gas-phase organic acids in ambient air of a developing Megacity

Presenter/First Author: Sumayya Saied, University of Karachi, Karachi,

Presenter/First Author Email: sumayyas@uok.edu.pk

Co-authors: Haider Abbas Khwaja, University at Albany, Albany; Mirza M Hussain, NYSDOH/Empire State Plaza, Albany, NY; Azhar Siddique, University of Karachi, Karachi, Pakistan; Celeste Butts, , , ; Syeda Shadia Kamran, , , ; Muhammad Kamran Khan, , ,

Published Material: First phase of the study was presented as poster in AAAR conference in 2012. Further results and interpertatins are compiled to be published in scientific journal

Abstract Body: According to UN estimates over 600 million urban populations in the world are exposed to dangerous levels of air pollutants and ambient air pollution is a significant factor shaping public health. Karachi, a developing Megacity with population over 18 million, served as a great focal point to observe the effects of industrial development on a growing city and how it contributes to the progression of environmental pollution. Results indicate that acetic and formic acids are important components of the Karachi atmosphere. The most abundant acids, by a substantial margin, were acetic acid and formic acid, with concentrations of 0.70 - 14.2 ppb and 0.82 - 11.0 ppb, respectively. On the average acetic acid levels exceeded those of formic acid. Concentrations of propionic acid, pyruvic acid, and glyoxalic acid ranged 0.03 - 1.41, 0.01 - 0.28, and 0.02 - 0.14 ppb, respectively. The gaseous acids showed diurnal cycles, with higher mixing ratios during nighttime. Compared with other metropolitans in the world, the level of acetic and formic acid concentration of Karachi is much higher. The ratio of formic to acetic acid was used to distinguish primary sources from secondary sources. A mean ratio of 0.85 was found. A positive correlation (r = 0.65 - 0.94) was observed between the acid concentrations suggesting that they have similar sources. Carboxylic acid concentrations appear to arise both from direct emissions and from atmospheric oxidation of hydrocarbons.

Title: Next Generation Sequencing Analysis: Impact of Bacteria in Snow and Frost Flowers on the Arctic Ecosystem

Presenter/First Author: Roya Mortazavi, McGill University, Montreal, QC

Presenter/First Author Email: romort2004@yahoo.com

Co-authors: Saeid Attiya, McGill University, Montreal, QC, Canada; Parisa A Ariya, McGill University, Montreal, QC, Canada

Abstract Body: During the OASIS 2009 campaign in Barrow, AK, different snow types namely accumulated snow, wind pack, blowing snow, snow hoar, frost flowers and fresh snow were collected on March (4 – 20) close to the Barrow Arctic Research Center (BARC). Microbial community of Arctic snow samples and frost flowers were compared to snow collected in the province of Quebec in Canada. Next Generation Sequencing (NGS) was used to characterize Arctic samples for their bacterial communities. Our results have indicated the existence of heterogeneous population of bacteria with diverse activities that potentially impact the Arctic ecosystem.

Title: Predicting Which 20% to 25% of Thunderstorms Will Develop Tornadoes

Presenter/First Author: Ronald Bryan Hardwig, Retired, Bloomington,

Presenter/First Author Email: rsdatainc@aol.com

Abstract Body:

This paper brings forth new research on predicting which 20% to 25% of thunderstorms will develop tornadoes, tornado genesis. The research was done over 25 years. Over 10,000 thunderstorms and tornadoes were investigated as to how, why, when and where tornadoes form, what is their source of energy and why they dissipate. The thunderstorms and tornadoes were chosen at random. Data was collected as to the relationship of the overhead jet stream and thunderstorms underneath. A definite relationship was noticed. The data showed how a tornado will only form in a thunderstorm which is developing under a jet stream with velocity ≥ 58 knots, the Tornado Threshold. It is thought that a tornado forms under these conditions because of the streamline flow of the jet stream passing over any vortex/mesocyclone created in the thunderstorm has the air entrained per the Bernoulli Effect and Entrainment, just as an atomizer, whenever the thunderstorm is high enough to interface with the overhead jet stream of high velocity. Anywhere in the world that has thunderstorms can have a tornado, if there is a jet stream with a high velocity overhead to energize the mesocyclone within the thunderstorm. Information also obtained, the higher the velocity of the jet stream corresponded to a stronger tornado. Also the higher the thunderstorm intersecting the jet stream the stronger the tornado due to the larger Relative Area of Interface. The tornado will dissipate any time the thunderstorm dissipates or moves out from under the high velocity jet stream. To better predict which thunderstorms will produce a tornado and with what intensity, we need to be looking at the overhead jet streams' velocity between 25,000 feet to 50,000 feet high any time the velocity is 58 knots.

Title: Return times of drought over West African Sahel

Presenter/First Author: Chamani Roméo, University of Yaoundé, Yaoundé,

Presenter/First Author Email: romeochamani@yahoo.fr

Co-authors: Monkam David, University of Douala, Douala, Cameroon

Abstract Body: Using Stationary stationary peaks-over-threshold model (POT), return times (RTs) of drought events are determined in West African Sahel (12-20°N, 17°W-15°E) using seasonal July-September (JAS) rainfall data from Climatic Research Unit for the period 1901-2009.Two metrics are used : the area-averaged precipitation and the fractional area of drought. The analysis revealed that RTs for the dry extremes have increased after 1970, implying that dry extremes (low values of precipitation with high value of fractional area) are higher after 1970 than they were before. The years 1984, 1972 and 1983 have been detected as the extreme years with rainfall amount (fractional area extend) of 167.80 (0.95), 177.17 (0.85) and 180.84mm (0.89), and RTs of 130 (125), 40 (20) and 30 (35) years, respectively. These results are also compared with those found by the most relevant study over the entire Sahel region. A RTs gap of 15 and 4 years were found for precipitation and fractional area respectively, when compared with the values of Greene *et al*. (2009).

Title: Global Warming Stopped in 1998 Because it is Controlled by Ozone Depletion, Not by Greenhouse Gases. The Montreal Protocol on Substances That Deplete the Ozone Layer Took Effect in 1989, Slowing Emissions of CFCs by 1993, Slowing Ozone Depletion by 1995, and Stopping Temperature Increase by 1998.

Presenter/First Author: Peter L Ward, , Jackson, WY

Presenter/First Author Email: peward@wyoming.com

Published Material: Developments leading to these ideas have been reported at the fall AGU meetings from 2008 through 2014 and at the annual meeting of the American Meteorological Society in 2015. Nine scientific papers have been rejected without review as described at ozonedepletiontheory.info/publications-ozone-depletion.html. This work is described in detail at ozonedepletiontheory.info and at www.youtube.com/watch?v=GyZDf3kMvwo, both released on November 18, 2014.

Abstract Body: In the late 1960s, chlorofluorocarbons (CFCs) became popular as spray-can propellants, refrigerants, and solvents. Emissions began increasing by 1970, as did ozone depletion. In 1974 Rowland and Molina showed that CFCs can be broken down by ultraviolet light in the coldest parts of the lower stratosphere to release chlorine that depletes ozone. In 1985, with discovery of the Antarctic Ozone Hole, scientists and politicians began working together to draft the Montreal Protocol that took effect in January, 1989, the first universally ratified treaty in United Nations history. CFC emissions stopped increasing in 1993; ozone depletion stopped increasing in 1995; global surface temperatures stopped increasing in 1998. For the last 17 years, CFC emissions and ozone depletion have been decreasing very slowly; global mean surface temperatures have remained nearly constant. Ocean heat content continues to rise because ozone remains depleted relative to levels before 1970.

Chlorine and bromine emitted by active volcanoes also deplete ozone as much as 6% for more than 5 years. Pinatubo (1991), a major explosive volcano, caused the lowest levels of ozone ever measured in mid-latitudes accompanied by winter warming of northern continents. But Pinatubo also ejected megatons of SO_2 and water into the lower stratosphere forming aerosols that reflected and scattered solar radiation causing net global cooling of 0.5°C for 3 years. Effusive, basaltic volcanoes, on the other hand, common in Iceland and Hawaii, cause net warming by extruding large lava flows, depleting ozone, but not forming aerosols. Major warming and drought in Central North America during 2012 was coincident with 14% ozone depletion caused by CFCs and the largely effusive eruptions of Eyjafjallajökull (2010) and Grímsvötn (2011).

Ozone depletion theory explains the details of global and regional climate change observed in recent decades and throughout geologic time much more accurately than greenhouse-gas theory.

Title: Study of climatology and thermal comfort on Rio de Janeiro City: Preliminary analysis for 2016 Olympic Games

Presenter/First Author: Mariana Pallotta, National Institute for Space Research, Sao Jose dos Campos,

Presenter/First Author Email: maripallotta@gmail.com

Co-authors: Dirceu Luis Herdies, Center for Weather Forecasting and Climate Research, Cachoeira Paulista, Brazil; Luis Goncalves, CPTEC/INPE, Cachoeira Paulista, Brazil

Abstract Body: Weather conditions analysis has proven to be an useful tool when directed specifically to sports. For outdoor activities one of the major themes in weather applied to sports comes up: the thermal comfort of the athlete (Perry, 2004). Some studies indicate that the evaluation of bio-climatological conditions and thermal comfort in endurance sports has fundamental importance in training programs, nutritional plan and also for improving evaluation of race strategies (Pezzoli et al., 2012). Hence, the main objective of this study is to develop climatological analysis and thermal comfort assessments directed to sports and applied to Rio de Janeiro city, in Brazil. It is also expected that the results obtained might help the development of products and services to be used on 2016 Olympic Games.

The area of interest for this study is Rio de Janeiro city ,with special focus on the places that will held outdoor competitions of the 2016 Olympic Games. In order to compose the climatology, two weather stations in that area were selected. The period of study was chosen according to the data availability in both stations (2003 to 2014 – 11 years), and also to the months of interest to the Games (July – Acclimation; August – Olympics; September – Paralympics). Different thermal comfort indices were calculated: Effective Temperature and Effective Temperature related to the wind, using equations of the literature (Suping et al., 1992), Physiological Equivalent Temperature, Predicted Mean Vote and Standard Effective Temperature, according to Matzarakis et al. (2007).

Results related to climatological analysis for Rio de Janeiro city, on the period of Olympic Games, show that situations of extreme weather, as storms or extremely low temperatures, are not expected. Thermal comfort assessment for Rio de Janeiro city in average situation did not indicate for the period extreme discomfort both for heat and cold. Just September afternoons are more susceptible to moderate heat stress than the other months, which in case of intense physical activity can even be strong. A climatological analysis similar to that developed in this work, if released in advance to competing delegations of a sport event could contribute to substantial improvement preparation and practice of the athletes.

Title: Analysis of Mesoscale Rapidly Occluding Storm Causing Severe Atmospheric Anomalies in Southern California on February 28th, 2014

Presenter/First Author: Alex A Mundo, California State Polytechnic University Pomona, Victorville, CA

Presenter/First Author Email: aamundo@csupomona.edu

Abstract Body: There are always good compliments on California's weather because no matter the season of the year a pleasant atmosphere usually prevails, until an alarming event changed the life course of 22 million of Southern Californians. On February 28th, 2014, Southern California experienced the largest thunderstorm since the storms of December 2010. The continuous progressivity of a strong and rapidly-occluding storm off the coast of California roaring from the Pacific Ocean led to flash flooding including mud and debris flows in certain zones. In order to understand the tough effect this storm had upon the zone, time-series of 125 NWS and RAWS weather stations are tested including at least 80% of hourly observations for a period of 72 hours. Analysis show the peak precipitation in the San Diego, Orange, Los Angeles and San Bernardino counties where precipitation reached 6 inches in various parts.

The substantial amounts of extreme precipitation were along the southern slopes of the San Bernardino County mountains, with Yucaipa Ridge reaching 11.11 inches, Lytle Creek with 9.67 inches and Cedar Glen with 9.10 inches. The occluding storm off Southern California's cost led to continuous flash flooding and winds of up to 77mph in different zones. An indication of the strength of the storm was the high amount of GOES-15 sounder Total Column Ozone associated with its circulation, which reached levels as high as 440-450 Dobson Units. These findings imply that the high levels of total column ozone are associated with potential vorticity anomalies and a dramatically lowered tropopause. Additional numerous arc-shaped mesospheric airglow waves in the storm circulation suggest that a 140-knot jet streak propagated them vertically in the southward direction.

Title: A Case Study Of Mesoscale Convective Complexes With Assimilation Of Radar Data

Presenter/First Author: Rute Costa Ferreira, CPTEC Center for Weather Forecasts and Climate Research, Cachoeira Paulista, SP

Presenter/First Author Email: rutecostferr@gmail.com

Co-authors: Dirceu Luis Herdies, Center for Weather Forecasting and Climate Research, Cachoeira Paulista, Brazil

Abstract Body: Mesoscale Convective Complexes (MCC) are responsible for intense storms in southern region of Brazil. Usually, the MCC events can cause significant damage and are related to strong winds, atmospheric electrical discharges, heavy rain, and, in more extreme cases, even hail. This work presents a detailed study of these events based on radar data assimilation. In numerical weather prediction, an adequate radar data assimilation leads to better representation of the MCC, improving the forecast of this event. Moreover, an accurate forecast model is an important tool for the meteorologist. Thus, in order to demonstrate the importance of data radar assimilation in a correct way, the results of operational models of CPTEC (Center of Weather Forecasting and Climate Research) and the radar data assimilation with WRF are compared for the western of Paraná state and southeastern of Paraguay. The results of this work may contribute to improve the alerting systems of this kind of event with better accuracy and in advance, reducing losses caused by landslides, destruction of plantations, falling trees, and others.

Leduc-Leballeur, 2014: Analysis of Strengthening and Dissipating Mesoscale Convective Systems Propagating off the West African Coast. *Mon. Weather Rev.*, 142, 4600–4623, doi:10.1175/MWR-D-13-00388.1.

Abstract Body: Alarge number of Atlantic tropical depressions are generated in the eastern basin in relation to the African
easterly wave (AEW) and embedded mesoscale convective systems (MCSs) coming from the African continent.
In this paper, the structures of strengthening and dissipating MCSs evolving near the West African
coast are analyzed, including the role of the ocean surface conditions in their evolution.
Satellite infrared brightness temperature and meteorological radar data over seven summer seasons between
1993 and 2006 are used to subjectively select 20 cases of strengthening and dissipating MCSs in the
vicinity of the Senegal coast. With these observed MCSs, a lagged composite analysis is then performed using
Interim ECMWF Re-Analysis (ERA-Interim) and Climate Forecast System Reanalysis (CFSR).
It is shown that the strengtheningMCS is generally preceded by prior passage of anAEWnear the West African
coast. This previous wave trough is associated with a convective cyclonic circulation in the low and middle troposphere,
which enhances the southwesterly flowand then provides humidity to the strengthening MCS, located in
the vicinity of the subsequent AEW trough. This is favored by the contraction of the wavelength associated with
the two troughs. The sea surface contributes to the MCS enhancement through surface evaporation flux. But this
contribution is found to be less important than advection of humidity from the previous wave trough. These
conditions are almost not found in the dissipating MCS cases, which dissipate in a dry environment dominated by
a subsident and anticyclonic circulation, with generally no interaction with a previous wave trough.

Title: What is the Cause of the Ongoing Global-Warming Pause?

Presenter/First Author: S Fred Singer, Science & Environmental Policy Project, Arlington, VA

Presenter/First Author Email: singer@sepp.org

Abstract Body: The observed absence of a global-warming trend ("pause"), beginning around Yr 2000 (or perhaps even earlier) contradicts the results of every IPCC climate model – all of them driven by a steady increase in anthropogenic carbon dioxide. This lack of model validation has obvious implications for model-based estimates of future climate. Until the cause of the pause is fully understood and incorporated into existing models, all policies aiming to stabilize climate are useless and nothing more than highly uncertain and hugely expensive undertakings.

Scientific efforts to discover appropriate mechanisms for the cause of the pause may be classified according to Forcing Imbalance (F.I.) at the TOA (top of the atmosphere):

1. FI unaffected and in accord with rising CO2: implies existence of "hidden heat" somewhere (deep ocean?)

2. FI reduced wrt rising CO2 by (internal) negative feedback (from increase in OLW [reduced WV in upper troposphere] or from increase in albedo [low-altitude clouds])
But can such negative feedback cancel nearly all of CO2 forcing?

3. FI reduced by external offsets, like volcanic aerosols or solar irradiance; but this raises many unanswered problems: how to match the steady increase in forcing from rising CO2?

All these proposed mechanisms should also be able to answer two puzzling questions:
Why did pause begin around Yr 2000?
When will it end – as implied by the word "pause"?

Finally, could the pause have started in the 1970s, much before 2000? Only land-surface stations show a distinct warming trend since the late 1970s; other data sets do not. The puzzle continues.

Title: The Operational World Meteorological Organization (WMO) Multi-Model Ensemble

Presenter/First Author: Bertrand Denis, Organization Not Listed, Dorval,

Presenter/First Author Email: bertrand.denis@ec.gc.ca

Abstract Body: This talk will give an overview of the operational WMO Multi-Model Ensemble (MME) for long range forecasts. This MME gets contributions in real-time and on a monthly basis from 12 WMO designated Global Producing Centers (GPCs). It is the role of the WMO Lead Center for Long Range Forecast MME (LC-LRFMME) to process the data into MME forecasts and also to give access to them to National Meteorological and Hydrological Services (NMHS) as well as to Regional Climate Outlook Forums (RCOFs) and Regional Climate Centers (RCC). To ensure high quality standards and to help interpreting the forecast skill coming from the GPCs, a comprehensive set of standard verification measures has been defined. The display of those metrics as well as the technical and scientific support in the domain of long range forecast verification are part of the responsibilities of the WMO Lead Centre for Standard Verification System for Long-Range Forecasts (LC-SVSLRF).

The presentation will give more details about the participating GPCs, the LC-LRFMME web site to view and access the forecasts, the forecast variables and other products, real-time forecast verifications, the forecast schedule and user access restrictions, amongst other things. An overview of its companion LC-SVSLRF web site used to display the expected skill from hindcasts will also be shown. Finally, plans for the future, including the sub-seasonal timescale will be given.

Title: Assessment of APCC Multi-Model Ensemble Prediction in Seasonal Climate Forecasting: Retrospective (1983-2003) and Real-time Forecasts (2008-2013)

Presenter/First Author: Sang Myeong Oh, APEC Climate Center, Busan,

Presenter/First Author Email: osm1006@apcc21.org

Co-authors: Young-Mi Min, APEC Climate Center, Busan, South Korea; Vladimir N. Kryjov, , ,

Published Material: Min, Y. -M., V. N. Kryjov, S. M. Oh, 2014, Assessment of APCC Multi-Model Ensemble Prediction in Seasonal Climate Forecasting: Retrospective (1983-2003) and Real-time Forecasts (2008-2013), J. Geophy. Res. Atmos., 119, 12,132-12,150, DOI:10.1002/2014JD022230.

Abstract Body: Since 2007, the Asia Pacific Economic Cooperation (APEC) Climate Center (APCC) has monthly issued multi-model ensemble (MME) seasonal predictions for three months, with one-month lead time, and disseminated it to APEC member economies. This paper gives a comprehensive documentation of the current status of the APCC operational multi-model performance, with a large set of retrospective (1983-2003) and real-time (2008-2013) predictions of temperature and precipitation. In order to investigate the enhancement in seasonal predictability that can be achieved by empirically-weighted MME (using multiple regression) and calibrated MME (by correcting single-model prediction using a step-wise pattern projection method) schemes, operationally implemented at the APCC, we compare them with a simple averaged MME (with equal weightings), for predicting seasonal mean temperature and precipitation one-month ahead. The results indicate that the simple averaged MME consistently outperforms the multiple regression-based MMEs, when considering all aspects of the predictions from operational prediction systems (i.e., in different variables, regions, seasons) whereas the calibrated MME shows the capability to reduce errors and improve forecast skills in a large proportion of cases. The possible causes of the failure and success of the different MME methods implemented in the APCC operations are discussed.

Title: Monthly Ensemble Forecasts from the NCEP GEFS

Presenter/First Author: Malaquias Peña, Environmental Modeling Center, Crofton, MD

Presenter/First Author Email: malaquias.pena.mendez@noaa.gov

Co-authors: Yuejian Zhu, NOAA, Boulder, CO; Xiaqiong Zhou, NOAA College Park, College Park, MD; Dingchen Hou, NOAA College Park, College Park, MD; Richard Wobus, Environmental Modeling Center, College Park, MD; Qin Zhang, CPC NCEP, College Park, MD; Wei Li, , ,

Abstract Body: A series of experiments of 35-days, 20 members ensemble forecasts based on the NCEP GEFS has been carried out to assess the ability to predict atmospheric and precipitation anomalies in current NWP systems. Model integrations initialized every 24 h during periods of regular, strong and weak MJO signal during the months JASO-2011, JFM-2012 and ND-2012, respectively were analyzed. Results indicate a correspondence between the intensity of the MJO signal and the skill of NH atmospheric anomalies. The enhancement of skill during high MJO signal indicates that the teleconnection responses to forcing in the tropical Pacific is to some degree adequately modeled by the GEFS. Another set of experiments with a more recent version of the GEFS was carried out to assess the impact of SST anomalies on the skill of predictions. In this set, three identical configurations of the GEFS that differ only on what SST anomalies are prescribed are compared. The first configuration uses initial

SST anomalies that decay towards observed climatology in a 90-days e-folding time as the forecast is integrated forward. The second configuration uses analyzed SST and a third configuration uses SST forecasts from the CFSv2 coupled model. Results indicate that prescribing realistic SSTs, particularly the analyzed SST, marginally improves the skill of prediction of some variables even during the first two weeks of the forecasts.

Title: Diagnostic Evaluation of Summer Precipitation over West Africa using three of CORDEX-Africa Simulations

Presenter/First Author: Akinsanola Akintomide Afolayan, Federal University of Technology Akure, Akure,

Presenter/First Author Email: mictomi@yahoo.com

Co-authors: Ogunjobi Kehinde Olufunso, , ,

Abstract Body: The study evaluates the ability of three Regional Climate model (RCMs) used in the Coordinated
Regional climate Downscaling Experiment (CORDEX) activity driven by the same initial and
boundary conditions (ERA-Interim) in simulating the characteristics of rainfall pattern over West
Africa from 1998-2008. The seasonal climatology, annual rainfall cycles, interannual variability
and the wind fields of RCMs output have been assessed over three homogenous sub-regions
against ground observed data of 81 meteorological stations in West Africa and TRMM
observational dataset. Furthermore, the study assessed the ability of the RCMs in simulating the
El Nino and La Nina events. Result shows that all the RCMs simulate the main features of the
rainfall climatology and associated dynamics over the three sub-regions (Guinea coast, Savannah
and Sahel) of West Africa. Furthermore, analysis shows significant biases in individual models
depending on sub-region and season. In general, the study shows that the three CORDEX RCMs
simulate West Africa rainfall and extreme events adequately and can therefore be used for the
assessment of future climate projections for the region taking into consideration the degree of
biasness.

Title: Urban Climate Downscaling Processes using Dynamical and Diagnostic Numerical Models Approach: Madrid Case Study

Presenter/First Author: Roberto San Jose, , Boadilla Del Monte,

Presenter/First Author Email: roberto@fi.upm.es

Co-authors: Juan Luis Perez-Camanyo, , , ; Julia Pecci, , , ; Antonio Garzon, , , ; Marino Palacios, , ,

Published Material: The 1st International Workshop on Smart City Clouds: Technologies, Systems and Applications in London, Dec. 10, 2014. Oral presentation. Not under review.

Abstract Body: Downscaling techniques are very important to assure the robustness and credibility of climate modelling exercises. Regional climate simulations use boundary conditions and initial conditions from global climate and meteorological models. The regional climate simulations (WRF/chem model) have much higher spatial resolution and using nesting approaches can be used to derive climate indicators at urban level. Dynamical nesting approaches – also known as dynamical downscaling procedures – use a substantial amount of computer power, particularly for urban applications; other alternatives such as CALMET diagnostic model (for meteorological applications) and CMAQ model (with linear chemistry) produce results faster and can be used for climate applications with reasonable required computer power. In this contribution, we are using the European Centre for Medium-Range Weather Forecasts (ECMWF) model data sets to provide boundary conditions for the mesoscale model WRF/Chem (NOAA, US) that has been ran over Europe with 23 km spatial resolution and 33 vertical levels up to 50 hPa. We have used the full nesting approach defined into WRF model to produce simulations centered over the city of Madrid (Spain) with 4.6 km spatial resolution (nesting level 1, l1), 0.92 km spatial resolution (nesting level 2, l2) and 0.184 km spatial resolution (nesting level 3, l3). In l3, we have run the CMAQ (full chemistry) model (EPA, US) to produce chemical pollution data. We have applied both downscaling techniques over Madrid area using Retiro meteorological and air pollution monitoring station as observational station. The comparison between both downscaling techniques shows that CALMET-CMAQL (linear chemistry) model is much faster and the results are good enough (compared with other simulations results) to consider this tool, when the number of simulations for climate purposes is very high (due to many years and several climate scenarios) and the application of the WRF/chem model (dynamical downscaling) is prohibited computationally.

Title: Analyzing future extreme rainfalls changes over the Central Africa using CMIP5 models.

Presenter/First Author: Siewe KAMEGNI André, Organization Not Listed, Douala,

Presenter/First Author Email: siewekamegni@yahoo.fr

Co-authors: Chamani Roméo, University of Yaoundé, Yaoundé, Cameroon; Monkam David, University of Douala, Douala, Cameroon; Yepdo Zephirin, , , ; Mkankam Kamga François, , ,

Abstract Body: Abstract

This paper examines future changes in extreme rainfall by using projected daily precipitations from the ensemble mean of 10 state-of-the-art global climate models from the fifth Coupled model inter-comparison project (CMIP5) under the high representative concentration pathways scenario (RCP 8.5) over the Central Africa. To analyze future changes, trends in the 90th and 99th percentiles of daily precipitation distributions were calculated for two sub periods (2035-2065 and 2071-2100). Results show robust signal in the strong rainfall response i.e., increasing amounts in central part of our region and the few areas in the northern and southern part characterized by a reduction of extreme rainfall or no trends.

Title: Impacts of high-end climate change scenarios on the Mediterranean coast

Presenter/First Author: Piero Lionello, University of Salento, Lecce,

Presenter/First Author Email: piero.lionello@unisalento.it

Co-authors: Dario Conte, CMCC Salento, Lecce, Italy; Luca Scarascia, CMCC Salento, Lecce, Italy; Agustin Sanchez-Arcilla, , , ; Joan Pau Sierra, University of Salento, Lecce, Italy; Cesar Mosso, , ,

Abstract Body: This contribution describes the impacts of high end climate change scenarios on the Mediterranean coast. The study is focalized on the maximum water level that will be reached in the future at the coast considering the superposition of waves, storm surge and mean sea level variations. The study compares results based on an ensemble of simulations CMIP5 RCP8.5 emission scenario to previous results based on the A1B emission scenario. The period considered in 1950-2051. Our goal is to analyze the effect of two factors that in the Mediterranean Sea are acting in opposite directions: the increase of mean sea level (due to regional steric effects and water mass addition through the Gibraltar Strait) and the decrease of storminess (due to the northward shift of the storm track across Europe) decreasing surge levels and wave heights. It shows that even a moderate mass addition due to melting of the ice caps will lead to a statistically significant increase of the extreme water level statistics along the Mediterranean coast. Impacts on the management of the coast defenses are discussed. This study is part of the RISES-AM project (FP7-EU-603396).

Title: Equatorial stratospheric thermal structure and ozone variations during the sudden stratospheric warming of 2013

Presenter/First Author: Oindrila Nath, National Atmospheric Research Laboratory, Tirupati,

Presenter/First Author Email: oindrila@narl.gov.in

Co-authors: Sundararajan Sridharan, National Atmospheric Research Laboratory, Gadanki, India

Published Material: This work has been published in Journal of Atmospheric and Solar-Terrestrial Physics in January 2015. Oindrila Nath, S. Sridharan, H. Gadhavi, Equatorial stratospheric thermal structure and ozone variations during the sudden stratospheric warming of 2013, *Journal of Atmospheric and Solar-Terrestrial Physics*, Volume 122, January 2015, Pages 129-137, ISSN 1364-6826, http://dx.doi.org/10.1016/j.jastp.2014.11.003.

Abstract Body: Ozone mass mixing ratio (OMMR) obtained from both European Centre for Medium Range Weather Forecasting (ECMWF) Reanalysis (ERA)-Interim and Sounding of Atmosphere by Broadband Emission Radiometry (SABER) instrument onboard Thermosphere, Ionosphere, Mesosphere Energetics and Dynamics (TIMED) satellite shows large values in the equatorial upper stratosphere during the occurrence of a major stratospheric sudden warming (SSW) in January 2013 preceded by a large reduction of planetary wave activity. However, surprisingly equatorial stratospheric temperature is found to decrease at pressure levels where the ozone mixing ratio is larger. The computed radiative heating rate using Santa Barbara DISORT Atmospheric Radiative Transfer (SBDART) model also shows positive heating rate indicating that the temperature should increase in response to the ozone accumulation over equator. In addition to radiative heating due to ozone, heating rate due to other dominant factors, namely, ascending motion and convergence of meridional heat flux, which could influence the thermal structure of the equatorial stratosphere, are estimated. It is found that the observed low temperature during SSW is mainly due to large upward motions. The estimated heating rates agree reasonably well with the observed heating rates at 10-8 hPa indicating the dominance of transport at lower stratosphere. The large discrepancy between the estimated and observed heating rates in the upper stratosphere may be due to the dominance of photochemistry.

Title: Quantifying the scales of coherence and causes of spatiotemporal variability of aerosol particle properties and extreme concentrations over eastern North America

Presenter/First Author: Ryan Sullivan, Cornell University, Ithaca, NY

Presenter/First Author Email: rcs365@cornell.edu

Co-authors: Paola Crippa, Newcastle University, Newcastle upon Tyne, United Kingdom; Robert C Levy, , Silver Spring, MD; Sara C Pryor, Cornell University, Ithaca, NY

Abstract Body: Aerosol optical depth (AOD) and Ångström exponent (AE) from the MODerate resolution Imaging Spectroradiometer (MODIS) on the Aqua and Terra satellites, and AErosol RObotic NETwork (AERONET) ground-based stations are used to deliver an evaluation of the spatially averaged (Level-3) MODIS aerosol particle products, and to characterize the spatiotemporal scales of variability of the aerosol particle population over eastern North America. Our analyses show (i) a high degree of consistency in AOD retrievals from Terra and Aqua, and between MODIS and AERONET, although larger discrepancies are observed in AE retrievals, and (ii) MODIS data indicate highest mean AOD and lowest day-to-day variability during the summer, but largest scales of spatial coherence in summer and fall. The frequency of co-occurrence of extreme AOD values (> local 90th percentile) decreases to below 50% at ~ 150 km from a reference grid cell in south-central Indiana, but is above that expected by random chance over almost all of eastern North America, indicating supra-regional scale extreme events. In both the MODIS and AERONET observations variability in AOD is manifest primarily on synoptic and annual scales. Conversely, AE variability in MODIS data is primarily focused on seasonal, semiannual, and annual time scales, and there is an additional mode of AE variability at ~ 30 days in the AERONET measurements. The results of these analyses are being used to diagnose the causes of the different spatiotemporal variability of columnar aerosol particle loading (AOD) and aerosol particle size (AE) and in a cross-comparison evaluation exercise of yearlong simulations (for 2008) conducted using WRF-Chem applied at 12 km spatial resolution.

Title: Investigation and intercomparison of ozone depletion in the Arctic polar vortex - using ground-based and space-borne FTIR measurements at Eureka between 2006 and 2013

Presenter/First Author: Debora Griffin, University of Toronto, Toronto,

Presenter/First Author Email: dgriffin@atmosp.physics.utoronto.ca

Co-authors: Kaley A Walker, University of Toronto, Toronto, ON, Canada; Stephanie Conway, University of Toronto, Toronto, ON, Canada; Dan Weaver, University of Toronto, Toronto, ON, Canada; Felicia Kolonjari, University of Toronto, Toronto, ON, Canada; Rodica Lindenmaier, , , ; Lin Dan, University of Toronto, Toronto, ON, Canada; Joseph Mendonca, University of Toronto, Toronto, ON, Canada; Ashley Harrett, University of Toronto, Toronto, ON, Canada; Rebecca Lee Batchelor, National Center for Atmospheric Research, Boulder, CO; Kimberly Strong, University of Toronto, Toronto, ON, Canada; Gloria L Manney, NorthWest Research Associates, Inc, Socorro, NM; Chris D. Boone, University of Waterloo, Waterloo, ON, Canada; Peter F Bernath, Old Dominion University, Gloucester, VA; James R Drummond, Dalhousie University, Halifax, NS, Canada

Published Material: The some initial components of this work were presented recently at an ACE Science Team meeting (Oct. 2014).

Abstract Body: During the Canadian Arctic ACE (Atmospheric Chemistry Experiment) Validation Campaigns from 2004-2014, ground-based measurements have been carried out during the polar sunrise period (from mid-February to mid-April) at Eureka, Nunavut (80.05°N, 86.42°W). As part of this project two ground-based Fourier Transform Spectrometers (FTSs) were used to measure total and partial columns of trace gases important to O_3 depletion, namely, O_3, HCl, and HNO_3, as well as HF. During the same time period, the satellite-based ACE-FTS made measurements over Eureka and provided profiles of the same trace gases.

An intercomparison of the latest version of the ACE-FTS retrieval product (v3.5) has been carried out for these stratospheric gases between 2006 and 2013. Instrument comparisons in the High Arctic during the polar sunrise period are challenging. Trace gas amounts inside and outside the polar vortex can be significantly different. We have used a smoothed partial column methodology for the ground-based to space-borne intercomparison; and selected coincident measurements based on time, distance and scaled potential vorticity (sPV).

Furthermore, we have investigated the springtime Arctic O_3 loss in each year and found significantly lower O_3 columns in 2011 for all instruments. To distinguish O_3 decrease caused by dynamics from that arising from chemical loss, we have applied a HF normalization and tracer-tracer (O_3-HF) correlation method. We used measurements between 2004 and 2013 to estimate the annual amount of springtime chemical O_3 loss. The results of the intercomparison and chemical O_3 loss analyses will be discussed in the presentation.

Title: Contribution of Different Ultrafine Aerosol Size Fractions to Ice Nucleation in Clouds

Presenter/First Author: Yevgen Nazarenko, McGill University, Montreal, QC

Presenter/First Author Email: yevgennazarenko@gmail.com

Co-authors: Rodrigo Benjamin Rangel-Alvarado, McGill University, Montreal, Canada; Parisa A Ariya, McGill University, Montreal, QC, Canada

Abstract Body: In the upper troposphere, aerosol particles serve as ice nuclei impacting precipitation and weather. The physico-chemical nature of these particles determines the highest temperature at which they nucleate ice crystals. One of these determinant physico-chemical characteristics is particle size. Most research to date suggests that micrometer-scale particles are more efficient ice nucleators than submicrometer particles. However, recent findings show the importance of nanoparticles. Due to previous technical limitations, it has been hard to investigate the role of ultrafine particles in ice nucleation. The recent instrumental advances, however, enable separation of different size fractions of even sub-100 nm particles using differential mobility analyzers (DMAs).

Aerosol particles that nucleate ice crystals in the atmosphere are trapped in the snowflakes. These particles are then present in meltwater that can be obtained from the snow. We designed a novel technique to aerosolize desalinized meltwater from natural snow, followed by subjecting the aerosol to drying and size classification in a DMA. The resulting monodisperse aerosol is collected in an electrostatic precipitator on 3 mm diameter disc substrate and then used in ice nucleation assays on a cold plate. We will present our data from several field campaigns in the Arctic and subarctic sites and discuss their role in nucleation processes.

Title: Lagrangian Analysis of Ozone Production in the Baltimore-Washington Metropolitan Area Based on Air Parcel Trajectories and In Situ Airborne Measurements from the 2011 DISCOVER-AQ Campaign

Presenter/First Author: Heather Leigh Arkinson, University of Maryland College Park, Swanton, VT

Presenter/First Author Email: heather@atmos.umd.edu

Co-authors: Lacey C Brent, NIST, Gaithersburg, MD; Hao He, University of Maryland College Park, College Park, MD; Christopher Loughner, University of Maryland College Park, College Park, MD; Jeff Stehr, University of Maryland College Park, College Park, MD; Andrew John Weinheimer, National Center for Atmospheric Research, Boulder, CO; Russell R Dickerson, University of Maryland College Park, College Park, MD

Abstract Body: Tropospheric O_3 is a reactive trace gas with a short atmospheric lifetime that absorbs infrared energy and thus acts directly as a greenhouse gas that contributes strong radiative forcing on regional scales. It is also the dominant component of summertime photochemical smog, and at high levels, has deleterious effects on human health, ecosystems, and materials. The University of Maryland (UMD) Regional Atmospheric Measurement Modeling and Prediction Program (RAMMPP) strives to improve air quality in the Mid-Atlantic States and to elucidate contributions of such pollutants from regional transport versus local sources. The National Aeronautics and Space Administration (NASA) Deriving Information on Surface Conditions from Column and Vertically Resolved Observations Relevant to Air Quality (DISCOVER-AQ) project investigates the connection between column measurements and surface conditions to explore the efficacy of remote sensing observations in quantifying atmospheric composition and diagnosing air quality at ground level. During the 2011 DISCOVER-AQ field campaign, in situ measurements were performed along the Baltimore-Washington corridor from the NASA P3B aircraft. To provide regional context, measurements were also performed by the RAMMPP Cessna 402B aircraft over nearby airports. This work presents an analysis of O_3 measurements made by the Ultraviolet (UV) Photometric Ambient O_3 Analyzer on the Cessna 402B and by the NCAR 4-Channel Chemiluminescence instrument on the P3B. Spatial and temporal patterns of O_3 data are examined within the context of forward and backward air parcel trajectories calculated from 12-km North American Mesoscale (NAM) meteorological data using the National Oceanic and Atmospheric Administration (NOAA) Hybrid Single Particle Lagrangian Integrated Trajectory (HYSPLIT) Model and from a high resolution Weather Research and Forecasting (WRF) model simulation in order to empirically calculate localized O_3 production rates and distinguish O_3 resulting from regional transport versus O_3 generated from local photochemistry. Preliminary examination of measurements from overlapping flight days and corresponding trajectories identifies 38 cases suitable for Lagrangian analysis, resulting in O_3 production rates ranging up to 14 ppbv hr^{-1} and 4 ppbv hr^{-1} on average.

Title: Using land surface information to inform back-trajectory analyses of aerosol measurements

Presenter/First Author: David Doughty, Oak Ridge Associated Universities Inc., Oak Ridge, TN

Presenter/First Author Email: davidcdoughty@gmail.com

Co-authors: Steven C Hill, , ,

Abstract Body: The land surface types that an airmass passes over can influence the trace-gas and aerosol properties observed downwind. The objective of the present study is to determine how particulate matter properties correlate with land surface types upwind of the measurement location. To do this, we combine high-resolution Geographical Information Systems (GIS) data with air-parcel back-trajectories, using a time-weighted residence time analysis, which we refer to as TWRTA. Additionally, we study the influence that changing model resolution has over the determined TWRTAs. Measured aerosol data from a site located near Beltsville, MD, in the mid-Atlantic region of the United States are used. Hybrid Single Particle Lagrangian Integrated Trajectory Model (HYSPLIT) back-trajectories are driven by Global Data Assimilation System data, which has a resolution of approximately 111x85 km at 40°N 77°W, and North American Model 12 km data. We calculate TWRTAs using land surface type data from the North American Land Change Monitoring System, and include coastal and deep waterways, cropland, temperate/subpolar broadleaf deciduous forest, and wetlands, among other land surface types.

Title: Features of Limited Organic-Inorganic Miscibility and Their Relation to Aerosol Hygroscopicity

Presenter/First Author: Andreas Zuend, McGill University, Montreal, QC

Presenter/First Author Email: andreas.zuend@mcgill.ca

Co-authors: Daniel M. Lienhard, , , ; Ulrich Karl Krieger, ETH Swiss Federal Institute of Technology Zurich, Zurich, Switzerland

Abstract Body: The water content of aerosol particles at atmospheric conditions depends on their chemical composition, which defines their hygroscopicity, and the environmental temperature and relative humidity (RH). Hygroscopicity is therefore an important property affecting aerosol size as well as phase transitions and viscosity of soluble or partially soluble particles. The chemical composition of ambient aerosol particles is complex, often involving hundreds to thousands of multifunctional organic compounds and several types of dissolved inorganic ions. The miscibility of all the chemical species is often limited, which can, e.g., lead to the separation of a particle into two or more liquid phases. The thermodynamics describing organic-inorganic molecular interactions lead to hygroscopicity behavior deviating from simple linear additivity assumptions at given RH. The latter assumptions are employed in the Zdanovskii-Stokes-Robinson (ZSR) mixing rule, which is typically found to describe hygroscopic mass growth well in the RH range of completely miscible liquid aerosol systems and therefore often employed in atmospheric models. We present new thermodynamic calculations based on the AIOMFAC activity coefficient model in comparison to hygroscopic growth factor data from measurements conducted with an electrodynamic balance (EDB). Different hygroscopicity features at relative humidity levels below the full deliquescence of multicomponent systems are found. We will present experiments and detailed model calculations performed for multicomponent systems showing varying degrees of organic-inorganic miscibility, including liquid-liquid phase separation and hysteresis effects between metastable and stable gas-particle equilibria. It is found that depending on the degree of miscibility, the aerosol water uptake prior to deliquescence can be substantial due to partial dissolution of electrolytes. Such behavior is not captured with a traditional ZSR parameterization.

Title: Evaluating IPCC and Other Scenarios of Future Climate for Regional-to-Local Water Resource Applications in the US

Presenter/First Author: J R Arnold, US Army Corps of Engineers, Seattle, WA

Presenter/First Author Email: jeffrey.r.arnold@usace.army.mil

Published Material: some general parts of this overview talk were given in the 2014 AGU Fall Annual Meeting session on societal decision-making (GC52A); no formal ms submission has been made or is planned fr it

Abstract Body: Assessments of projected climate change impacts to water resources at regional-to-local scales typically use a combination of numerical models for evaluating the various differences across projected scenarios and impacts. However, the sets of approaches for projecting regional climate and its possible effects - statistical or dynamical models, e.g., to generate the regional-to-local climate and weather - together with the hydrologic models used to transfer changes in these model outputs into changed hydrologic processes most often include only one or a few models, and thisinhibits their depiction of the uncertainty space around the projected climate and impacts. Additionally, inter-model differences are often not constrained to define the uncertainties in the simulations consistently. And more generally, the community performing water-resource impacts assessments (among most others) has focused very intently on characterizing uncertainty across climate projections produced by multiple climate models running several emission scenarios, but have done little work to understand the interacting uncertainties in the driving climate and hydrologic models.

Water-resource managers face a linked series of questions about using these models related to their decision-making for climate-changed futures, including: 1) how do different climate downscaling approaches affect the projection of relevant hydrometeorological variables? 2) how can observational datasets best be used to drive analyses of downscaled climate and hydrology? and 3) how many/which hydrologic model/s can be used, and how can they best be configured and calibrated for these applications?

This talk will summarize some of the methods and results coming from the US Army Corps of Engineers' work with partners to help provide fuller answers to those questions. Two salient points are: 1) different methods for producing gridded meteorological fields can have very different effects on projected hydrologic outcomes, with uncertainties as large as the climate change signal; 2) many popular statistical downscaling methods produce hydroclimate representations with too much drizzle, wrong extreme events representations, and improper spatial scaling characteristics relevant to hydrology.

Title: A tool to communicate to the adaptation community: a guidebook on climate scenarios

Presenter/First Author: Isabelle Charron, Ouranos, St-Basile-le-Grand,

Presenter/First Author Email: charron.isabelle@ouranos.ca

Abstract Body: Climate change is a reality that is forcing decision-makers to assess its related risks, vulnerabilities and opportunities. This requires decision-makers to improve their general understanding of climate information. This guide on climate scenarios constitutes a new tool with the objective of helping users become more familiar with different types of climate information so that this information is increasingly incorporated into adaptation frameworks. The guide is intended to all actors involved in climate change adaptation, from the early stages of general climate change awareness to the implementation of adaptation measures. The document is organised around three main sections. The first section presents a unique way to classify climate information using a decision tree. This tool allows users orient themselves toward one of three large climate information categories, namely basic, intermediate, or detailed, based on several factors such as the use of the information, the climate variables of interest, and the spatial and temporal scales of the information provided. The next section presents a catalogue of numerous different formats that can be used in order to customize and present climate information to various users, according to their expertise and personal preference, among others. This section aims to help users better analyse different climate information products and to better evaluate the usefulness and limitation of the climate information that is presented. Finally, a third section describes many key concepts in climate modeling. The guide highlights the fact that all climate information, regardless of its complexity, can be used to make decisions. It is important to recognize the right information for the right use or purpose.

Title: Inter-Variable Dependence in Climate Scenarios at Daily Resolution: Testing a 2D Statistical Adjustment of CMIP5 Simulations at Canadian Arctic Coastal Sites

Presenter/First Author: Fabio Gennaretti, Ouranos, Montreal,

Presenter/First Author Email: gennaretti.fabio@ouranos.ca

Co-authors: Lorenzo Sangelantoni, , , ; Patrick Grenier, Ouranos, Montreal, QC, Canada

Published Material: A part of the results were already described in a poster presented at 2 meetings (Arctic Change 2014 and Ouranos Symposium). Currently, we are writing a scientific paper on our findings.

Abstract Body: The interdependence between climatic variables is a critical feature which should be taken into account when developing local climate scenarios for the next decades. For example, in the Arctic the temperature-precipitation interdependence is particularly strong and determines other physical characteristics such as the snow cover extent and duration. However, this interdependence is often misrepresented in climate simulations. Here, we propose a two-dimensional (2D) statistical adjustment of climate model simulation data for the development of plausible local daily temperature and precipitation scenarios with more realistic inter-variable dependence. This method is based on the quantile mapping technique and furthermore it uses temperature time trend removal to obtain a stationary correction procedure and moving windows to adjust the correction to the specificities of each day of the year. This method was tested at 30 Canadian Arctic coastal sites, and was applied to an ensemble of 13 CMIP5 simulations (selected for representativeness of the variability of a larger ensemble). The inter-variable dependence was evaluated in terms of correlation values and with empirical conditional probability distributions of standardized temperature ranks given standardized precipitation ranks. The results show that the proposed 2D statistical adjustment corrects individual distributions of climatic time series as well as a standard one-dimensional (1D) statistical adjustment. Furthermore, the 2D adjustment outperforms raw and 1D corrected simulations in the reproduction of the observed temperature-precipitation interdependence. Where this interdependence is important (e.g. characterization of extreme events and of snow cover extent and duration), the proposed 2D adjustment definitely represents a good alternative for the production of plausible local climate scenarios.

Title: High-resolution climate change projections over Australia: producing policy-relevant information

Presenter/First Author: Alejandro Di Luca, University of New South Wales, Sydney,

Presenter/First Author Email: alejandrodiluca@gmail.com

Co-authors: Jason Peter Evans, University of New South Wales, Sydney, NSW, Australia; Daniel Argüeso, University of New South Wales, Sydney, Australia; Roman Olson, University of New South Wales, Sydney, NSW, Australia; Lluis Fita, , ,

Published Material: Evans, J. P., F. Ji, C. Lee, P. Smith, D. Argeso, and L. Fita (2014), Design of a regionalclimate modelling projection ensemble experiment NARCliM, Geosci. Model Dev., 7 (2),621–629, doi:10.5194/gmd-7-621-2014.

Abstract Body: °C (CNFD) and the annual minimum temperature (AnnTasmin). Results shows a poleward migration of the suitability of wine-making in the next decades. By 2040-2050, strictly from a climatic perspective, most of the southern part of Québec (Cantons-de-l'est, Montérégie) can expect favorable conditions, as well as the southern shore of the St-Lawrence River. Over those regions, the probability that the climatic indices exceed a suitable threshold for wine-making is over 80%. With respect to the methodology used, we note that the quantile-quantile statistical adjustment is modifying the climate change (CC) signal of the annual minimum value. To what extent this modification of the CC signal is affecting the conclusions related to Anntasmin needs to be determined in future work. The proposed methodology is an example of probabilistic regional climate scenarios that can be produced by large climate simulations ensembles which can be used by the local, regional and national stakeholders.

Title: Assessing hydrological impacts from climate change with hourly precipitation using temporal downscaling over South Korea

Presenter/First Author: Taesam S Lee, Gyeongsang National University, Jinju, Gyeongnam,

Presenter/First Author Email: tae3lee@gnu.ac.kr

Co-authors: Taewoong PARK, Gyeongsang National University, Jinju, South Korea

Abstract Body: The assessment of hydro-climatological variables through climate scenarios from the outputs of Global Climate Model (GCM) is essential for adapting and mitigating the changes. However, GCM outputs are too coarse to apply a basin scale. Temporal downscaling is required to obtain the hourly precipitation for analyzing a small or medium basin since only few or several hours are taken to peak flows after it rains. In the current study, the spatiotemporal distribution of downscaled hourly precipitation for RCP4.5 and RCP8.5 scenarios over South Korea is presented as well as its implications over hydrological responses. The results indicate that the mean of hourly precipitation significantly increases over the southern part of South Korea especially for the morning time and its increase gets lower at the later time of a day in the RCP8.5 scenario. However, the increase cannot be propagated to the mainland due to the mountainous areas in the southern part of the country. Furthermore, the

hydrological responses employing a distributed rainfall-runoff model (Vflo™) show that there is significant increase in peak flow for RCP8.5 scenario while slight decrease for RCP4.5. The current study concludes that the employed temporal downscaling method is suitable for obtaining the hourly precipitation data from daily GCM scenarios. In addition, the rainfall runoff simulation through the downscaled hourly precipitation is useful for investigating the variations of the hydrological responses related with future scenarios.

Co-authors: Sharmistha Swain, Climate Science Center, Texas Tech University, Lubbock, TX

Abstract Body: Assessing the potential impacts of climate change is essential to setting sound targets that minimize the costs and maximize the benefits of both adaptation and mitigation for society. Conventional wisdom, first codified in the UNFCCC's 1992 agreement to stabilize greenhouse gas concentrations at levels that would prevent dangerous anthropogenic interference with the climate system, suggests that impacts are expected to scale with the magnitude of human emissions. Since then, further research has elucidated how the relationship between carbon emissions, global temperature, and impacts may be complicated by non-linear responses of the physical system to global forcing.

We present projected changes in a collection of CMIP5-based climate metrics based on high-resolution downscaled projections for North America that are relevant to climate impacts on infrastructure, natural resources, energy use, and human health. We then explore the extent to which many of these metrics scale with global temperature and hence carbon emissions at the local to regional scale. This novel approach, which combines multiple RCP scenarios and CMIP5 simulations into a single framework based on increases in global mean temperature (GMT) from +1 to +4°C, provides an unprecedented opportunity to connect local and regional impacts directly to global emission targets. With this methodology, we are able to explore the extent to which projected future changes in impact-relevant metrics scale with carbon-equivalent greenhouse gas emissions and global mean temperature, information which can in turn be used to distinguish between the implications of international climate targets under discussion at the UNFCCC Conference of Parties for individual nations, states, and even cities.

Title: Improving climate projections using "intelligent" ensembles

Presenter/First Author: Noel C Baker, NASA Langley Research Center, Tempe, AZ

Presenter/First Author Email: noel.c.baker@nasa.gov

Co-authors: Patrick C Taylor, NASA Langley Research Center, Hampton, VA

Published Material: Some of the work mentioned in the abstract is under review in Atmospheric Chemistry and Physics. The majority of findings in this presentation are new work building on that previous work.

Abstract Body: Recent changes in the climate system have led to growing concern, especially in communities which are highly vulnerable to resource shortages and weather extremes. There is an urgent need for better climate information to develop solutions and strategies for adapting to a changing climate. Climate models provide excellent tools for studying the current state of climate and making future projections. However, these models are subject to biases created by structural uncertainties. Performance metrics—or the systematic determination of model biases—succinctly quantify aspects of climate model behavior. Efforts to standardize climate model experiments and collect simulation data—such as the Coupled Model Intercomparison Project (CMIP)—provide the means to directly compare and assess model performance. Performance metrics have been used to show that some models reproduce present-day climate better than others. Simulation data from multiple models are often used to add value to projections by creating a consensus projection from the model ensemble, in which each model is given an equal weight. It has been shown that the ensemble mean generally outperforms any single model. It is possible to use unequal weights to produce ensemble means, in which models are weighted based on performance (called "intelligent" ensembles). Can performance metrics be used to improve climate projections? Previous work introduced a framework for comparing the utility of model performance metrics, showing that the best metrics are related to the variance of top-of-atmosphere outgoing longwave radiation. These metrics improve present-day climate simulations of Earth's energy budget using the "intelligent" ensemble method. The current project identifies several approaches for testing whether performance metrics can be applied to future simulations to create "intelligent" ensemble-mean climate projections. It is shown that certain performance metrics test key climate processes in the models, and that these metrics can be used to evaluate model quality in both current and future climate states. This information will be used to produce new consensus projections and provide communities with improved climate projections for urgent decision-making.

Title: Regional Estimates of the Transient Climate Response to Cumulative Carbon Emissions

Presenter/First Author: Martin Leduc, Concordia University, Montréal, QC

Presenter/First Author Email: leduc@sca.uqam.ca

Co-authors: Damon Matthews, Concordia University, Montreal, QC, Canada; Ramón de Elía, Ouranos, Montreal, QC, Canada

Published Material: Paper submitted to Journal of Climate (under review).

Abstract Body: The Transient Climate Response to cumulative Emissions (TCRE) is a new metric that quantifies the response of the climate system to anthropogenic CO2 emissions. Defined as the ratio between the global mean temperature change and the amount of CO2 emitted into the atmosphere, the TCRE accounts for interactions between human activity, the climate and the Earth's carbon cycle dynamics.

It is now well known that the TCRE metric is fairly stable in time, that is, approximately independent of the emission pathway. While this has been widely shown in terms of the global mean surface air temperature from observational data as well as in results from state-of-the-art Earth System Models, this study shows that the TCRE stability hypothesis also applies locally in a broad diversity of regions. The largest source of uncertainty affecting the TCRE residing in the sensitivity of the climate-carbon system, we hence attribute a range of confidence to the TCRE spatial pattern based on an ensemble of twelve Earth System Models from the CMIP5 archive. Brought together, the global and regional estimates of the TCRE form a simple but powerful set of tools for synthesizing complex climate models output to non-expert users and hence nourish current discussions for mitigating greenhouse gases emissions.

Title: An improved algorithm for trace gas retrieval from satellite measurements

Presenter/First Author: Edward Abram Celarier, NASA Goddard Space Flight Center, Greenbelt, MD

Presenter/First Author Email: edward.a.celarier@nasa.gov

Co-authors: Sergey V Marchenko, SSAI, Lanham, MD; Lok N Lamsal, Universities Space Research Association Columbia, Columbia, MD; Nickolay Anatoly Krotkov, NASA GSFC, Greenbelt, MD; William Swartz, Johns Hopkins Univ, Laurel, MD; Eric J Bucsela, Organization Not Listed, Washington, DC

Published Material: Parts of this work have been submitted, as a paper, to the Journal of Geophysical Research. That paper is currently under review.

Abstract Body: The popular differential optical absorption spectroscopy (DOAS) method
is a "curve fitting" approach to retrieving trace gas slant column densities (SCD) from atmospheric measurements, using a multiparameter, nonlinear least-squares algorithm. A number of problems arise from the sensitivity of the retrieval to (a) "cross-talk" between retrieved species, (b) differences in wavelength registration of the radiance and irradiance measurements, and (c) changes in the performance (noise, throughput, etc.) of the instrument.

We show that a straightforward DOAS calculation may produce systematic biases of up to 30\% in the retrieved NO$_2$ SCDs. We have developed an algorithm in which the radiance/irradiance wavelength registration is carefully refined, and the previously-mentioned error sources are greatly reduced before the final, sequential retrieval of the trace-gas slant columns.

We apply the new approach to the Aura/Ozone Monitoring Instrument (OMI)
data and show that the revised OMI NO$_2$ SCDs are reduced by $15-35\%$,
bringing them much closer to SCDs retrieved from independent measurements and models. The approach described is a major revision to the standard algorithm, and affects both stratospheric and tropospheric NO$_2$
retrieved columns.

Title: FTIR measurements of biomass burning species from the 2014 Canadian wildfires

Presenter/First Author: Erik Lutsch, University of Toronto, Toronto, ON

Presenter/First Author Email: elutsch@physics.utoronto.ca

Co-authors: Stephanie Conway, University of Toronto, Toronto, ON, Canada; Joseph Mendonca, University of Toronto, Toronto, ON, Canada; Kimberly Strong, University of Toronto, Toronto, ON, Canada; James W Hannigan, National Center for Atmospheric Research, Boulder, CO; Eric Nussbaumer, NCAR/ACD, Boulder, CO

Abstract Body: We present time series of the total column amounts of carbon monoxide (CO), hydrogen cyanide (HCN) and ethane (C_2H_6) obtained by Fourier Transform Infrared (FTIR) spectrometer measurements at three sites. Two are located in the high Arctic at Eureka, Nunavut (80.02°N, 86.42°W) and Thule, Greenland (76.53°N , 68.74°W), and the third is at Toronto, Ontario (43.66°N, 79.40°W).

Total column amounts of each target species are obtained from the measured mid-infrared spectra using the SFIT4 retrieval algorithm based on the optimal estimation method, along with spectral line parameters from the HITRAN 2008 spectroscopic database as part of the Network for the Detection of Atmospheric Composition Change (NDACC). Total column amounts of CO are also obtained from near-infrared spectra measured at Eureka as part of the Total Carbon Column Observing Network (TCCON).

The total column time series allow for biomass burning events during July-August 2014 to be identified at both sites by enhancements of the total column amounts above ambient levels. HYSPLIT back-trajectories and MODIS fire hot spot data are used to determine the burning source regions in northern Canada and the travel time durations of the plumes. By accounting for the effect of the aging of the smoke plumes, the measured FTIR enhancement ratios are corrected to obtain emission ratios and emission factors, which are needed to improve the simulation of fire emissions in chemical transport models.

Title: Long Distance Pollen Transport to the Canadian High Arctic as a Tracer for Atmospheric Circulation

Presenter/First Author: Elisabeth Levac, Bishop's University, Sherbrooke, QC

Presenter/First Author Email: elevac@ubishops.ca

Published Material: Some of the pollen data was presented at the 9th European Palaeobotany-Palynology Conference in Padova, Italy in August 2014. However, none of the results for back trajectories and air mass circulation were available at that time.

Abstract Body: Airborne pollen and spore concentrations were monitored daily at Eureka, on Ellesmere Island in the Canadian high Arctic during the summer seasons 2009-2012. A pollen sampler was installed at PEARL station (Polar Environment Atmospheric research Laboratory) as part of CANDAC (Canadian Network for detection of Atmospheric Change). A volumetric Burkard-type sampler was used to take samples following criteria established by IAAAA. The goal of this project is to quantify how much tree pollen is transported by air masses over long distances, since no trees are growing in the vicinity of this station. The sampler provides hourly pollen concentrations. Pollen counts are generally low, averaging 2-3 pollen grains per day, but a few high-pollen episodes are recorded during the summer season. Pollen grains from conifers are dominant, constituting more than 2/3 of the counts. *Pinus* and *Tsuga* are the most abundant genus, with minor numbers of *Picea*, *Abies*, and *Larix*. In the deciduous

trees, *Ulmus* and *Acer* are the most abundant, but *Juglans*, *Quercus* and *Fraxinus* are also recorded. Other pollen types could be from more regional sources (*Betula*, *Alnus*, *Populus* and *Salix*). Preliminary work has been done to attempt to identify the sources of the tree pollen. Potential sources for the tree pollen are North America and Russia. Back trajectories were performed for large-pollen episodes, to trace the path of air masses and the source of the pollen, but more work is needed to understand the role of weather patterns and determine the altitude of the air mass travel.

Title: A Two Beam Cavity-Enhanced Absorption Spectrometer for Atmospheric Trace Gas Sensing

Presenter/First Author: Satheesh Chandran P M, National Institute of Technology Calicut, Calicut,

Presenter/First Author Email: pmsc85@gmail.com

Co-authors: Ravi M Varma, NIT Calicut, Calicut, India

Abstract Body: Detection of trace gas pollutants with high temporal and spatial resolution is a key problem in atmospheric science. The new instrumentation for detecting trace pollutants and their laboratory demonstration is a vibrant research area. Cavity-enhanced absorption spectroscopy (CEAS) techniques are widely used in atmospheric pollutant monitoring as a non- invasive way for the in-situ detection of trace species. A two-beam cavity-enhanced absorption spectrometer has been developed with the ability of monitoring sample and reference cavity signals simultaneously. We present the laboratory demonstration this instrument and its feasibility for fast and reliable measurement of trace pollutant NO_2 for a wide concentration ranges.

First Author Student?: No

Co-authors: Daniel A Vila, INPE National Institute for Space Research, Sao Jose dos Campos, Brazil

Published Material: 94th AMS Meeting (Atlanta 2014)

Abstract Body: An overwhelming number of applications depend on reliable precipitation estimations. However, over complex terrain in regions such as the Andes or the southwestern Amazon, the spatial coverage of rain gauges is scarce. Two reanalysis datasets, a satellite algorithm and a scheme that combines surface observations with satellite estimations were selected for studying rainfall Bolivia. The selected reanalyses were the Modern-Era Retrospective Analysis for Research and Applications, which has a horizontal resolution conducive for studying rainfall in relatively small precipitation systems, and the Climate Forecast System Reanalysis and Reforecast, which features an improved horizontal resolution. The third dataset was the seventh version of the Tropical Rainfall Measurement Mission 3B42 algorithm. The fourth dataset utilizes a new technique known as the Combined Scheme, which successfully removes satellite bias. All four of these datasets were interpolated to a coarser resolution. This research aimed to describe and compare precipitation in the two reanalysis datasets, the satellite-algorithm dataset, and the Combined Scheme with ground observations. Two seasons were selected for studying the precipitation estimates: the rainy season (December–February) and the dry season (June–August). The average, bias, standard deviation, correlation coefficient, and root mean square error were calculated. Moreover, a contingency table was generated to calculate the accuracy, bias frequency, POD, FAR, and ETS.

All four datasets correctly depicted the spatial rainfall pattern. However, CFSR and MERRA overestimated precipitation along the Andes' eastern-facing slopes and exhibited a dry bias over the eastern Amazon; TRMM3B42 and the Combined Scheme depicted a more realistic rainfall distribution over both the Amazon and the Andes. When separating the precipitation into classes, MERRA and CFSR overestimated light to moderate precipitation (1–20 mm/day) and underestimated very heavy precipitation (>50 mm/day). TRMM3B42 and CoSch depicted behaviors similar to the surface observations; however, CoSch underestimated the precipitation in very intense systems (>50 mm/day)

The statistical variables indicated that CoSch's correlation coefficient was highest for every season and basin.

Title: Assimilation of Doppler weather radar data and their impacts on the simulation of squall events during pre-monsoon season

Presenter/First Author: Mohan Kumar Das, SAARC Meteorological Research Centre (SMRC), Dhaka,

Presenter/First Author Email: mohan28feb@yahoo.com

Co-authors: Someshwar Das, India Meteorological Department, New Delhi, India; Md. Abdul Mannan Chowdhury, Jahangirnagar University, Savar, Bangladesh; Sujit Kumar Debsarma, , ,

Published Material: under review in Natural Hazards Journal

Abstract Body: The quantitative data such as Doppler Weather Radar (DWR) radial winds and reflectivity are useful for improvement of the numerical prediction of weather events like squalls. Mesoscale convective systems (MCS) are responsible for majority of the squall and hail events and related natural hazards that occur over Bangladesh and surrounding region in pre-monsoon season. In this study, DWR observations (radial winds and reflectivity) of Bangladesh Meteorological Department (BMD) are used during May 2011 squall events in order to update the initial and boundary conditions through three-dimensional variational assimilation (3DVAR) technique within the Advanced Research Weather Research and Forecasting model (WRF ARW). The simulated sea level pressure, thermodynamic indices, 850 hPa wind fields, cloud hydrometeors from eight experiments are presented in this study in order to analyze the observed and simulated features of the squall events that occurred in the month of May 2011. The model results are also compared with the Kalpana-1 satellite imagery and the India Meteorological Department (IMD) observations. Further, the intensity of the events, generated from the simulations is also compared with the in-situ meteorological observations in order to evaluate the model performance.

Keywords Squall, MCS, 3DVAR assimilation, DWR radial winds, reflectivity.

Title: Investigations on Water Vapor, Total Column Ozone and Aerosol Optical Thickness over Western Sites of India

Presenter/First Author: Som Kumar Sharma, Physical Research Laboratory, Ahmedabad,

Presenter/First Author Email: somkumar@prl.res.in

Abstract Body: Atmospheric water vapour, ozone, and aerosols play important role in various atmospheric processes and impact human life in several ways. Water vapor, Ozone and aerosols modulate Earth's radiation budget and play important role in weather and climate. In the Total Column Ozone (TCO) the contribution is mainly from the stratosphere while in case of water vapour (WV) and aerosols, major contribution is from the troposphere. For the present study the measurements of TCO, water vapour and aerosol optical thickness (AOT) were made using MICROTOP II instrument. It utilizes five wavelengths viz., 380, 440, 500, 675, 870 nm for measuring AOT. The TCO is measured using three channels at 305.5, 312.5 and 320.0 nm, and the column WV at two wavelengths of 940 and 1020 nm. Observations were taken at Ahmedabad and at Mt Abu during 2013-14. Ahmedabad is an urban polluted site while Mt. Abu is a cleaner high altitude free tropospheric site. Variability of TCO,WV and AOT have been studied using diurnal, daily and monthly observations over Ahmedabad and over Mt. Abu. Correlations between TCO-WV, TCO-AOT, WV–AOT for daily observations are analyzed. Observation during 0900 to 1700 hrs on 6 and 8 March 2013 which were clear sunny days showed significant variability. On 6 March, the TCO varied from 256-268 DU, water vapour 0.73-0.86 cm, and AOT 0.13-0.21 with a peak at ~1500 hrs. On 8 March TCO varied from 252-261 DU, WV 0.75-0.95 cm, and AOT 0.22-0.31 with an abrupt decline at ~1330 hrs. On 11 March, sky was visibly hazy and it is found that AOT and WVwere much higher than the measurements on clear sky days . A set of observations during 6-7 April 2013 at Abu Road (MSL~0.2 km), Mt. Abu (MSL ~1.1 km) and at Gurushikhar (MSL ~1.7 km) provided the relative contributions of planetary boundary layer in the total column measurements of Ozone, WV and AOT. These results and other observed features during pre-monsoon and monsoon seasons over the western sites of India will be presented.

Title: ANALYSIS OF RAIN DROP SIZE DISTRIBUTION AND THEIR EFFECT ON RADIOWAVE PROPAGATION IN AKURE SOUTH – WEST, NIGERIA.

Presenter/First Author: Adewumi Oluwatoyin Ayo, Organization Not Listed, Akure,

Presenter/First Author Email: oluwawumiadetoyin@yahoo.com

Published Material: No

Abstract Body: Understanding the detailed structure and behavior of rainfall parameters estimated from radar is very important for improving the efficiency of space borne satellite sensors as well as ground based stations. Attenuation due to rain has been recognized as one of the major causes of unavailability of radio communication systems operating at frequencies above 10 GHz for space-Earth links. In order to design radio links for telecommunication and evaluate the attenuation due to rainfall, it is important to have a good model for the rain Drop-Size Distributions (DSD). Two years of rainfall data obtained using the vertically looking low power micro rain radar at the Department of Physics, the Federal University of Technology, Akure, (7˚15'N, 5°15'E) has been analyzed to develop empirical model of raindrop size distribution (DSD) and their effects on radio wave propagation in Akure South-West, Nigeria. The rain rate was observed within the height range of 0 – 160 m up to 4800 m. For all the heights considered, rain drop size of diameter 0.246 mm had the largest concentrations in the height range 0 – 4800 m. Empirical relations in the form of vertical profile of Z –R relation were also obtained for different rainfall types in order to understand the variability of the relationship at this location.

KEYWORDS: RAINRATE, RAIN DROP SIZE, RAIN ATTENUATION, RADAR REFLECTIVITY.

Title: The climate impact of short wave upwelling radiative flux on the global energy budget using GENSPECT synthetic model along with Argus 1000 spectrometer.

Presenter/First Author: Rehan Siddiqui, York University, Mississauga, ON

Presenter/First Author Email: rehanrul@yorku.ca

Co-authors: Brendan M Quine, , , ; Rajinder K Jagpal, York University, Toronto, ON, Canada; Naif Al Salem, , , ; Sanjar Abrarov, , ,

Abstract Body: The integrated absorption technique is applied to develop a synthetic model to determine the magnitude of Shortwave upwelling Radiative Flux (SWupRF) by O_2, H_2O, CO_2 and CH_4. This new synthetic model is used to estimate the magnitude and expected magnitude variation over spectral range of 900nm to 1700nm by varying surface temperature to assess effect on outgoing (upwelling) forcing term. In this work we employ satellite real observation of space orbiting Argus 1000 especially for O_2, H_2O, CO_2 and CH_4 together with synthetic model by using line by line GENSPECT radiative transfer model. All the radiative transfer simulations have been performed by varying over a different range of percentages of water vapor contents and carbon dioxide with the fixed concentration oxygen and methane. This large scale results of synthetic and observed spectrums have been used to develop an algorithm for SWupRF of given greenhouse gases. We calculate and compare both the synthetic and real measured observed data set. The minimum and maximum range of SWupRF are 0.235 [0.13 to 0.34] W/m^2 and 0.835 [0.05 to 1.62] W/m^2 of the few selected set of week per pass of the ARGUS observed data. The simulated range of synthetic model also represents 1 to 32 K rise of temperature within the different concentration of water vapor and other gases. The authors concluded that the satellite observed data of week 2 pass 94 with packet number 98 & week 71 pass 27 with packet 17 showing maximum 1.62 W/m^2 and minimum 0.05 W/m^2 SWupRF respectively.

Title: Signature of Greenhouse Cooling in the Earth's Middle Atmosphere Observed by Lidar and Satellite over Sub-tropical Locations

Presenter/First Author: Som Kumar Sharma, Physical Research Laboratory, Ahmedabad,

Presenter/First Author Email: somkumar@prl.res.in

Co-authors: Harish Chandra, , , ; Shyam Lal, Physical Research Laboratory, Ahmedabad, India; Y B Acharya, , ,

Abstract Body: Lidar is a versatile atmospheric probe for providing height profile of temperature in the middle atmospheric region. A Nd:YAG laser based Rayleigh Lidar was set up, at a high altitude observatory near Mt. Abu (24.5° N, 72.7° E, altitude 1.7 km), in the Indian sub-tropical region. Temperature climatology in the middle atmosphere has been studied using about 17 years (1997 to 2014, with some data gaps) lidar observations. Consistently good data series has been used for deriving long term trends in the middle atmosphere. A multivariable analysis is used to consider natural variability (Solar Cycle and QBO) and similarly the changes in stratospheric ozone concentration due to anthropogenic activity have also been taken into account in trends estimations. We have selected different height regions 30-40, 40-50 and 50-60 km for trends analysis. Linear Regression analysis is applied to calculate temperature trend in different altitude regions. Considering the signature of seasonal, QBO and solar cycle variability, a linear decreasing temperature (cooling) has been found. Observed temperature trend is the strongest (-0.38 ± 0.15 K/year) at stratopause level (45 km) and the weakest (-0.13 ± 0.28 K/year) at 55 km during April. Seasonally, stronger temperature trends are found during winter -4.4 ± 2.8, -5.1 ± 2.1 and -2.3 ± 1.9 K/decade at 35, 45 and 55 km, respectively. The temperature trends during summer months are -2.2 ± 1.8, -2.8 ± 1.4 and -2.5 ± 1.6 K/decade at 35, 45 and 55 km, respectively. Lidar observed temperature trends over Mt. Abu are also compared with HALOE (onboard UARS) and SABER (onboard TIMED) temperature observations.

Title: Mass-dependent (MDF) and mass-independent (MIF) sulfur isotope compositions of aerosols in the atmosphere of Montréal (Canada)

Presenter/First Author: David Au Yang, GEOTOP-UQAM, Montreal, QC

Presenter/First Author Email: auyang@ipgp.fr

Co-authors: Guillaume Landais, , , ; Nelly Assayag, Institut de Physique du Globe de Paris, Paris, France; Thi Hao Bui, McGill University, Montreal, QC, Canada; Boswell A Wing, McGill University, Montreal, QC, Canada; David Widory, GEOTOP-UQAM, Montreal, QC, Canada; Pierre Cartigny, Institut de Physique du Globe de Paris, Paris, France

Abstract Body: We report improvements for the simultaneous determination of multiple sulfur isotope compositions for both $\delta^{33}S$, $\delta^{34}S$ and $\delta^{36}S$ on the SF_6 molecule (m/z: 127, 128, 129, 131) for quantities down to 0.4 micromoles, and $\delta^{33}S$, $\delta^{34}S$ for quantities down to 20 nanomoles. Multiple analyses of two international Ag_2S standards, IAEA-S1 and IAEA-S3, yield a narrow range of $\delta^{34}S$ values vs CDT, with a standard deviation of ± 0.2‰. This ultimately allows the determination of the $\Delta^{33}S$ with an accuracy of ± 0.03‰ (1σ), $\Delta^{36}S$ from IAEA-S3 measurements still show larger variations with a standard deviation of ± 1‰ (1σ).

The sulfur multi-isotope analysis of atmospheric emissions from the major sources in the urban environment (road traffic, waste incinerators, heating, thermal plants and cement factories) shows that they can unambiguously be discriminated when coupling their S MDF-MIF isotope compositions. We are currently analyzing PM_{10} (aerodynamical diameter <10µm) samples collected by the *Ville de Montreal* within the Montreal island since 1969 at 6 stations typical of distinct environments including road traffic, harbor, downtown, and natural background.

This temporal recording will allow us 1) to characterize the sources and processes controlling the atmospheric sulfur budget and 2) to evaluate potential variations with time resulting from the implementation of the Canadian and Quebecoise air regulations regarding sulfur.

Title: Characterising VOC emissions from Australian forest fires on the ground: results from field and laboratory measurements

Presenter/First Author: Elise-Andree Guerette, , Fairy Meadow, NSW

Presenter/First Author Email: eag873@uowmail.edu.au

Co-authors: Clare Paton-Walsh, University of Wollongong, Wollongong, Australia

Published Material: Part of this work has been presented at Australian scientific meetings.

Abstract Body: Australia's climate is hot, dry and fire-prone. Average gross annual emissions of total carbon from fires actually exceed those from burning fossil fuels, although net emissions are lower due to rapid regrowth [*Haverd et al.*, 2013]. An estimated 12 Mha of southern Australian forests were burnt in bushfires between 2001 and 2010, undoubtedly impacting atmospheric composition and regional air quality, yet measurements of emissions from Australian forest fires are scarce and include very few volatile organic compounds.

Emissions from dry sclerophyll forest fuels were measured at prescribed burns in Australian temperate forest during the 2012 and 2013 controlled burn seasons and at a combustion wind tunnel facility in 2014. VOCs were characterised in grab samples collected at the fires using a Selected Ion Flow Tube Mass Spectrometer and a White cell Fourier Transform Infrared (FTIR) system. The FTIR system also yielded mixing ratios for CO_2 and CO, enabling the determination of emission ratios for the VOCs measured in the grab samples. An open-path FTIR system was also deployed at some of the prescribed fires [*Paton-Walsh et al.*, 2014] and at the combustion wind tunnel facility. This open-path system provided continuous measurements of CO_2, CO, methane and some VOCs from which whole-fire emission factors were derived. Emission factors for the VOCs measured in the grab samples were then calculated from their emission ratio to CO (or CO_2) and the open-path emission factors. The emission ratios from the grab samples are compared to those obtained by open-path FTIR when possible (i.e. when a species was measured by both methods) and to values listed in the literature for similar ecosystems. The relationship between combustion efficiency and emissions is discussed.

Title: Mineralogical study of Particulate Matter in the Urban environment of Pune

Presenter/First Author: Suman Yadav, Department of Chemistry, Savitribai Phule Pune University, Pune , India, Pune,

Presenter/First Author Email: suman.yadv@gmail.com

Published Material: Some part had been published in IJEST

Abstract Body: The study of toxic metals and mineral components in atmospheric particulate matter is important in discerning and improving air quality in terms of both climate and health aspects. Present study reports quantification of PM bound metals, morphology of PM and their associated minerals. PM_{10} samples were collected by Mini-Vol TAS sampler at an urban site of Pune. In the present study Ca was highest (3.1 µg m^{-3}) followed by Fe > K > Al > Mg > Ni > Zn > Cr > Co > Cu > Cd > Mn > Pb > Ba. The morphology and mineralogical composition of the PM samples was studied by scanning electron microscopy–energy dispersive spectrometer and X-ray diffraction (XRD). Quantitative image analyzer (Image J) was used to study 620 individual particles and found that value of roundness (R) varies from 0.26 to 1.0 (mean 0.72) which suggests that particles vary in shape from nearly irregular to perfectly spherical shape. Various shaped particles such as spherical, cube, needle shaped, rectangular, irregular and agglomerates types were observed. Based on the morphology of the particles, the analyzed particles are classified into various groups such as crust originated particles, fuel and biomass burning associated particles, biological particles and unidentified particles. The XRD results showed that minerals in the PM were dominated by silicates (quartz, wollastonite, vermiculite, kaolinite and calcium aluminum silicates) followed by oxides (calcium iron oxide, magnetite and wuestite), sulfates (gypsum, koktaite), phosphates (magnesium and silicon phosphates) carbonate (dolomite), iron–zinc and halite.

Title: A Two Beam Cavity-Enhanced Absorption Spectrometer for Atmospheric Trace Gas Sensing.

Presenter/First Author: Satheesh Chandran P M, National Institute of Technology Calicut, Calicut,

Presenter/First Author Email: pmsc85@gmail.com

Co-authors: Ravi M Varma, NIT Calicut, Calicut, India

Abstract Body: Detection of trace gas pollutants with high temporal and spatial resolution is a key problem in atmospheric science. The new instrumentation for detecting trace pollutants and their laboratory demonstration is a vibrant research area. Cavity-enhanced absorption spectroscopy (CEAS) techniques are widely used in atmospheric pollutant monitoring as a non- invasive way for the in-situ detection of trace species. A two-beam cavity-enhanced absorption spectrometer has been developed with the ability of monitoring sample and reference cavity signals simultaneously. We present the laboratory demonstration this instrument and its feasibility for fast and reliable measurement of trace pollutant NO_2 for a wide concentration ranges.

Title: Deforestation in Cameroon and its Consequences to the Natural Environment

Presenter/First Author: Dominic Alemanji Bezejouh, Organization Not Listed, Washington, DC

Presenter/First Author Email: dominicalemanji@yahoo.com

Abstract Body: The 17 million hectares of humid forest covering the southern part of Cameroon have received much attention in recent years, including its estimated annual loss of forest cover of 129,000 hectares or 0.6% of total forest between 1990 and 1995. Shifting cultivation and population growth are the main causes of deforestation in Cameroon. Through shifting cultivation farmlands are repeatedly burnt down leading to exposure of forests and soil erosion. Bush burning also produces carbon dioxide which impacts climate by destroying the ozone layer. Other factors contributing to deforestation are the cutting down of tress for timber, road construction, and cultivation of cash crops like coffee and cocoa.

The rapid deforestation process in Cameroon has consequences, such as global warming, loss of biological and genetic diversity, land degradation, soil erosion, watershed destruction, flooding and siltation, loss of income from timber and non timber forest products, loss of wildlife especially Some important species of animals like the chimpanzees and gorillas. Cameroon is blessed with a variety, of climate and ecosystems, harboring some 8260 plant species of which 156 are endemic, about 2000 animal species, and is 5th in Africa in terms of biodiversity. The soil can be exploited only one to three years before the nutrients are exhausted and farmers are forced to move to sites thereby destroying more forest.

Plantation agriculture, which covers extensive areas in southern Cameroon, plays a vital role in its economy. To reduce the rate of deforestation in Cameroon, the government needs to encourage mechanized agriculture that will occupy a particular piece of land for continuous cultivation. By so doing, shifting cultivation which is the main cause of deforestation will eventually reduce.

Title: Role of metal induced free radical generation by ambient particulate matter in Pune, India

Presenter/First Author: Gursumeeran P Satsangi, Savitribai Phule Pune University, Pune,

Presenter/First Author Email: pgsatsangi@chem.unipune.ac.in

Co-authors: Suman Yadav, Department of Chemistry, Savitribai Phule Pune University, Pune , India, Pune, India; Ritwika Roy, , , ; Rohi Jan, , ,

Published Material: Abstract Free radical generation in particulate matter has been cited as potential contributors to particle toxicity leading to large number of health effects. In this present study the association between the metals, free radical and DNA damage was assessed in Pune. ICP-AES was used to examine the metal composition, EPR technique for free radical detection and plasmid DNA assay was utilized to study the oxidative potential of ambient PM. The results of ICP-AES analysis showed that Fe was the metal present in the highest concentrations followed by Zn and Pb. EPR analysis shows 'g' value for free radicals ranging from 2.002 – 2.003 in PM samples of Pune. PM contains both purely C-centered (g = 2.0023) and C- centered radical with vicinal oxygen atom (g = 2.003). The indirect assays (DTT and DPPH) were performed for ensuring the existence of specific free radicals (such as superoxide and hydroxyl radical) which supported the presence of higher redox activity in PM. The assays performed for assessing oxidative stress showed significant correlation with transition metals such as Fe (r= 0.67) and Cu (r= 0.63), suggesting that these metals play an important role in generation of free radicals and its related toxicity. Toxicity of collected samples was evaluated by gel electrophoresis technique and results showed 70% of DNA damage in collected PM. Key words: Toxic metals, free radicals, DNA plasmid assay, DPPH

Title: Facilitating JPSS-1 algorithm development using EPL review process

Presenter/First Author: Valerie Jean Mikles, IMSG, College Park, MD

Presenter/First Author Email: valerie.mikles@noaa.gov

Co-authors: Kristina Sprietzer, IMSG, College Park, MD; Bigyani Das, IMSG, College Park, MD; Walter Wolf, NOAA/NESDIS/STAR, College Park, MD; Marina Tsidulko, IMSG, College Park, MD; Weizhong Chen, IMSG, College Park, MD

Abstract Body: The NOAA/NESDIS Center for Satellite Research and Applications (STAR) Algorithm Integration Team (AIT) provides technical support of the Joint Polar Satellite System (JPSS) algorithm development and integration tasks. STAR AIT is well-integrated in the algorithm change process, coordinating between science algorithm developers and operational engineers to smooth the transition of a code from research to operation. AIT facilitates the development of JPSS-1 algorithms by implementing a review approach based on the Enterprise Product Lifecycle (EPL) process. Building on relationships established during the Suomi-NPP algorithm development process and coordinating directly with science algorithm developers, the AIT has implemented structured reviews with self-contained document suites. We have completed multiple reviews for Sensor Data Record (SDR) and Environmental Data Record (EDR) algorithms, ensuring that all stakeholders are kept apprised of development decisions and that our delivered algorithm packages are functional and complete. STAR AIT also maintains configuration management on the algorithm and documents and has developed tools to more efficiently manage parallel content between the existing requirements and review documents. The process has supported algorithm improvements for products such as ozone, active fire, vegetation index, and temperature and moisture profiles. The review process, its implementation, and the content management shall be discussed.

Title: Development of the Novel Green Hybrid Bio-Reactor-Oxyfuel-Nano/Micro Interface

Presenter/First Author: Andrea A Rocha, McGill University, Montreal,

Presenter/First Author Email: andrea.rocha@mail.mcgill.ca

Co-authors: Christian Wilde, , , ; Parisa A Ariya, McGill University, Montreal, QC, Canada

Abstract Body: Carbon dioxide is one of the main greenhouse gases, known to contribute to global warming. A major source of anthropogenic CO_2 is from the combustion of fossil fuels, hence the application of mitigation techniques on combustion processes to capture CO_2 are of great importance to reduce emissions being released to the atmosphere. We proposed development on a novel green algal bioreactor-oxyfuel system coupled with natural nano- and micro-particle interfaces containing magnetite, hematite and alumina. Two systems were considered: a semi-continuous oxygen production system, and a batch oxygen enrichment system. We will present our results and discuss the cost-effectiveness of the newly developed system with a potential to couple it to existing industrial setups.

Title: Optical and physical characteristics of biomass-burning aerosols over Alberta

Presenter/First Author: Hebaalah S Marey, University of Alberta, Edmonton, AB

Presenter/First Author Email: marey@ualberta.ca

Co-authors: Zaher Hashisho, University of Alberta, Edmonton, AB, Canada; Long Fu, AEMERA, Edmonton, AB, Canada; John C Gille, NCAR, Boulder, CO

Abstract Body: Aerosol emissions from biomass burning have a large effect on the atmospheric composition and climate change. In summer (June-August) 2012, Alberta faced the highest number of fire events in the last decade as indicated by MODIS fire count (~9,000 fire counts) and total CO column derived from the Atmospheric InfraRed Sounder (AIRS) instrument (> 3×10^{18} molecules cm^{-2}). The present study examines the impact of these fire events on aerosol properties, as well as the long-range transport of smoke plumes, and altitude characteristics using satellite data and AErosol RObotic NETwork (AERONET) measurements. During July 2012, Moderate Resolution Imaging Spectroradiometer (MODIS) images show a thick smoke/hazy aerosol layer covering northern Alberta. The increased number of fire counts is associated with severe aerosol-laden atmosphere as indicated by the high values of aerosol optical depth (AOD) (> 1.0), high values of Angstrom exponent (>1.2), and enhanced Ozone Monitoring Instrument (OMI) UV Aerosol Index (AI) (> 4.0) which are significantly higher than monthly means. Good agreement with linear correlation of ~95% was found for MODIS and AERONET AOD at Fort McMurray station. The AERONET aerosol size distribution is shifted toward the fine-mode fraction which is corroborated by the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) depolarization ratio, indicating dominance of smoke aerosols. The air mass trajectories originating from northern Alberta regions with biomass-burning sources together with CALIPSO backscatter profiles at 532 nm reveal a potential aerosol transport pathway from west to east of Alberta, resulting in a strong AOD gradient with a maximum plume top height of 5 km. These results show that the synergistic use of several remote sensing instruments, results in a more comprehensive view of potential atmospheric impacts of long-range transport of smoke emissions.

Title: Extreme Cases of Tropospheric Convergence of Moisture Transport and their Relationships to Precipitation for the US Midwest

Presenter/First Author: Laura Twidle, McGill University, Montreal,

Presenter/First Author Email: laura.twidle@gmail.com

Co-authors: John R Gyakum, McGill University, Montreal, QC, Canada; Eyad Atallah, McGill University, Montreal, QC, Canada

Abstract Body: The Midwest US is prone to receiving heavy precipitation events, including Mesoscale Convective Systems (MCSs), during the warm season. These MCSs may produce rainfalls, in a 1-2 day period, with amounts well above the monthly climatology. The ability to recognize the patterns and mechanisms that accompany these convective systems is crucial for forecasting their timing and location. Convergence of moisture transport (CMT) is a useful tool in short-term prediction of convection since it contains information on the low-level forcing and the amount of moisture available. However, if there is no support in the upper levels then the likelihood of thunderstorm development is significantly diminished. Using the NARR (North American Regional Reanalysis) data set, the column integrated CMT was computed every 3 hours during a 36-year period (1979-2014) through the months of May to August. A 24-hour running mean was applied to the 3-hourly column-integrated CMT, and the 99th percentile of events were selected. An additional criterion ensuring synoptic independence (five days before/after the largest event) was applied, yielding 65 cases. The low-level moisture transport (1000-700hPa) was analyzed for each case, facilitating the classification of cases. Classifications include 1) southwesterly, 2) high amplitude, 3) low amplitude, 4) cold surge, and 5) southeasterly flow. The overall atmospheric circulation structures differ substantially among the categories. Perhaps surprisingly, there were several cases that actually showed very little precipitation. Further analyses of these light precipitation cases are being studied.

Title: Does the helium isotope composition of air vary with latitude ? A new high precision study.

Presenter/First Author: Christine Boucher, CRPG Centre de Recherches Pétrographiques et Géochimiques, Nancy,

Presenter/First Author Email: christinebouc@hotmail.com

Co-authors: Bernard Marty, CRPG Centre de Recherches Pétrographiques et Géochimiques, Vandoeuvre-Les-Nancy, France; Pete Burnard, CNRS, Paris Cedex 16, France

Abstract Body: Crustal, mantle and atmospheric sources have characteristic helium isotope signatures. Compared to the atmosphere, crust derived volatiles are enriched in radiogenic helium-4, while gases of mantle origin are enriched in primordial helium-3. The atmospheric helium isotope ratio, $(1.39 \pm 0.01) \times 10^{-6}$, is conventionally considered to be constant on a global scale [2]. This convention is questionable, however, since Sano et al. (1988) [3] reported a lower ratio of $(1.343 \pm 0.013) \times 10^{-6}$ from Tokyo, Japan. In 2010, a further study showed an increase of $(0.16 \pm 0.08) \times 10^{-5}$ R_{HESJ}/degree of latitude, where R_{HESJ} is the $^3He/^4He$ ratio of the Helium Standard of Japan [5]. This could be linked to release of crustal helium into the atmosphere from mining and burning of fossil fuels on short timescales, which is more prevalent in the northern atmosphere [3, 4; see also 1]. Thus, fluxes and retention of anthropogenic CO_2 in the atmosphere could be traced by helium isotope variations in air [3]. Nevertheless, others parameters could explain the reported variations in atmospheric $^3He/^4He$ such as local natural or anthropogenic phenomena at the sampling sites, weather patterns or experimental/analytical problems. Since the variation seems to be less than one ppm, substantial refined statistical analysis is essential in order to discern the accuracy of analyses. Ten samples from different latitudes around the world were repeated analysed by the multi-aliquot measurement method (based on [6]). No evidence of a systematic variation in the atmospheric $^3He/^4He$ ratio at the three permil level is found in air samples from Tokyo (35.69°N), Yellowstone (45.28°N), Svalbard (78°N), Hawaii (21.31°N), Sicily (37.48°N), Djibouti (11.57°N), South Africa (25.79°S) and Tasmania (40.68°S).

Title: The Relevance of Aerosols to Ice Formation in Clouds

Presenter/First Author: Rodrigo Benjamin Rangel-Alvarado, McGill University, Montreal,

Presenter/First Author Email: rodrigo.rangel-alvarado@mail.mcgill.ca

Co-authors: Yevgen Nazarenko, McGill University, Montreal, QC, Canada; Parisa A Ariya, McGill University, Montreal, QC, Canada

Abstract Body: Clouds contribute to the total radiative forcing that drives climate change. However, one of the major causes of uncertainty of the total radiative forcing is related to aerosols and their interactions with clouds. It is known that ice clouds can form spontaneously from pure water, but the temperatures at which this happens are extremely low, around -38°C. The presence of aerosols facilitates ice cloud formation by providing a nucleus, on which ice can start growing at temperatures closer to the melting point of water in a process called heterogeneous ice nucleation. The process of heterogeneous ice nucleation exhibits dependency on the size of participating aerosols. Furthermore, it has been demonstrated that many aerosols that are smaller than 800 nm in diameter, start nucleating ice at very low temperatures, close to the temperatures of ice nucleation of pure water. Thus, they are not considered in cloud modelling. Additionally, aerosols efficient at higher temperature ice nucleation with low number densities are disregarded. In summary, many models of cloud formation do not take into account the possible contributions of a fraction of aerosols. We herein show the existence of aerosols from < 100 nm to ~ 1 µm in diameter within snow that could be responsible for the nucleation of ice clouds where the snow formed. We will present our data on number density, size distribution and ice nucleation of the detected particles and will discuss their impact on atmospheric processes.

Title: Assessing U.S. Embassy in Beijing's measurements of $PM_{2.5}$

Presenter/First Author: Anondo D Mukherjee, University of Colorado at Boulder, Boulder, CO

Presenter/First Author Email: anondo.mukherjee@colorado.edu

Co-authors: Darin W Toohey, Univ Colorado, Boulder, CO

Abstract Body: The United States Embassy in Beijing, China, has been measuring mass concentrations of particulate matter of particle diameters 2.5 micrometers and smaller ($PM_{2.5}$) since 2008. Results were initially reported in near-real time on Twitter and, more recently, archived results have been made available at the U.S. Embassy website. Here, we combine the U.S. Embassy $PM_{2.5}$ measurements with other concurrent observations recorded nearby from several sources, including visibility index available from the U.S. National Climatic Data Center and a recent paper by J. K. Zhang et al, (Atmospheric Chemistry and Physics, vol. 14, 2887-2903, 2014) to examine the validity of the U.S. Embassy measurements. We find a good relationship between $PM_{2.5}$ and visibility, with a strong dependence of the latter on relative humidity as expected. The slope of a plot of $PM_{2.5}$ to the inverse of visibility length is consistent with values expected from Koschmieder's equation. Embassy $PM_{2.5}$ values measured from January 1st to February 1st 2013 agree well with values reported form a nearby site using the techniques of TEOM $PM_{2.5}$ and aerosol mass spectrometry PM_1, with important deviations between $PM_{2.5}$ and PM_1 during periods of likely enhanced transport of larger particles (e.g., dust) from nearby and distant sources. We conclude that the U.S. Embassy observations could represent a useful historical dataset for studies of improvements in air quality in Beijing as China implements measures to reduce emissions of particles and their precursors. Preliminary comparisons of similar data sets from other cities in China with similar U.S.-installed instruments also appear to be valuable in this regard.

Title: Characterizing the role of natural and forced air temperature variability in the Labrador region of northeastern Canada

Presenter/First Author: Robert G Way, University of Ottawa, Ottawa, ON

Presenter/First Author Email: rway024@uottawa.ca

Co-authors: Andre E Viau, University of Ottawa, Ottawa, ON, Canada

Published Material: Some materials were published in:Way, R.G. and Viau, A.E. (In press). Natural and forced air temperature variability in the Labrador region of Canada during the past century. Theoretical and Applied Climatology.

Abstract Body: Air temperatures in the Labrador region of northeastern Canada are particularly sensitive to ocean-atmospheric telleconnections due to the region's proximity to the Labrador Current and its position near the Canadian Polar Trough. Instrumental and paleoclimate reconstructions show pronounced multidecadal variability in regional air temperatures over the past several centuries highlighting the importance of unforced and forced variations in the region's climate. Throughout much of the past century, air temperatures in Labrador remained fairly stable albeit with multidecadal variations. However, over the past 20 years regional warming has accelerated rapidly according to both instrumental and satellite datasets. Recent winter positive anomalies, in particular, have had negative impacts on the region's aboriginal populations who rely on ice and snow for accessing traditional grounds. Coupled with the strains of living in an isolated northern environment, recent warming has challenged the adaptive capacity of communities to cope with recent environmental change.

Expanding upon recent work by Way and Viau (*in press* - Theoretical and Applied Climatology) this paper provides a detailed examination of the main drivers of regional climate variability over both long and short timescales. We show that rapid regional warming over the past two decades is linked to both natural and anthropogenic factors with several anomalously warm years related to recent anomalies in the Arctic Oscillation (AO) and North Atlantic sea surface temperatures (AMO). This contribution also provides a comparison with another recent climate analysis of Labrador by Finnis and Bell (*in press* - Canadian Geographer) showing that certain data selection choices in the latter study exaggerated the role of natural variability in recent warming. In comparing with future climate scenarios, our results suggest that the anomalously warm conditions observed in 2006 and 2010 are similar in magnitude to climate conditions projected for the mid-21st century under high emissions scenarios (i.e. RCP 8.5). The largest sources of uncertainty in projecting regional climatic changes appear to result from differences between the various emission scenarios and the variability in North Atlantic sea surface temperatures.

Title: Projection of late 21st century (2071–2100) fine-scale climate changes over the Korean Peninsula using RegCM4 based on four RCP scenarios

Presenter/First Author: Myoung-Seok Suh, Kongju National University, Gongju,

Presenter/First Author Email: sms416@kongju.ac.kr

Co-authors: Young-Seok Lee, Kongju National University, Gongju, South Korea; Seok-Geun Oh, Kongju National University, Gongju, South Korea

Abstract Body: In this study, we projected late 21st century (2071–2100) fine-scale climate changes over the Korean Peninsula using RegCM4 based on the four Representative Concentration Pathway (RCP) scenarios (2.6, 4.5, 6.0, and 8.5). HadGEM2-AO data provided by the National Institute of Meteorological Research was used as the lateral boundary conditions for RegCM4 with a horizontal resolution of 12.5 km. The simulation skills of RegCM4 for the spatio-temporal variations of current climate (1981-2010) over Northeast Asia are evaluated using CRU data. The annual mean temperature over South Korea in the late 21st century is expected to increase by about +1.62°C, +2.71°C, +2.76°C, and +4.53°C, respectively, compared with the present climate under the RCP scenarios. Annual precipitation is projected to increase by about +0.24 mm/day and +0.40 mm/day under the RCP2.6 and RCP8.5 scenarios, respectively. Interannual variability (IAV) of temperature is projected to increase and decrease significantly under RCP6.0 and RCP8.5 and RCP2.6 and RCP4.5, respectively. The significant increase in IAV of temperature under RCP6.0 and RCP8.5 indicates the possibility that abnormal temperatures may be increased in the late 21st century. Additionally, the IAV of summer precipitation is also projected to clearly increaseunder RCP6.0. The portion of heavy rainfalls (> 50 mm/day) is also expected to increase irrespective of scenarios, which indicates the possibility that extreme droughts and heavy rainfalls may be increased.This is considered to be related to the fact that destabilized atmospheric environmentsby the combined effects of increased temperature and mixing ratio at the lower troposphere and the increased cold advection at the upper troposphere.

Abstract Body: In this study, we assessed the simulation skills of RegCM4 for the diurnal variations of temperature and precipitation over South Korea using the 30-year (1981-2010) fine-scale simulation results over North-East Asian region. The simulations performed by RegCM4 with 12.5 km of horizontal resolution driven by the Hadley Center Global Environmental Model version 2 coupled with the Atmosphere–Ocean (HadGEM2-AO). The model configuration is same as the study of Hong *et al.*(2013) and simulation skills of RegCM4 were evaluated with the hourly observations of Korea Meteorological Administration (KMA). In general, the simulations skills of RegCM4 for the diurnal variations of temperature and precipitation vary depending the geographic locations and seasons. RegCM4 well simulated the diurnal variation of temperature as compared with KMA observation, with better skills during morning and significantly less skills during afternoon, regardless of months. The less skills of RegCM4 during afternoon are mainly caused by the significant under-simulation of temperature over inland areas without regard to seasons. As the results, the magnitude of diurnal range of temperature strongly underestimated in inland areas. However, the simulations skills for diurnal variations of precipitation are not so promising, in particular, during summer, with relatively better skills during afternoon and significantly less skills during early morning. The significant underestimation of precipitation during early morning at the western area of the Korean peninsula resulted in the low spatial correlations and underestimation of variance compared to the observations.

Title: Climate Change and Climate Variability Effects on Agricultural Food Production in Kieni East District, Nyeri County, Kenya.

Presenter/First Author: Eunice WANJIRU Kibung`a, Regional Centre for Mapping of Resources for Development, Nairobi,

Presenter/First Author Email: ekibunga@rcmrd.org

Co-authors: Osunga MICHAEL Otieno, Regional Centre For Mapping Resource For Development, Kasarani, Kenya

Abstract Body: Kenya like the rest of the world is experiencing climate change and climate variability and the associated adverse effects with significance on food security. Rainfall trends and temperature variance are evidence of climate change and variability through heat stress, droughts, rainfall variations, distribution changes and flooding leading to crop failure and reductions in yields. The purpose of the study is to assess the effects of climate change and variability on agriculture, estimate rainfall amounts, distribution, trends, temperature variance, vegetation health and vigor of the study area, crop yields per crop type over a continuous period of time. The target population is eco-climatic variables Rainfall amounts, distribution and trends, Temperature variance, vegetation cover, vegetation health and vigor, and crop yield. The sampling technique will be purposive sampling for vegetation index, rainfall amounts, temperatures and crop yields. Research instruments for data collection are Satellite Data Analysis using GIS/Remote Sensing Techniques, interviews with agricultural officers and local farmers, Questionnaires and Field Surveys. Datasets to be used will include SPOTVGT 1Km, climate data from satellite measurements of FEWSNETRFE 1Km and KMD, temperature using MODIS and Crop Yields from KNCPB and the collection procedure for satellite imagery acquisition, preprocessing, interpretation, analysis scheduled interviews, Questionnaires and field observation and validation and acquire information impossible to obtain from satellite data. Data processing will use GIS/RS Software ArcGIS, Erdas, Envi, Ilwis and Microsoft Access. Supervised Classification of Landsat image to identify agricultural landextent and crop type. Vegetation Index will be derived from SPOTVGT NDVI and a temporal analysis to illustrate trends of vegetation vigor using Erdas/ ILWIS/ ENVI. Cumulative Rainfall amounts trendsanalysis distribution and Yields data will be generated. The time frame for the study will be 25yrs. This study looks forward to improving community livelihoods through sustainable utilization of available resources and reduce food shortage and insecurity.

Title: Assessment of South-West and North-East Monsoon over Indian continent using CMIP5 models

Presenter/First Author: Dipti Swapnil Hingmire, Indian Institute of Tropical Meteorology, Pune,

Presenter/First Author Email: diptikalyanshetti@gmail.com

Co-authors: Milind Mujumdar, Indian Institute of Tropical Meteorology, Pune, Pune, India; Sooraj K.P., Indian Institute of Tropical Meteorology, Pune, Pune, India; Ashok Karumuri, , , ; R Krishnan, Indian Institute of Tropical Meteorology, Pune, Pune, India

Abstract Body: India is benefited by two distinct Monsoons. One is the South-West Monsoon (SWM), spanning from June to September, covering almost entire country and bringing about 75% of annual rainfall to India. Another is North-East Monsoon (NEM), commencing from October to December, confined to southern peninsular region and bringing about 11% of annual rainfall to India.

This study compares the present-day skill of 36 state-of-the-art coupled global climate models (GCM) taking part in Coupled Model Intercomparison Project 5 (CMIP5) in simulating NEM and SWM of India. Our analysis uses the simulations from historical runs of CMIP5 models during 1979-2005. The performance of 36 coupled models for the present-day climate is assessed using Taylor diagram, based on the consensus in simulating climatology and interannual variability of NEM and SWM rainfall. The Global Precipitation Climatology Project (GPCP) monthly precipitation dataset is used as reference data. Our analysis reveals large model spread in simulating the observed climate statistics for NEM and SWM rainfall. Considering this large model spread, the selection of best performing models are performed using the following criteria: (1) the pattern correlation in seasonal climatology is above 0.6 (2) the normalized standard deviation of seasonal climatology is between 0.75 and 1.25 (3) the pattern correlation in the interannual standard deviation is above 0.5 and (4) the normalized spatial standard deviation of interannual standard deviation is between 0.75 and 1.25. Out of 36 models, 5 models (BNU-ESM, IPSL-CM5A-MR, GFDL-ESM2G, CNRM-CM5, MRI-CGCM3) are qualified as optimally best performing models in simulating NEM. In contrast for SWM, none of the CMIP5 models satisfies the prescribed criteria, indicating that the models show better skill in simulating NEM compared to SWM. The process studies focusing on systematic errors at regional scale are performed to understand the differences in model skills. Our study has huge implications for useful regional projections as downscaling of the local precipitation is subjected to this inherent uncertainty.

Title: Sensitivity of snow crystal habit on the formation of winter precipitation types

Presenter/First Author: Julie M Theriault, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: theriault.julie@uqam.ca

Co-authors: Housseyni Sankare, Université du Québec à Montréal, Montréal, QC, Canada

Published Material: Some of the preliminary findings have been presented as a poster presentation at the CMOS congress in 2014. The submitted abstract to AGU presents new updated results.

Abstract Body: During winter storms, it is common to observe several types of precipitation, in particular, when the temperature is near 0°C. These can be on the form of supercooled liquid, solid and a mixture of both solid and liquid water. For example, wet snow and freezing rain are the most damaging. They are formed when a warmer layer (T> 0°C) is located above a sub-freezing layer (T<0°C) near the surface. The precise prediction of the type of precipitation at the surface is critical because it affects the severity of the storm. The goal of this study is to assess the impact of the snow crystal habit on the formation of winter precipitation types aloft and at the surface. To address this, a one dimensional cloud model coupled with a bulk microphysics scheme is used. Different crystal habits have been added to a bulk microphysics scheme to account for many types of winter precipitation. Note that this microphysics scheme originally accounted for only an average type of snow. The results will show how the terminal velocity of these types of snow varies with the liquid fraction. Based on this assumption, systematic studies on, for example, the link between the vertical temperature profile characteristics, the thickness of the warm layer aloft, precipitation rates, initial snowflake types and the production of surface precipitation types will be conducted. Overall, this study contributes to a better understanding of winter precipitation type formation mechanisms, which can lead to catastrophic weather events.

Title: A Comparison of the Winters of 2013-2014 and 2014-2015

Presenter/First Author: Eyad Atallah, McGill University, Montreal, QC

Presenter/First Author Email: eyad.atallah@gmail.com

Published Material: Early results were presented at the WWOSC in Montreal this past August.

Abstract Body: Observations since the 1940’s have shown that the preferential formation zones for the coldest air masses in the Northern Hemisphere are generally located near the Northwest Territories and Yukon of Canada as well as the Siberian regions of Russia. However, considerable inter-annual and decadal variability exists with recent decades (the past 30 years) indicating that the coldest air masses have been more commonly found over northwestern Canada and/or Greenland. The winter of 2013-2014 however deviated significantly from climatology in that the coldest air masses consistently formed over Canadian provinces that are east of the usual formation zones, in association with a polar vortex that generally resided in the vicinity of Hudson Bay. In fact, the persistence of the cold pool in the vicinity of Hudson Bay was unprecedented in the 66 year record of the reanalysis. Meanwhile, most of the rest of the Northern Hemisphere was experiencing near record warmth associated with similarly persistent flow regimes. The persistence of the flow regime over North America was seemingly related to an extreme warm pool over the east portion of the North Pacific which served as an anchor for a strongly diffluent jet exit region at the end of an abnormally retracted Pacific basin jet. The warm pool in conjunction with extremely favorable dynamics for ascent in the poleward jet region resulted in persistent storminess and diabatic heating that in turn was responsible for developing and anchoring a strong ridge along the western seaboard of North America. As this warm pool has propagated eastward toward the North American coast-line for this winter, we will investigate whether there is a corresponding phase shift in the pattern relative to 2013-2014. We will also investigate an apparent warm bias in medium range weather prediction in the vicinity of Hudson Bay for the winter of 2014-2015.

Title: Identifying synoptic-scale sources of short-term (3-10 day) zonal available potential energy generation

Presenter/First Author: Kevin Bowley, McGill University, Montreal, QC

Presenter/First Author Email: kevin.bowley@mail.mcgill.ca

Co-authors: John R Gyakum, McGill University, Montreal, QC, Canada; Eyad Atallah, McGill University, Montreal, QC, Canada

Abstract Body: Available potential energy (APE) is an estimate of the amount of potential energy in the atmosphere available for conversion to kinetic energy, providing a good proxy for the overall strength of the general circulation. In previous studies, estimates of total hemispheric APE, APE generation, and conversion to kinetic energy have been used to explain the annual APE cycle as well as shortterm APE depletion events by midlatitude cyclones. Here, we focus instead on how APE can be built up on short time scales (3-10 days). Using a standardized-anomaly based criteria, we identify a climatology of continuous build-up events of zonal APE in the Northern Hemisphere. These are divided into two subsets based on the final value of APE anomaly, either anomalously high or neutral. Several case studies are conducted to identify synoptic features in the Northern Hemisphere general circulation that help contribute to the generation of zonal APE. These include, but are not limited to, the filling of low-latitude low pressure systems, and collapses of high-latitude high pressure systems. Using a thermodynamic budget, we further explore sources of heating and cooling in the atmosphere in association with these changes to the mass fields. By exploring the changes to the thermodynamic structure of the troposphere, we will be able to assess the roles of static stability and horizontal temperature gradients, the two contributing terms in the zonal APE equation.

Title: Experimental Characterization of Turbulence in the Arctic Lower Troposphere Using Aircraft Measurements

Presenter/First Author: Amir Abbas Aliabadi, Environment Canada Dorval, Toronto, ON

Presenter/First Author Email: Amir.Aliabadi@ec.gc.ca

Co-authors: Ralf M Staebler, Environment Canada Toronto, Toronto, ON, Canada; Michael Liu, , ,

Abstract Body: It is known that atmospheric turbulence persists even in statically stable conditions. Such conditions are prevalent above the Planetary Boundary Layer (PBL) and also within the nocturnal or polar PBL. Characterization of turbulence under statically stable conditions is difficult since eddies form and disintegrate in an intermittent fashion. Due to the coarse grid resolutions and computational limits in Numerical Weather Prediction (NWP), turbulence modeling is typically treated in the form of vertical diffusion using the concept of eddy diffusivity. Thus, modeled turbulent fluxes of atmospheric quantities only depend on local diffusivities and are always directed in the opposite direction of the gradient of mean atmospheric quantities; i.e. they are proportional to the vertical gradients of mean momentum, temperature, or atmospheric constituents multiplied by a diffusivity term. This approach becomes less valid when prevalent eddies are large enough to cause transport of turbulent fluxes that appears counter-gradient on a local scale. Such is the case in statically stratified conditions.

The main effort of this study is to quantify such behavior in the Arctic lower troposphere, which is typically statically stable, and to further parameterize 'counter-gradient' transport of turbulent fluxes without compromising NWP model grid resolutions. Data was collected in the Canadian Arctic around Resolute, Nunavut, in the summer of 2014 using the Polar 6 aircraft equipped with a 40Hz meteorology sensor and other analyzers measuring atmospheric constituents including gases and particles. We have determined, experimentally, turbulent fluxes and diffusivities of momentum and heat, turbulent kinetic energy, mixing length, turbulent Prandtl number, local Richardson number, cross spectra, structure functions, and other local/non-local quantities which are essential parameters in atmospheric modeling. Functional dependencies are investigated among the measured quantities. This analysis further elucidates physical processes and may suggest improvements to parameterizations of turbulence within NWP algorithms.

Title: Characterizing the Structure and Behavior of Extreme Weather Events over the United States

Presenter/First Author: Robert X Black, Georgia Inst Tech School EAS, Atlanta, GA

Presenter/First Author Email: rob.black@eas.gatech.edu

Co-authors: Taewon Park, Georgia Institute of Technology, Atlanta, GA; Yi Deng, Georgia Institute of Technology Main Campus, Atlanta, GA

Abstract Body: Regional climate includes extreme weather events such as cold air outbreaks, heat waves, floods and droughts, all with substantial societal impacts. Such events are most commonly studied in terms of a station-based or ad hoc regional approach. We present a pilot study focusing on the objective isolation of the typical spatial structure and synoptic time evolution of extreme temperature events (ETEs) having a widespread impact over the continental United States. Using reanalysis data, segregated by season, we define ETEs using a threshold crossing procedure applied to local time series of surface air temperature. More specifically, we isolate uncommon, large amplitude events with anomaly magnitudes greater than 1.5 standard deviations. Simple point-wise statistical analyses are first performed. On any given day a certain fraction of the continental US will be affected by either anomalous cold or warm air anomalies satisfying the above criterion. To restrict attention to those ETEs having widespread impact, we then set an additional criterion: a minimum threshold for the percentage areal coverage (of the continental US) by such cold (or warm) anomalies. We then group together all days falling within the same event category (e.g., the cold threshold is exceeded over a sufficiently large fraction of the US). Each subgroup is then separately subjected to a cluster analysis to identify the most commonly occurring regional patterns. Once the clusters are identified, we then use the cluster occurrence as a basis for more fully characterizing the spatial structure and synoptic evolution of the different categories of ETEs. Results are presented for both cold and warm events occurring during the extended boreal warm and cool seasons, respectively. Each category of ETE event (e.g., cold air outbreaks during the cool season) is typically characterized by 4-5 distinct clusters. Events typically form and decay on synoptic time scales (3-4 days). The synoptic evolution contains dynamical elements at both synoptic and planetary spatial scales. Cold and warm events are found to sometimes coincide as high amplitude Rossby wave patterns can lead to their simultaneous (albeit regionally distinct) occurrence. Implications of the results for our physical understanding, simulation and prediction of ETEs are discussed.

Title: WRF and MM5 Modeling of the 1999 North American Monsoon Onset and the Las Vegas Flood

Presenter/First Author: Dorothea Ivanova, Embry-Riddle Aeronautical University, Prescott, AZ

Presenter/First Author Email: ivanovad@erau.edu

Co-authors: David L Mitchell, Desert Research Institute Reno, Reno, NV

Published Material: The Arizona/Great Basin onset of the 1999 North American monsoon (NAM) was simulated using the WRF and MM5 models. This onset also produced a major flooding event in Las Vegas, Nevada. Our working hypothesis states that sea surface temperatures (SST) in the northern Gulf of California (GC) may play a critical role in the timing and amount of summer rainfall over the U.S. southwest. In particular, the onset of relatively heavy rainfall occurs after these SSTs exceeded 29°C. This study explores the impact of GC SSTs on factors affecting deep convective precipitation: the regional atmospheric circulation, water vapor mixing ratio, convective available potential energy (CAPE) and convective inhibition (CIN). The impact of GC SSTs on rainfall is also addressed. The results generally reproduce the observations under “local scale mechanism”, with the removal of the Gulf of California marine boundary layer inversion as SSTs in the northern GC approach 30°C. This increased the water vapor mixing ratio at lower levels over the GC and over the southwestern United States, as low-level winds over the northern GC were from the southeast. This in turn increased thunderstorm activity and rainfall amounts over the Southwest. The northern GC SST-rainfall relationship shown under “local scale mechanism” was reproduced in this modeling study. This study indicates that in order to capture the physics that is mechanistically related to NAM rainfall, high vertical resolution of the boundary layer and good boundary layer physics is a must. Also critical is the use of reliable SST data.

Abstract Body: The Arizona/Great Basin onset of the 1999 North American monsoon (NAM) was simulated using the WRF and MM5 models. This onset also produced a major flooding event in Las Vegas, Nevada. Our working hypothesis states that sea surface temperatures (SST) in the northern Gulf of California (GC) may play a critical role in the timing and amount of summer rainfall over the U.S. southwest. In particular, the onset of relatively heavy rainfall occurs after these SSTs exceeded 29°C. Title: Acoustic imaging of thunder from rocket-triggered lightning

Presenter/First Author: Maher A Dayeh, Southwest Research Institute San Antonio, San Antonio, TX

Presenter/First Author Email: maher.aldayeh@swri.org

Co-authors: Neal Evans, Southwest Research Institute, San Antonio, TX

Published Material: Partially presented at the Fall AGU

Abstract Body: Acoustic signatures from rocket-triggered lightning are measured by a 15m long, one-dimensional microphone array consisting of 16 receivers situated 95 meters from the lightning channel. Measurements were taken at the International Center for Lightning Research and Testing (ICLRT) in Camp Blanding, FL during the summer of 2014. The linear array was oriented in an end-fire position so that the peak acoustic reception pattern can be steered vertically along the channel with a frequency-dependent spatial resolution, enabling us to sample the acoustic signatures from different portions along the lightning channel.

We report on the characteristics of acoustic signatures associated with several return strokes in two measured flashes comprising 2 and 7 return strokes. Results show a significant high frequency component measured in the near-field of the channel that enables acoustic imaging along the vertical profile of the channel and for individual return strokes, thus inferring the radiated acoustic energy as a function of altitude.

Title: Hilbert transform over the upper half-plane and its high accuracy quadrature scheme: technique renovation of the gravity wave reconstruction

Presenter/First Author: Huijun Li, Organization Not Listed, Najing,

Presenter/First Author Email: hjli@spaceweather.ac.cn

Co-authors: Chongyin Li, College of Meteorology and Oceanography, PLA University of Science and Technology, Nanjing, China; Xue Shang Feng, State Key Laboratory of Space Weather, Center for Space Science and Applied Research, Chinese Academy of Sciences, Beijing 100190, China;, Beijing, China; Xiaobin Pan, Institute of Meteorology and Oceanography, PLA University of Science and Technology, Nanjing 211101, China;, Nanjing, China; Yingying Huang, School of Electronic Information, Wuhan University, Wuhan, 430079, China;, Wuhan, China; Jie Xiang, College of Meteorology and Oceanography, PLA University of Science and Technology, Nanjing, China

Abstract Body: Abstract. In our previous study [1], it's found that a couple of Hilbert transform exists there between the gradient components of potential field within a plane circular. The self ad-joint and symplectic characteristics of this linear integral operator have successively been applied to the solving of the problem, i.e., the ill-posedness for the essential Grad-Shafranov (GS) reconstructions. Then in another work [2], we extend it to a plane rectangular region, and a modified Hilbert transform (MHT) operator is deduced, which keeps the same properties as the one within a unit circle. The MHT operator has also been used to solve the inverse boundary problem for the GS reconstruction. Benchmark results highlight its efficiency and robustness of the proposed method. In this work, we report our new results in technique renovation of the mountain gravity wave reconstruction. Firstly, we extended the Hilbert transform within the plane unit circle to the upper half-plane. In contrast to the MHT for a plane rectangle, the new Hilbert transform operator is essentially a Cauchy Principle (CP) integrator except the point at infinity, where it shows a singularity in Hadamarda sense. Secondly, with some variable transforms the MHT for upper half-plane has been reduced to the sum of a Hadamarda Finite Part (HFP) integral and a CP integral within the half-infinite real axis, with an end-point singularity at zero. Thirdly, high accuracy quadrature scheme is developed for these two improper integral operators, and it is also applied to the inverse boundary value problem in solving the Long equations for the stationary structure of the mountain gravity waves. Lastly, reconstructed wave structures are compared with the MHT in the plane rectangle and the one in this study.

Title: Land-Surface-Cloud-Climate Coupling on the Canadian Prairies

Presenter/First Author: Alan K Betts, Institute of Global Environment and Society Calverton, Pittsford, VT

Presenter/First Author Email: akbetts@aol.com

Co-authors: Ray Desjardins, Agriculture Canada, Ottawa, Canada; Ahmed Tawfik, , ,

Published Material: This is an update on an on-going series of papers: four were published in JGR in 2013, 2014. Two more are in preparation: these are the main focus of this talk. Some preliminary results were presented at the AGU Dec 2014 meeting in 2 invited presentations.

Abstract Body: The long-term hourly Canadian Prairie data set (1953-present) is transforming our understanding of land-atmosphere coupling and hydrometeorology, because the opaque/reflective cloud observations can be calibrated to give daily mean SWCF and LWCF using BSRN data. An ongoing series of papers (see http://alanbetts.com) is mapping the coupling between the diurnal climate of temperature, humidity, precipitation and cloud from the daily to annual timescales. Sub-stratifying by wind-speed, precipitation anomalies and day-night cloud symmetry gives observational insight into the physical processes driving the fully coupled surface diurnal cycle in the warm season, as a baseline for model evaluation.

Title: Stubble Height Effects on Canola Microclimate on the Canadian Prairies.

Presenter/First Author: Michael Cardillo, University of Manitoba, Winnipeg, MB

Presenter/First Author Email: mike.cardillo@hotmail.com

Co-authors: Paul Bullock, University of Manitoba, Winnipeg, MB, Canada; Aaron J Glenn, Agriculture and Agri Food Canada, Brandon, MB, Canada

Abstract Body: Previous research in the most arid region of the Canadian Prairies indicated that alteration of the early season microclimate using tall stubble from the previous year can create more favorable conditions which improve the performance of the following crop. Research on large-scale plots with canola seeded into either tall stubble (50 cm) or short stubble (20 cm) showed the canola yield was significantly higher in the tall stubble across 6 site-years where the stubble remained intact (i.e. not damaged or flattened). The yield advantage was not a result of additional snowcatch or higher spring soil moisture in the tall stubble because the sites all experienced higher than normal spring precipitation and wet spring moisture conditions across both tall and short stubble. However, the mid-season was warm and relatively dry for all the site-years. It is hypothesized the intact tall stubble slowed down evapotranspiration (ET) sufficiently compared to the short stubble to confer both reduced soil moisture stress to the canola as well as a yield advantage At each site, air temperature was measured 50, 20 and 5 cm above the soil surface and soil temperature 5 cm below the surface in all plots. Meteorological data was recorded by weather stations adjacent to the plots or obtained from the nearest provincial or Environment Canada stations. Following early season rainfall events, surface soil moisture at a site should be similar between treatments. If the hypothesis is correct (tall stubble reduced the rate of ET), the surface soil moisture in the days following rainfall at a site should remain higher in the tall stubble than the short stubble. If this is the case, then the soil temperature near the surface should warm more rapidly in the short stubble over the days following the rainfall. Initial analysis suggests this was occurring. Further analysis will attempt to quantify the effect across the range of site-years and for various days following rain in the early season.

Title: Global Carbon Cycle and Temperature Impacts of Future Changes in Fire Regime

Presenter/First Author: Jean-Sébastien Landry, McGill University, Montreal, QC

Presenter/First Author Email: jean-sebastien.landry2@mail.mcgill.ca

Co-authors: Damon Matthews, Concordia University, Montreal, QC, Canada; Navin Ramankutty, McGill University, Montreal, QC, Canada

Published Material: Our study is currently under review with Climatic Change.

Abstract Body: Changes in the current fire regime would directly affect carbon cycling, land–atmosphere exchanges, and atmospheric composition, and could therefore modulate the ongoing climate warming. We used a fully coupled climate–carbon model to quantify the effect of different non-deforestation fire scenarios from 2015 to 2300. When considering only CO_2 fire emissions, the impacts from changes in fire frequency were limited for the global carbon cycle, and almost negligible for the global atmospheric surface temperature. The net fire emissions were only a fraction of the CO_2 directly emitted during combustion due to vegetation regrowth and climate–CO_2 feedbacks, and the albedo increases caused by changes in vegetation cover countered the effect of increased atmospheric CO_2 on global temperature. When employing a simplified approach based on global-mean radiative forcings in order to account for non-CO_2 fire emissions, the effect of increased fire frequency on global temperature depended critically on the uncertain net aerosol forcing. Overall, our results do not support the hypothesis of a strong positive climate–fire feedback for the coming centuries, and suggest that more frequent non-deforestation fires may even represent a net negative feedback to ongoing global warming.

Title: Investigation of the Sensitivity of Snow and Energy-Flux Conditions to Surface and Vegetation Parameters for Forest Sites Using the Multi-Energy Balance Option in SURFEX

Presenter/First Author: Patrick Samuelsson, Swedish Meteorological and Hydrological Institute, Norrköping,

Presenter/First Author Email: patrick.samuelsson@smhi.se

Co-authors: Aaron anthony Boone, Météo-France Toulouse, Toulouse Cedex 01, France; Stefan Gollvik, , , ; Christer Jansson, , , ; Adrien Napoly, , ,

Published Material: A more limited and earlier version of this study was presented at the 3rd International Lund Regional-scale climate modelling workshop, Sweden. International Baltic Earth Secretariat Publication No. 3, June 2014

Abstract Body: Interaction between vegetation and snow is usually modelled in a quite simplified manner in most Numerical Weather Prediction (NWP) and climate models. This simplified manner may have a few consequences for the model performance: (i) wrong timing in spring snow melt and river discharge peaks (usually too early in forest dominated regions). (ii) wrong energy flux exchange between surface and atmosphere (radiation and sensible and latent heat fluxes). (iii) wrong soil temperatures (too much cooling of soil in autumn and winter, too much warming in spring and summer). (iv) wrong snow area fraction (usually underestimated in forest regions). Here we will illustrate a few of these issues.

We do that by the introduction of explicit canopy energy balance in the externalized surface model SURFEX where turbulent and radiation fluxes within the canopy layer are parameterized. This Multi-Energy Balance (MEB) parameterization is part of latest release of SURFEXv8.

The snow accumulation is related to the height of the canopy (forest, shrubs, grass,…). The simulated turbulent and radiation fluxes, the snow accumulation and the soil heat flux will all be sensitive for surface and vegetation characteristics as e.g. Leaf-Area Index, surface albedo, surface roughness, vegetation extinction coefficient, vegetation heat capacity. We optimise the values of these parameters by setting up SURFEX offline for a number of flux-tower sites for which we correlate observed and simulated variables. Also, since SURFEX makes it easy to switch between different physical options we can quantify how the classical ISBA land-surface option performs compared to MEB.

We show that with the MEB option in SURFEX we get quite a good correspondence between simulated and observed snow depth and heat fluxes at forest sites. However, with the classical ISBA option it is not possible to get both snow depth and heat fluxes to correspond well with observations.

Title: Playa Soil Moisture and Evaporation Dynamics in an Arid Intermountain Basin

Presenter/First Author: Daniel F Nadeau, INRS - ETE, Quebec City, QC

Presenter/First Author Email: daniel.nadeau.1@gmail.com

Co-authors: Chaoxun Hang, University of Utah, Salt Lake City, UT; Derek D Jensen, University of Utah, Salt Lake City, UT; Sebastian Hoch, University of Utah, Salt Lake City, UT; Eric Pardyjak, University of Utah, Salt Lake City, UT

Published Material: Most of these findings are under review for publication in Boundary-Layer Meteorology.

Abstract Body: The Mountain Terrain Atmospheric Modeling and Observations (MATERHORN) program was designed to better understand atmospheric fluid dynamic processes across a large range of scales over mountainous terrain. As part of MATERHORN, a large field campaign was conducted in May 2013, which is typically one of the most synoptically active months in the western Utah desert (USA). This study focuses on one of the main field sites, a desert playa, characterized by a shallow water table and significant soil moisture spatial heterogeneity. Recent studies have shown that soil moisture plays a critical role in the dynamics of boundary-layer flows over desert playas. Thus, the objective of this study is to better understand the temporal and spatial evolution of soil moisture and evaporation dynamics under contrasting conditions. During a total of 10 intensive observation periods, soil moisture was monitored with the gravimetric method at 20 sites evenly spread on a 240 x 180 m grid. Near-surface standard meteorological variables, atmospheric fluxes as well as ground heat flux and soil heat transfer properties were also measured. The data analysis reveals that decreasing surface albedo, decreasing Bowen ratio and increasing net radiation with increasing soil moisture all promoted large evaporation rates immediately following rain events. Additionally, it was found that while nocturnal evaporation was negligible during dry periods, it was quite significant (up to 30% of the daily cumulative flux) during nights following rain events. Our results further show that the highest spatial variability in surface soil moisture is found under dry conditions. Finally, we report strong spatial heterogeneities in evaporation rates following a rain event. The cumulative evaporation for the different sampling sites over a five-day period varied from ~0.1 mm to ~6.6 mm. Overall, this study allows us to better understand the mechanisms underlying soil moisture dynamics of desert playas as well as evaporation following occasional rain events.

Abstract Body: As a part of ongoing development of plant functional traits (FTs) hybrid model, Gaussian Mixture Model (GMM) has been applied for predicting the vegetation distribution and investigating the sensitivity of vegetation to changing climate conditions based on trait-climate relationships in China. Firstly, we have collected three key plant functional traits (FTs) including leaf mass per area (LMA), area-based leaf nitrogen (N_{area}), mass-based leaf nitrogen (N_{mass}) from published papers and available literatures as well as one structural trait of plant community - leaf area index (LAI) extracted from MODIS products across China. Secondly, we have derived and developed the trait-climate relationships and used different trait combinations to train GMM for vegetation classification. Finally, the GMM trained by LMA-N_{mass}-LAI combination was applied to investigate the climate sensitivity of vegetation under different climate scenarios in China. The results showed that (1) all four traits are well captured the relationships between climate variables and traits and work well in predicting the vegetation distribution and analyzing the environmental sensitivity; (2) the LMA-N_{mass}-LAI combination with a accuracy of 72%, which could provide more parameters information about communities structure and ecosystem function was selected to train GMM for predicting the vegetation distribution; (3) Sensitivity analysis indicated that increasing temperature shifted boundaries of most vegetation northward and westward; for the reason that forest is more suitable for growing in rainy conditions, increasing precipitation expanded the boundaries of forest to a larger area compared with baseline vegetation distribution. Despite limitations and uncertainties in using plant trait-climate relationships to predict future vegetation dynamics under different climate conditions, it laid a good foundation and demonstrated a great potential for constructing the next generation of DGVMs based on FTs and would provide more flexible approaches in modeling global vegetation dynamics under a changing climate.

Title: Ecological dimension of 21st century land-atmosphere interactions in the Arctic

Presenter/First Author: Ben Smith, Lund University, Lund,

Presenter/First Author Email: ben.smith.lu@gmail.com

Co-authors: Wenxin Zhang, Lund University, Lund, Sweden; Paul A Miller, Lund University, Lund, Sweden

Abstract Body: Structural and compositional changes in the vegetation cover of the Arctic land surface have been documented in many areas and attributed to recent decades' climate trends, in particular a warming-driven increase in growing season length, enhancing net primary production (NPP) and potentially resulting in greener, denser, higher stature vegetation with a greater representation of woody elements. Vegetation trends like these are relevant to consider in climate models as they will affect energy, water and momentum fluxes, potentially modifying simulated climate trends. Findings are presented from simulations across the Arctic and high boreal zone using a regional Earth system model, RCA-GUESS, that couples a detailed individual-based model of climate-driven vegetation dynamics to a regional climate model, accounting for albedo and evapotranspiration-mediated feedbacks to climate. Forced by RCP radiative forcing scenarios for the 21st century, the model simulates poleward expansion of the boreal forest treeline, increased coverage of shrub tundra and a shift in phenology favouring evergreen over deciduous trees. These effects are more pronounced the higher the radiative forcing level assumed. The vegetation changes feed back to climate by lowering albedo particularly in the late snow season, promoting an earlier, warming spring. By contrast, increased evapotranspiration dampens peak season warming, resulting in a longer growing season with lower temperature amplitude compared to the climate predicted in the absence of vegetation-mediated feedbacks. Summer precipitation is also projected to increase in conjunction with vegetation changes. Ecological implications are discussed.

Title: A stand-alone demography and landscape structure module for Earth system models: integration with forest inventory data, and impact on land-atmosphere exchange.

Presenter/First Author: Vanessa Elizabeth Haverd, CSIRO Canberra, Canberra, ACT

Presenter/First Author Email: vanessa.haverd@csiro.au

Co-authors: Benjamin Smith, Department of Physical Geography and Ecosystem Science, Lund University, Lund, Sweden; Lars Peter Nieradzik, CSIRO Marine and Atmospheric Research Hobart, Hobart, Australia; Peter Briggs, CSIRO, Canberra, Australia

Published Material: These findings were partially reported at the AGU Fall Meeting (2014) and in the following journal article: Haverd, V., Smith, B.; Nieradzik, L.; Briggs, P. R. (2014) A stand-alone tree demography and landscape structure module for Earth system models: integration with inventory data from temperate and boreal forests *Biogeosciences* ,11(15): 4039-4055.

Abstract Body: Poorly constrained rates of biomass turnover are a key limitation of Earth system models (ESM). In light of this, we recently proposed a new approach encoded in a model called Populations-Order-Physiology (POP), for the simulation of woody ecosystem stand dynamics, demography and disturbance-mediated heterogeneity. POP is suitable for continental to global applications and designed for coupling to the terrestrial ecosystem component of any ESM. POP bridges the gap between first generation Dynamic Vegetation Models (DVMs) with simple large-area parameterisations of woody biomass (typically used in current ESMs) and complex second generation DVMs, that explicitly simulate demographic processes and landscape heterogeneity of forests. The key simplification in the POP approach, compared with second-generation DVMs, is to compute physiological processes such as assimilation at grid-scale (with CABLE or a similar land surface model), but to partition the grid-scale biomass increment among age classes defined at sub grid-scale, each subject to its own dynamics. POP was successfully demonstrated along a savanna transect in northern Australia, replicating the effects of strong rainfall and fire disturbance gradients on observed stand productivity and structure. (Haverd et al. 2013)

Here, we extend the application of POP to a range of forest types around the globe, employing paired observations of stem biomass and density from forest inventory data to calibrate model parameters governing stand demography and biomass evolution. The calibrated POP model is then coupled to the CABLE land surface model and the combined model (CABLE-POP) is evaluated against leaf-stem allometry observations from forest stands ranging in age from 3 to 200 years. Results indicate that simulated biomass pools conform well with observed allometry. POP represents an ecologically plausible and efficient alternative to large-area parameterisations of woody biomass turnover, typically used in current ESMs.

Further, we use CABLE-POP to investigate the sensitivity of modeled land-atmosphere exchanges to incorporation of vegetation structure into a land surface model.

Title: Exploring interflow – soil moisture – climate linkages: Case study for northeast Canada

Presenter/First Author: Oleksandr Huziy, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: guziy.sasha@gmail.com

Co-authors: Laxmi Sushama, University of Quebec at Montreal UQAM, Montreal, QC, Canada

Published Material: Some results from this work were presented at AGU 2014 Fall meeting.

Abstract Body: Several of the recent interflow studies looked at the combined effect of adding interflow and baseflow processes to a land surface or river routing schemes. Although these modifications improve simulated streamflow, it is still not clear what is the contribution of the interflow parameterization to the combined effect, or to the regional climate as these simulations were run offline. In this study, using experiments performed with the fifth generation of the Canadian Regional Climate Model (CRCM5), which includes Canadian Land Surface Scheme (CLASS) and a river routing scheme (WATROUTE modified), the impact of interflow process on regional climate is assessed. The analysis of results from high-resolution (10km) current climate simulations with and without interflow, over northeast Canada, shows modest streamflow increase for majority of the rivers, and some impacts on the land atmosphere interactions via modified soil moisture.

Title: Snow-atmosphere coupling over North America in the fifth generation of the Canadian Regional Climate Model (CRCM5)

Presenter/First Author: Gulilat Tefera Diro, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: diro@sca.uqam.ca

Co-authors: Laxmi Sushama, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Oleksandr Huziy, University of Quebec at Montreal UQAM, Montreal, QC, Canada

Abstract Body: In this study, two sets of CRCM5 simulations were carried out, with and without interactive snow, to investigate the role of snow-atmosphere coupling in modulating climate variability during cold season over North America. In the coupled simulation, snow interacts freely with the atmosphere at each time step, while in the uncoupled simulation, snow related model variables (i.e. snow mass, snow density and snow depth) are replaced with climatological values, derived from the coupled simulation, to suppress the snow-atmosphere interactions. Results indicate that a strong land–atmosphere coupling (mainly via snow cover variability) is noted in winter and spring over northern US and most parts of central Canada including the prairies. Over these regions, snow plays an important role in amplifying winter and spring surface air temperature variability through its influence on surface albedo.

Title: Implementation of Dynamic Rooting Depth and Phenology into a Land Surface Model: Evaluation of Carbon, Water, and Energy fluxes for the High Latitude Ecosystems

Presenter/First Author: Atul K Jain, University of Illinois at Urbana, Urbana, IL

Presenter/First Author Email: jain1@uiuc.edu

Co-authors: Bassil El Masri, University of Illinois at Urbana, Urbana, IL

Abstract Body: Ecosystem models are important tools to understand and assess the impact of environmental change on northern high latitude ecosystems (NHLEs), but many lack processes that are essential for modeling the ecosystem dynamics important for NHLEs. In this study, we implement NHLE-specific dynamic phenology schemes and dynamic rooting distribution in a state-of-the-art land surface model, the Integrated Science Assessment Model (ISAM), to improve the estimated carbon, energy, and water fluxes for the NHLEs. These schemes account for light, water, and nutrient stresses while allocating the assimilated carbon to leaf, stem and root pools. To evaluate model performance related to these processes, we use measured data from more than 15 sites representing the dominant NHLE. To quantify the implication of these processes on the carbon water and energy fluxes, we performed a number of modeling experiments. Our data-modeling analyses indicates that after accounting for dynamic processes ISAM is able to capture the seasonal variability in leaf area index (LAI), and root distribution in the soil layers and the root response of soil water uptake and transpiration. In addition, without accounting the dynamic processes, modeled growing season length for NHLEs were almost two times higher as compared to measurements. The results also show that the model is better able to capture the seasonal variability in GPP and energy and water fluxes.

Title: Sedimentation for 2-moments microphysics models: How to make it fast, interactive, and avoid excessive size sorting.

Presenter/First Author: Frederick Chosson, McGill University, Montreal,

Presenter/First Author Email: frederick.chosson@mcgill.ca

Published Material: Under review. Journal of Atmospheric Research.

Abstract Body: We present a new sedimentation scheme for 2-moments microphysical models that mimic Eulerian or Lagrangian
classical approaches with three major advantages. First, it is much faster and numerically efficient than
classical Eulerian/Lagrangian methods and it is easy to implement. Second, it allows the microphysical
processes to take into account the sedimenting particles during sedimentation; and vice versa. That is to
say that sedimentation and microphysical processes are computed at the same time. Third, it manages the
sedimenting fluxes of the two moments (particles number concentration and mass content) together to excessive size sorting, accordingly to a minimum and a maximum mean mass particle size observable in nature. In contrast to currently used sedimentation approaches, these characteristics also allow
much longer time step for the microphysics model with a satisfying precision, and total conservation of both
mass and concentration of hydrometeor particles, paving the way toward the use of 2-moments microphysics
schemes within operational numerical weather prediction from regional to global scales and climate models.

Title: Wind and sea waves analysis for the Greek area with application to renewable energy.

Presenter/First Author: George Emmanouil, , Athens,

Presenter/First Author Email: george.emmanouil@yahoo.gr

Abstract Body: Wind and sea waves energy seem to be promising solutions for the production of renewable energy in coastal and island countries, like Greece. In this presentation, results of a study in which *an integrated, high resolution system is developed for exploring and monitoring the wind and sea waves patterns in the region of Eastern Mediterranean Sea, with special emphasis to the Greek area, are presented.*

The models for the wind and sea waves simulation, will be discussed. Moreover, atmospheric (WRF) and sea wave (WAM) numerical models will be evaluated. Then, high resolution maps *for the coastal and offshore areas of Greece will be produced,* in which se*a wave and wind climatological characteristics* will be monitoring.

Title: Occurrence of scintillation over Lagos within equatorial anomaly

Presenter/First Author: Oladayo Olayiwola Afolabi, Ladoke Akintola University of Technology, Ile ife,

Presenter/First Author Email: oladayo.afolabi@yahoo.com

Abstract Body: This work examines the statistical analysis of occurrence of scintillation index over Lagos Nigeria within the equatorial Anomaly region (6.45^0N, 3.40^0E) for the year 2009. The variation of occurrence of scintillation varies with local time, Season, magnetic activity, pre-midnight, post- midnight and day time. The occurrence of scintillation was found to be maximum in equinox month and minimum in December solstice. Different levels of occurrences in some months were found with moderate Scintillation ($0.4<S_4\leq0.6$) being dominant throughout the period examined.

Title: Application of Recurrence Quantification Analysis (RqA) to Climatic Studies

Presenter/First Author: Samuel Toluwalope Ogunjo, Federal University of Technology Akure, Akure,

Presenter/First Author Email: stogunjo@futa.edu.ng

Co-authors: Ibiyinka A Fuwape, , , ; Joseph B Dada, , ,

Abstract Body: Scientists generally agree that climate change is real but there is no consensus on the cause. Statistical tools such as correlation, averaging are generally used to detect causes of climate change. However, this will not give a true picture since atmospheric parameters is nonlinear and chaotic. Poincare introduced recurrence in 1890 to investigate fundamental characteristics of dynamical systems. It has been used by researchers in fields such as astrophysics, neurosciences, earth sciences, amongst others to detect structures in time series data. Over the years, the field has extended to include Recurrence Quantification Analsysis (RQA), which has led to the introduction of indicators such as Recurrence rates (RR), Determinisim (DET), e.t.c. The applications of RQA to atmospheric sciences include detection of change points in time series e.g. when did significant changes occur in time series data. Complex relationship such as effect of global warming indicators (e.g carbon(iv) oxide) on atmospheric parameters (e.g. rainfall) can be investigated through phase, lag, generalized or complete synchronization. RQA can also be used to analyse spatial data for relationship. This technique can be used to validate results using other techniques. Examples will be presented using NCEP Reanalysis data for selected locations across the world to show the efficiency of the technique.

Title: Causative Mechanisms of Low-Latitude Mesospheric Inversion Layers

Presenter/First Author: K Ramesh, Sri Venkateswara University, Chittoor,

Presenter/First Author Email: karanamram@gmail.com

Co-authors: S Sridharan, National Atmospheric Research Laboratory, Gadanki, India; S Vijaya Bhaskara Rao, Sri Venkateswara University, Tirupati, India

Published Material: Published onlline in Journal of Geophysical Research: Space Physics on 19 May 2014. doi:10.1002/2013JA019750.

Abstract Body: ABSTRACT

Mesospheric Inversion Layer (MIL) refers to the inversion of temperature gradient from negative to positive superposed upon the characteristically decreasing mesospheric thermal structure. Though morphological characteristics of MIL events have been known for several decades, their causative mechanisms are still unknown. Gravity wave breaking, panetary wave critical level interaction, Gravity wave tidal interaction and chemical heating have been suggested as possible causative mechanisms of the MIL events. However, their relative importance and seasonal and altitude dependences are relatively unknown. Considering several case studies, all the dominant causative mechanisms for the occurrence of MILs over a low latitude region, Gadanki (13.5°N, 79.2°E) are investigated using mainly the Rayleigh lidar temperatures over Gadanki, MF radar winds over Tirunelveli (8.7°N, 77.8°E), TIMED-SABER temperature, volume mixing ratios of O, H, O_3 etc and the chemical heating rates of various exothermic reactions. Based on the detailed investigation, it is found that the lower MILs (~70 km) are due to planetary wave-critical level interaction, the middle MILs (~80-85 km) are dominantly caused either by chemical heating due to $H+O_3 \rightarrow OH+O_2$ or by gravity wave breaking. The upper MILs (above 90 km) are found to be due to the exothermic chemical reaction, $O+O+M \rightarrow O_2+M$.

Title: Changes in the stratospheric composition during the major stratospheric warming of 2013

Presenter/First Author: Oindrila Nath, National Atmospheric Research Laboratory, Tirupati,

Presenter/First Author Email: oindrila@narl.gov.in

Co-authors: Sundararajan Sridharan, National Atmospheric Research Laboratory, Gadanki, India

Abstract Body: Volume mixing ratios (VMR) of different chemical components obtained from Microwave Limb Sounder onboard Aura satellite show distinct variations at high and low latitudes in the upper stratosphere (30-50 km) during the occurrence of a major stratospheric sudden warming (SSW) in January 2013. Zonally averaged ozone VMR as well as chlorine monoxide (ClO) VMR are found to increase over higher latitudes (60-90°N) whereas hydrogen chloride (HCl) VMR shows decrement as the warming proceeds. At higher latitudes, as O3/O partitioning controls the ClO/Cl ratio, the increase of ozone during SSW shifts the ClO/Cl partitioning in favour of ClO, thereby decreasing Cl which indirectly results in decrease of HCl. In the equatorial stratosphere, the ozone VMR is found to increase because of weakening of Brewer-Dobson circulation (BDC) due to reduction in planetary wave activity with the onset of warming. However, methane is expected to decrease due to weakening of upwelling branch of BDC resulting in decrease of HCl VMR. Cl i.e. active chlorine converts to ClO by reacting with ozone molecule and this active Cl comes from the reaction of HCl and water vapour (H2O). As both HCl and water vapour are found to decrease during the SSW, the production of active Cl is also getting reduced. As a result, the amount of ClO also reduces during the SSW thereby partly decreasing the depletion of ozone. The decrement of ClO persists for quite a long time even after the end of the stratwarm event.

Title: Effects of Increased Horizontal and Vertical Grid Spacing on Mixing in a Simulated Continental Squall Line

Presenter/First Author: Zachary J Lebo, National Center for Atmospheric Research, Westminster, CO

Presenter/First Author Email: lebo@ucar.edu

Co-authors: Hugh Morrison, National Center for Atmospheric Research, Boulder, CO

Abstract Body: The sensitivity of an idealized squall line to horizontal (and vertical) grid spacing is investigated using a new approach. Simulations are first performed at a modest horizontal resolution. Once the storm reaches a quasi-steady state, model output is interpolated to a higher resolution domain and the model is restarted using the interpolated state. This framework allows for investigating both the response *and* sensitivity of the simulated squall line to horizontal grid spacing (Δ). The results demonstrate that there are two resolution-dependent regimes; the transition between regimes occurs for Δ between 250 and 500 m. This transition is found to be independent of the vertical resolution. Mixing in the context of varying resolution is also investigated via passive tracers that are initialized 1 hr after restarting the simulations at higher resolution. The state of the tracer field at the end of the simulations reveals that entrainment and detrainment at mid-levels are suppressed in the simulations with $\Delta \geq 500$ m. For smaller Δ, entrainment and detrainment at mid levels become substantially more important, limiting the flux of low-level tracer to the upper-troposphere, which has important implications for modeling studies of atmospheric transport from the boundary layer to the free-troposphere.

Title: Data Assimilation and Simulation of Mesoscale Convective Systems Associated with Squalls

Presenter/First Author: Mohan Kumar Das, SAARC Meteorological Research Centre (SMRC), Dhaka,

Presenter/First Author Email: mohan28feb@yahoo.com

Co-authors: Md. Abdul Mannan Chowdhury, Jahangirnagar University, Savar, Bangladesh; Someshwar Das, India Meteorological Department, New Delhi, India

Abstract Body:
Improving the simulation of the squall events is important as such events routinely result in strong gusty wind, hails, rain and significant loss of life and property over Bangladesh, Indian eastern, northeastern region and neighbourhood. Performance of the mesoscale models is sensitive to the quality of initial conditions. This study deals the improvement of numerical simulation of squall events during pre-monsoon season with improved initial condition through mesoscale data assimilation system. Advanced Research Weather Research and Forecasting model (WRF ARW) along with three dimensional variational (3DVar) data assimilation (DA) technique are used to improve the simulation of these intense events. Pre-monsoon squalls and tornado are studied employing observations from ground based radar, TRMM and synoptic stations. Subsequently, an attempt is made to simulate the storms using WRF model at 4 km and 1 km horizontal resolution, and 40 vertical levels.

Several sensitivity experiments were conducted with different combinations of cloud microphysics schemes, planetary boundary layer schemes and cumulus parameterization schemes to examine the RMSE of forecasts.

Title: A Comparison of GCM and RCM resolution Climate Projections in the Great Lakes - Effort, Efficiency, Uncertainty Considerations

Presenter/First Author: Neil Comer, Risk Sciences International, Ottawa,

Presenter/First Author Email: ncomer@risksciences.com

Abstract Body: High-resolution output is a necessity for the Great Lakes region as conditions vary significantly in this heterogeneous environment. The procedures to obtain this spatially precise information are largely determined by financial resources of the end-user, whether a large well-funded municipality or a smaller community with no dedicated climate adaptation funding or staff. The latter better describes the majority of these stakeholders. In an ideal case, all users would have access and expert interpretation of many high-resolution RCM model runs, but this is not realistic.

This has led to many different approaches from high-resolution customized approaches, to much simpler delta approaches where multi-model GCM ensemble values are applied to a high resolution observed historical baseline climate. Both of these approaches generate high-resolution future projections, but a balance of many factors must be weighed. Often these factors are not fully appreciated by the non-expert end users of the information. Generally projections are practically limited by many GCM-scale projections (over 40 models in the last IPCC assessment) which can provide more comprehensive information on uncertainty versus a single (or few) high-resolution RCM projections which provide greatly reduced uncertainty estimates – and if one model run – no estimate at all. The fundamental question is: Do simpler approaches provide valuable guidance within accepted uncertainty bounds in these heterogeneous environments?

Given the obstacle of financial resources available for climate adaptation in most locations, it is crucial that such studies go forward without the hurdle of cost, yet of course still be scientifically defensible. The comparative accuracy of final output of these two approaches is considered vis-à-vis the costs and benefits through a specific example location in Ontario.

Abstract Body: Projected changes in lake-effect snowfall by the mid- and late 21st century are explored for the Laurentian Great Lakes Basin. Simulations from two state-of-the-art global climate models within the latest Coupled Model Intercomparison Project Phase Five (CMIP5) are dynamically downscaled according to the representative concentration pathway 8.5 (RCP8.5). The downscaling is performed using the Abdus Salam International Centre for Theoretical Physics (ICTP) Regional Climate Model Version Four (RegCM4) with 25-km grid spacing, interactively coupled to a one-dimensional lake model. Both downscaled models produce atmospheric warming and increased cold-season precipitation. Great Lakes' ice cover is projected to dramatically decline and, by the end of the century, become confined to the northern shallow lakeshores during mid-late winter. Projected reductions in ice cover and greater dynamically-induced wind fetch lead to enhanced lake evaporation and resulting total lake-effect precipitation, although with increased rainfall at the expense of snowfall. A general reduction in the frequency of heavy lake-effect snowstorms is simulated during the 21st century, except with increases around Lake Superior by the mid-century when local air temperatures still remain low enough for wintertime precipitation to largely fall in the form of snow.

Title: Probabilistic Climate Change Projections for the Great Lakes Basin Using a High-Resolution Regional Climate Model Ensemble

Presenter/First Author: Xiuquan WANG, University of Regina, Regina, SK

Presenter/First Author Email: xiuquan.wang@gmail.com

Co-authors: Gordon Huang, University of Regina, Regina, SK, Canada

Abstract Body: Current observations in the Laurentian Great Lakes demonstrate that some changes in climate are already occurring, including increases in surface water and air temperatures and decreases in the extent and duration of ice cover. These changes have a significant influence on the surrounding region by affecting local temperature, precipitation, water vapor, cloud coverage, cyclones and anticyclones, as well as other important aspects of regional climate. Planning of appropriate mitigation and adaptation strategies against these changes in

the context of global warming, which requires a better understanding of possible future climate outcomes over the Great Lakes basin, is of great interest to local policy makers, stakeholders, and development practitioners. Therefore, a high-resolution regional climate model ensemble based on the PRECIS regional climate modeling system will be developed in this study to help explore the possible outcomes of future climate over the Great Lakes basin. A Bayesian hierarchical model is then proposed to quantify the uncertain or unknown parameters involved in the modeling results. Probabilistic projections of changes in temperature and precipitation at grid point scales are obtained by feeding the ensemble simulations into the Bayesian model. The high-resolution probabilistic projections developed in this study can provide direct inputs for climate impact researchers to study the possible impacts of global warming on the Great Lakes basin, meanwhile the results are potentially helpful for assessing the risks and costs associated with climatic changes as well as for planning the appropriate mitigation and adaptation strategies.

Title: Seasonal and Interannual Variability of Great Lakes Climate and Ice Cover: From Research to Forecast

Presenter/First Author: Jia Wang, NOAA Great Lakes Environmental Research Laboratory, Ann Arbor, MI

Presenter/First Author Email: jia.wang@noaa.gov

Co-authors: Xuezhi Bai, CILER, University of Michigan, Ann Arbor, MI; Haoguo Hu, CILER, University of Michigan, Ann Arbor, MI; Ayumi Fujisaki, NOAA/GLERL, Ann Arbor, MI

Abstract Body: Over the past six years (since 2007), GLERL and CILER team has studied Great Lakes ice and regional climate in response to global climate changes and how to transfer scientific research results into predictions of lake ice on the scales of several days to several months. It was found that both NAO and AMO have a linear impact on lake ice, while ENSO and PDO have nonlinear (quadratic) impacts on lake ice, but none of them solely dominates the Great Lakes regional climate and lake ice cover. The combined effects of NAO, ENSO, AMO, and PDO on lake ice provide high predictability skills using statistical regression models. The new findings were incorporated into a statistical regression model, which can project medium-range lake ice cover only using projected indices of NAO, Nino3.4, AMO, and PDO one to several months ahead of time. For the first time, fully-coupled Great Lakes Ice-circulation Models (GLIM) with both dynamics and thermodynamics have been developed at GLERL/CILER to simulate and investigate the lake ice variations on the synoptic, seasonal, interannual, and decadal time scales. The hindcast results were validated using in situ, airborne, and satellite measurements. The validated GLIM has been used since the 2010-2011 ice season to forecast Great Lakes ice cover concentration, thickness, velocity, and associated air-ice-sea variables for up to five days in advance.

Title: Development of a reference potential evapotranspiration climatological dataset for the Great Lakes region

Presenter/First Author: Jeff Andresen, Michigan State University, East Lansing, MI

Presenter/First Author Email: andresen@msu.edu

Co-authors: Michael T. Kiefer, Michigan State University, East Lansing, MI; Dana Doubler, , ,

Abstract Body: This study describes the development of a gridded historical climatological dataset of reference potential evapotranspiration (ET0) for the Great Lakes region using the Penman-Monteith methodology following Allen et al. 1998. The rate of ET0 is dependent on meteorological conditions including the intensity of solar radiation, air temperature, humidity and wind speed. Following international convention, we calculate ET0 assuming a flat, unshaded, 12 cm-tall grass-covered surface with no soil water limitations. Although ET0 is a primary input variable for most irrigation scheduling systems, little is known regarding its temporal and spatial variability.

Given the limitations of objectively analyzing single site station data (e.g., incomplete station records, heterogeneous station density), we used the North American Land Data Assimilation System (NLDAS) gridded analysis as a source of weather information for computing ET0. Before calculation, adjustments were made to the NLDAS solar radiation field to reduce bias and correct for a tendency of NLDAS to be too conservative in the tails of the distribution. NLDAS fields were then used as input to generate hourly ET0 estimates at each grid point in a domain covering the entire Great Lakes watershed over the 30-year period from 1983-2012.

Preliminary analysis of the NLDAS-derived dataset shows a pronounced influence of the lakes on ET0 spatial and seasonal patterns, distinct links with drought years in 1988 and 2012, and a general increasing trend of ET0 with time over the 1993-2012 period of record. Future efforts planned include coupling the ET0 dataset to a precipitation dataset, evaluating the sensitivity of ET0 to its individual components, developing future climate projections, and linkage to an operational irrigation scheduling decision support system.

Title: Quantifying Uncertainties in Wind Atlases

Presenter/First Author: Paula Doubrawa, Cornell University, Ithaca, NY

Presenter/First Author Email: pd343@cornell.edu

Co-authors: Rebecca J Barthelmie, Cornell University, Ithaca, NY; Sara C Pryor, Cornell University, Ithaca, NY; Merete Badger, , , ; Hui Wang, , ,

Abstract Body: The Great Lakes present a large potential for offshore wind development due to the abundant wind resource and the proximity to large population centers. With low water depths, Lake Erie has been a focus of wind energy projects for the past few years. In this study, observed winds from 12 coastal stations, 4 buoys, and ESA's Synthetic Aperture Radar during 2002-2012 are used to generate an observational wind atlas for Lake Erie. The in situ data provide temporally consistent data at various heights and at point locations. The satellite data represent equivalent neutral winds at 10 m, provide spatial information at a relatively high resolution but are temporally sparse. Each data set is treated separately to take advantage of their respective strengths and address their weaknesses. A methodology is presented to correct for the

consistent temporal gaps introduced in offshore observations when the buoys are removed from the lake and the satellite platforms cannot estimate the wind stress due to ice formation. A method of ratios is applied on the mean wind and power density to correct the buoy generalized wind climates. The wind class method is used to address the disjunction in the available satellite scenes. All processing steps reduce the uncertainty in the results. A method is presented that integrates the individual wind climates into a wind atlas for the region, under the common assumption of neutral stratification offshore. The final area-averaged RMSE is 0.1 m/s and the mean predicted resource is < 314 W/m2 at 90 m in the center of the Lake. To test the neutral stratification assumption, observations over Lake Erie were obtained during a one-month measurement campaign from a buoy, a sonic anemometer, a profiler lidar and a scanning lidar. These data are used to investigate in detail the local characteristics of the wind flow and quantify the impact of stability on the wind climate of the region and the uncertainty in the wind atlas estimation.

Co-authors: Kelli Paige, , ,

Published Material: AWRA, Latornell - both Fall 2014

Abstract Body: A barrier to effective decision support using today's wide array of research and monitoring data is the difficulty of discovery. There are many potentially useful data collections whose existence is not widely appreciated. One way of increasing the discoverability (and transparency) of datasets is to develop and publish standard-compliant metadata that describe the who, what, when, where, why, and how for each collection. Metadata publication through portals like the Global Earth Observation System of Systems (GEOSS) provides the opportunity to find datasets and evaluate their utility. Interoperability - furnishing the data as well for standards-compliant direct access - is another best practice that makes use of data easier. Examples of standards-based discoverability, transparency and interoperability will be presented from the Great lakes Observing System (part of NOAA's Integrated Ocean Observing System) and GEOSS-GL (the Great Lakes node of GEOSS. The examples define a vision for data management that, although not inexpensive, may be the right approach for supporting complex decisions in an international context.

Title: A new Approach to Interpret Multi-Angle Spectral Reflectance of Dense Vegetation

Presenter/First Author: Yuri Knyazikhin, Boston University, Boston, MA

Presenter/First Author Email: jknjazi@bu.edu

Co-authors: Jian Bi, Boston University, Boston, MA; Sungho CHOI, Boston University, Boston, MA; Taejin Park, Boston University, Boston, MA; Ranga B Myneni, Boston University, Boston, MA

Abstract Body: Monitoring of dense vegetation represents the most complicated case in optical remote sensing because reflectances saturate and are weakly sensitive to changes in canopy properties. A new approach to interpret such data based on analyses of relationships between forward and adjoint radiative transfer equations is discussed in this presentation. This approach was applied to monitor seasonality in phenology of Amazonian rainforests using data from Terra MODIS, MISR and Aqua MODIS sensors. These three independent satellite datasets consistently show higher greenness level during the dry season relative to the wet season. This result is consistent with the light limitation hypothesis, i.e., light is the limiting factor for productivity of well-hydrated equatorial Amazonian rainforests.

Title: High Spatial Resolution Three Dimensional Atmospheric Radiative Transfer in SASKTRAN

Presenter/First Author: Daniel Zawada, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: daniel.zawada@usask.ca

Co-authors: Seth Dueck, University of Saskatchewan, Saskatoon, SK, Canada; Adam E Bourassa, University of Saskatchewan, Saskatoon, SK, Canada; D A Degenstein, University of Saskatchewan, Saskatoon, SK, Canada

Published Material: Parts of this work were presented at the 2013 AGU Fall Meeting and are currently under review in Atmospheric Measurement Techniques.

Abstract Body: The SASKTRAN radiative transfer model has been used successfully for more than a decade to simulate Odin-OSIRIS measurements of vertically resolved profile of limb scattered sunlight. These radiance simulations are used, along with OSIRIS measurements, within a Multiplicative Algebraic Reconstruction Technique in order to retrieved vertically resolved profiles of atmospheric constituents including ozone, nitrogen dioxide and sulphate aerosol within the stratosphere. The original SASKTRAN is a fully spherical model that accurately accounts for the three-dimensional nature of the incoming sunlight but had the limitation of only modelling a one dimensional, vertical, distribution of the atmospheric state. For example the first version of SASKTRAN only allowed the atmospheric density, temperature, ozone, nitrogen dioxide and bromine monoxide profiles to vary in the vertical dimension and homogeneity was assumed across the other dimensions. Recent modifications have been made to the SASKTRAN model that have eliminated this homogeneity constraint allowing for a more accurate simulation of OSIRIS and other scattered sunlight measurements. An adaptive integration technique has been introduced to handle areas of high extinction (e.g. cirrus clouds) and regions with large horizontal inhomogeneity. In addition, the capability to compute analytic weighting functions in one and two dimensions for inversion purposes has been added. This poster details these changes and their expected benefits to the data products retrieved from OSIRIS measurements. The use of the new High Resolution SASKTRAN within a two-dimensional tomographic retrieval technique that can be used with measurements made by microCATS, an OSIRIS follow-on mission, is also discussed.

Title: Monte-Carlo SASKTRAN for Stratospheric Radiative Transfer

Presenter/First Author: Seth Dueck, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: srd740@mail.usask.ca

Co-authors: Daniel Zawada, University of Saskatchewan, Saskatoon, SK, Canada; Adam E Bourassa, University of Saskatchewan, Saskatoon, SK, Canada; D A Degenstein, University of Saskatchewan, Saskatoon, SK, Canada

Published Material: Parts of this work were presented in a poster at AGU Fall Meeting 2013, and are under review in Atmospheric Measurement Techniques (High Resolution and Monte Carlo Additions to the SASKTRAN Radiative Transfer Model, D.J. Zawada, S.R. Dueck, L.A. Rieger, A.E. Bourassa, N.D. Lloyd, and D.A. Degenstein).

Abstract Body: The SASKTRAN radiative transfer model is a spherical, successive orders, discrete ordinates model used for operational processing of the OSIRIS limb scattered sunlight measurements for one dimensional profile retrievals of stratospheric ozone, nitrogen dioxide and stratospheric aerosol extinction. In this work, we study the effects of two and three dimensional structures in the retrieved fields and in clouds within and near the line of sight using a Monte Carlo version of the model. This version uses identical atmospheric state, optical property parameters and ray tracing to facilitate direct comparison to the one dimensional discrete ordinates model. A speed improvement using variance distributed orders of scattering is presented, as well as effects of polarization and the finite size of the solar disk.

Title: Ground-Based Multi-Angle Imaging Network for 3D Atmospheric Sensing

Presenter/First Author: Amit Aides, Technion Israel Institute of Technology, Haifa,

Presenter/First Author Email: amitibo@campus.technion.ac.il

Co-authors: Dmitri Veikherman, , , ; Aviad Levis, Technion Institute of Technology, Haifa, Israel; Yoav Y Schechner, Technion Institute of Technology, Haifa, Israel

Published Material: This work was presented in part in the 12th Asian Conference on Computer Vision (ACCV 2014), Nov 2014.

Abstract Body: There is much to benefit from 3D recovery of clouds and aerosol distributions, in high spatio-temporal resolution and wide coverage. Algorithms are developed for such tasks, including stereo triangulation (clouds) and tomography (aerosols). However, existing remote sensing instruments may lack the spatio-temporal resolution desired to properly exploit these algorithms. There is a need to capture frequent samples of the atmospheric radiance field from many viewpoints. To help achieve this, we develop a new imaging system, based on a wide, dense, scalable network of wide-angle cameras looking upward. The network uses low-cost units, to enable large scale deployment in the field. We demonstrate high-resolution 3D recovery of clouds based on data captured by a prototype system. We use space carving to recover the volumetric distribution of clouds. This method leads directly to cloud shapes, bypassing surface triangulations that are based on image correspondence. Furthermore, network redundancy solves various radiometric problems that exist in monocular or stereoscopic systems.

Title: A new Approach to Cloud Optical Depth Estimates from Sky Images based of SHDOM Simulations

Presenter/First Author: Felipe Alejandro Mejia, University of California San Diego, San Diego, CA

Presenter/First Author Email: famejia@ucsd.edu

Co-authors: Jan P Kleissl, Univ of California, San Diego, San Diego, CA

Abstract Body: A method for retrieving cloud optical depth (OD) using a ground-based sky imager (USI) developed at the University of California, San Diego is presented. Using data from images taken by a USI in the Oklahoma ARM site over the course of 220 days, as well as synthetic images produced by a 3-D Radiative Transfer Model (SHDOM) the basic parameters affecting an image were identified as the solar zenith angle (SZA), OD, solar pixel angle (SPA), pixel zenith angle (PZA), and 3-D radiative effects. The effects of these parameters are described in this paper as well as the algorithm used to retrieve OD. Comparison between OD retrieved from the USI and a microwave radiometer (MWR) is presented as well as DNI estimates from the USI and actual measurements.

First Author Student?: Yes

Co-authors: Alexander Marshak, NASA Goddard Space Flight Center, Greenbelt, MD

Abstract Body: This work explores the three-dimensional (3D) nature of the radiative processes that take place in partly cloudy scenes. While, until now, most studies focused on visible (VIS) and near-infrared (NIR) wavelengths, this study extends the analysis to ultraviolet (UV) wavelengths and examines the way 3D processes change with wavelength, spatial resolution, cloud type, solar and viewing geometry.

With this aim, 3D and 1D-IPA (Independent Pixel Approximation) simulations were carried out for UV, VIS and NIR wavelengths and for a variety of solar and viewing geometries. The differences between the 1D and 3D model outputs show that 3D effects on average reflectances are smaller for UV wavelengths. Moreover, 3D effects for this wavelength show a weaker dependence on solar and viewing geometry.

Additionally, 1D-IPA simulations have been carried out at various spatial resolutions, and their differences from the 3D simulations have been analyzed. The results show that for UV wavelength, the 1D-IPA approximation is most accurate at the highest resolution. This is also true for VIS and NIR wavelengths in back scattering directions, but not in forward scattering directions.

The same analysis has been performed for two different scenes: a cumulus and a stratocumulus cloud field used in the Intercomparison of 3D radiation codes (I3RC) project. It is observed that 3D effects on scene average reflectances are much stronger for cumulus than for stratocumulus. Taking into account that the mean optical thickness of the analyzed scenes are similar, the differences are attributed to differences in the spatial distribution of clouds.

This analysis helps identify situations where the interpretation of satellite-based cloud observations can be most affected by 3D radiative processes. Additional studies using other wavelengths and cloud fields are expected to further improve the understanding of 3D radiative effects.

Title: Statistics About Shortwave 3D Radiative Effects in Cloudy Scenes

Presenter/First Author: Tamas Varnai, University of Maryland Baltimore County, Greenbelt, MD

Presenter/First Author Email: tamas.varnai-1@nasa.gov

Co-authors: Alexander Marshak, NASA Goddard Space Flight Center, Greenbelt, MD; Guadalupe Sanchez, University of Extremadura, Badajoz, Spain; K Franklin Evans, University of Colorado, Boulder, CO

Abstract Body: This study aims at helping better understand, in which situations it is important for remote sensing applications to consider the three-dimensional nature of solar radiative processes. For this, the presentation compares statistics from 1D and 3D radiation simulations performed for a large number of scenes. Some cumulus and stratocumulus scenes are specified by Large-Eddy Simulations, other scenes are from a global dataset of satellite images. The study examines the way 3D effects vary with wavelength in the ultraviolet-to-near infrared range, and puts their impact in perspective through comparisons with other remote sensing uncertainties. The study also examines the way 3D effects depend on view direction when looking down from above or looking up from below. Finally, the presentation will discuss the statistical influence of relevant scene parameters on 3D effects, and highlights the type of situations in which 3D effects are most or least important to consider.

Title: Effects of Clouds Inhomogeneities on LIDAR and Doppler RADAR Observations : Application to A-train and EarthCARE Space missions

Presenter/First Author: Frédéric Szczap, Organization Not Listed, Aubière,

Presenter/First Author Email: szczap@opgc.univ-bpclermont.fr

Co-authors: Alaa Alkasem, , , ; Céline Cornet, University of Lille 1, Villeneuve d'Ascq, France; Olivier Jourdan, , , ; Valery Shcherbakov, , ,

Published Material: Some prelimenary results presented during AGU Joint Assembly were reported during the French scientific meeting EECLAT (Expecting EarthCARE, Learning from A-Train)

Abstract Body: Clouds show complex tridimensional (3D) variabilities in their horizontal/vertical geometrical, optical, microphysical and dynamical properties at different averaging scales. Effects of cloud and wind inhomogeneities on LIDAR and Doppler RADAR observations, such as the backscatter coefficient, the depolarization ratio, the reflectivity factor, the Doppler velocity, have to be considered in direct radiative transfer calculations (i.e. simulation of LIDAR and RADAR observations from mesoscale models outputs) as well as in the inverse problems (i.e. retrievals of cloud parameters from LIDAR and RADAR observations). Generally and for practical reason, clouds are assumed to be horizontally homogenous and plane parallel in LIDAR and Doppler RADAR signal calculation algorithms (direct problem) and in cloud-property retrieval algorithms (inverse problem).

A study has been undertaken to quantify the effects of high resolution 3D cloud inhomogeneities on the LIDAR and Doppler RADAR observations of A-train and EarthCARE space mission. These investigations are performed using numerical simulations and the classical approach of the radiative transfer community. For direct problem, this approach consists in comparison between the mean of the 3D cloud LIDAR and Doppler RADAR observations and those of the homogenous and plan parallel equivalent clouds with the same mean cloud properties. We have to develop two numerical tools for these purposes. The first one is the 3D multiple scattering polarized LIDAR and Doppler RADAR simulator, which is based on the 3D polarized Monte Carlo model (Cornet et al., 2010). It will be compared to the DOMUS model (Battaglia and Tanelli, 2011) and to the Hogan's model (Hogan et al., 2008). The second tool is the high-resolution synthetic 3D cloud and wind field generator. It will be based on the 3DCLOUD model (Szczap et al., 2014) that is now in use for stratocumulus, cumulus and cirrus clouds cases.

Title: 3D Cloud Observations: Synergy Between Scanning Radars and Shortwave Radiation Measurements

Presenter/First Author: Jui-Yuan Christine Chiu, University of Reading, Reading,

Presenter/First Author Email: C.J.Chiu@reading.ac.uk

Co-authors: Mark D. Fielding, , , ; Robin James Hogan, ECMWF, Reading, United Kingdom; Graham Feingold, NOAA Boulder, Boulder, CO

Published Material: published in JGR in 2014.

Abstract Body: Ground-based cloud observations have been primarily made from a vertically pointing view in the past. Consequently, cloud evolution and 3D structures must be derived based on certain assumptions, making it difficult to tackle cloud problems in a fully 3D situation. The new scanning cloud radars from the Atmospheric Radiation Measurement (ARM) Climate Research Facility provide an excellent opportunity for characterizing detailed 3D cloud macrophysical and microphysical properties. In this paper, we will introduce a new ENsemble ClOud REtrieval method (ENCORE) that combines scanning cloud radar and shortwave zenith radiances, using an iterative Ensemble Kalman Filter with a 3D radiative transfer forward model. Based on large eddy simulations and real data collected from the Azores in the northeast Atlantic, we will

show examples from relatively easy stratocumulus to challenging shallow cumulus that tends to have a strong 3D radiative effect. These new cloud observations open the door to many new lines of research, helping unravel the influence of aerosol on clouds, as well as giving insight to the 3D radiative properties of boundary-layer clouds.

Title: *Cirrus cloud heterogeneity effects and their implications for MODIS-like retrievals using solar and IR observations*

Presenter/First Author: Thomas Fauchez, Oak Ridge Associated Universities Inc., Greenbelt, MD

Presenter/First Author Email: thomas.j.fauchez@nasa.gov

Co-authors: Steven Platnick, NASA Goddard Space Flight Center, Greenbelt, MD; Zhibo Zhang, University of Maryland Baltimore County, Baltimore, MD; Céline Cornet, University of Lille 1, Villeneuve d'Ascq, France; Philippe Dubuisson, Lab. d'Optique Atmosphérique, Villeneuve D'Ascq, France; Frédéric Szczap, Organization Not Listed, Aubière, France

Published Material: Fews results are already presented in Fauchez et al., 2014, AMT, accepted.

Abstract Body: Cirrus clouds are important actors in the Earth radiation budget but an accurate assessment of their role remains highly uncertain. Cirrus optical properties such as Cloud Optical Thickness (COT) and ice crystal effective particle size are often retrieved with a combination of Visible/Near InfraRed (VNIR) and ShortWave-InfraRed (SWIR) reflectance channels. Alternatively, Thermal InfraRed (TIR) techniques, such as the Split Window Technique (SWT), have demonstrated better accuracy for thin cirrus effective radius retrievals with small effective radii. However, current global operational algorithms for both retrieval methods assume that cloudy pixels are homogeneous (Plane Parallel Approximation (PPA)) and independent (Independent Pixel Approximation (IPA)). The impact of these approximations on ice cloud retrievals needs to be understood and, as far as possible, corrected. Horizontal heterogeneity effects can be more easily estimated and corrected in the TIR range because they are mainly dominated by the PPA bias, which primarily depends on the COT subpixel heterogeneity. For solar reflectance channels, in addition to the PPA bias, the IPA can lead to significant retrieval errors if there is large photon transport between cloudy columns and brightening/shadowing effects that are more difficult to quantify.

A study has been undertaken to improve MODIS TIR retrievals at 1 km by taking into account cirrus heterogeneity effects using higher resolution MODIS VNIR through (SWIR) measurements (two channels at 250 m, five channels at 500 m). Differences between heterogeneity effects in the VNIR/SWIR and TIR are also investigated in order to estimate their impact on cloud products retrieved using a combination of the VNIR/SWIR and TIR retrieval methods. These investigations are performed using a cirrus 3D cloud generator (3DCloud), a 3D radiative transfer code (3DMCPOL) as well as two retrieval algorithms: the official MODIS retrieval algorithm (MOD06) and an algorithm based on the infrared SWT.

Title: Assessment of OCO-2's Vulnerability Against Spatial Variability of Surface Reflectivity in "Glint" (over Land), "Nadir" and "Target" Modes

Presenter/First Author: Anthony B Davis, NASA Jet Propulsion Laboratory, Pasadena, CA

Presenter/First Author Email: Anthony.B.Davis@jpl.nasa.gov

Co-authors: Zheng Qu, Raytheon/JPL, Pasadena, CA

Published Material: AGU Fall Meeting 2014, but only for "Target Mode" findings.

Abstract Body: The goal of NASA's Orbiting Carbon Observatory (OCO-2) mission is to measure the X_{CO2} column from space at an unprecedented (~1 ppm) precision to enable globally mapping of CO_2 sources and sinks. To achieve that goal, the mission depends critically on X_{CO2}product validation that, in turn, hinges on successful exploitation of OCO-2 data acquired in "target mode." That is, when OCO-2 rotates in such a way that, for almost as long as it is above the horizon, it stares at a Total Carbon Column Observing Network (TCCON) ground station equipped with a powerful Fourier transform spectrometer.

TCCON measures X_{CO2} by looking straight at the Sun. This leads to a far simpler forward model for TCCON than for OCO-2. In the ideal world, OCO-2's spectroscopic signal results from the cumulative gaseous absorption for one direct transmission of sunlight to the ground (as for TCCON), followed by one diffuse or specular reflection, and one direct transmission back to the sensor, at a series of viewing angles in target mode. In the real world, all manner of multiple surface reflections and/or scatterings contribute signal. See figure. In the idealized world of OCO-2's operational forward model, horizontal variability of the scattering atmosphere and reflecting surface are ignored, leading to the adoption of a 1D radiative transfer (RT) model. We investigate part of this source of forward model error in target as well as nadir and glint-over-land modes.

In principle, atmospheric variability in the horizontal plane, largely due to clouds, can be avoided by careful screening. Also, it is straightforward to account for the angular variability of surface reflection in the 1D RT framework. But it is not clear how the unavoidable horizontal variations of surface reflectivity affects the OCO-2 signal, even if said reflection was Lambertian. To quantify this OCO-2 "adjacency" effect, we drive a 3D RT model with realistic aerosol and molecular profiles, but use (at present) a simplified surface variability model: a single spatial frequency in each horizontal direction, and a single albedo contrast. This specific kind of 3D RT error will be compared with other documented forward model errors and instrumental uncertainties. It can thus be translated into X_{CO2}error, for programmatic consideration and eventual mitigation.

Title: Radiative effects of in-situ observed ice supersaturated regions and cirrus clouds in the extratropical upper troposphere and lower stratosphere

Presenter: Xiaoxiao Tan, McGill University, Montreal, QC

Presenter Email: xiaoxiao.tan@mail.mcgill.ca

First Author: Minghui Diao, National Center for Atmospheric Research, Boulder, CO

First Author Email: diao@ucar.edu

First Author Student?: No

Co-authors: Yi Huang, McGill University, Montreal, QC, Canada

Abstract Body: Cirrus clouds are important modulators on the Earth's climate budget. The prerequisite condition for ice crystal formation is ice supersaturation (ISS, where relative humidity with respect to ice > 100%). A recent observational study shows that the spatial distribution of ISSRs is highly heterogeneous, with a median horizontal length of ~1 km (Diao et al. ACP 2014), which is much smaller than climate model grid scales. In addition, a previous study shows that the radiative effects of an idealistic clear-sky ISSR and an artificial cirrus cloud can be very different (Fusina et al. 2007). However, it is unclear how much radiative impact it would make if ISSRs in the real atmosphere were to be replaced by artificial cirrus clouds.

In this work, we compare the radiation impacts of three scenarios: 1) in-situ observed ISSRs, 2) excluding ISS by removing the excess water vapor over saturation, and 3) artificial cirrus clouds (i.e., replacing the observed ISS with ice crystals). The first scenario is based on high-resolution (~200 m) aircraft observations in the extratropical upper troposphere and lower stratosphere (Diao et al. ACP 2014). The radiative impact of each scenario is calculated by the rapid radiative transfer model (RRTM) of AER (Mlawer et al. JGR 1997), with atmospheric conditions (e.g., cloud distributions) adopted from the ERA-Interim data.

By calculating the radiation impacts of 184 cases of clear-sky ISSRs, we find that the clear-sky ISSRs lead to higher vertical heating rate by ~0.2–1.5 K d^{-1} than the ISS exclusion scenario. In contrast, replacing the observed ISSRs with artificial ice crystals can generate even larger perturbations on the vertical heating rate by up to ~8.6 K d^{-1}, as well as on the net radiation at 100 hPa and surface by up to ~20 W m^{-2} and ~ -25 W m^{-2}, respectively. More work is in progress to examine the radiative effects when ISS and ice crystals coexist. Overall, our results show that instantaneously replacing ISS with ice crystals after ice nucleation (e.g., a cirrus cloud scheme by Tompkins et al. (2007)) can potentially generate large perturbations on the net radiation at the Top of Atmosphere (TOA) and surface. Our work helps to quantify the radiation perturbations when ISS is misinterpreted as artificial ice crystals in cloud and climate models.

Title: Clouds, Precipitation and Marine Boundary Layer Structure during the MAGIC Field Campaign

Presenter/First Author: Xiaoli Zhou, McGill University, Montreal,

Presenter/First Author Email: xiaoli.zhou@mail.mcgill.ca

Co-authors: Pavlos Kollias, McGill University, Montreal, QC, Canada; Ernie R Lewis, Brookhaven National Laboratory, Upton, NY

Published Material: These findings were reported in the ASR (Atmospheric System Research) meeting, and were accepted by Journal of Climate

Abstract Body: The recent ship-based MAGIC field campaign with the marine-capable Second ARM Mobile Facility (AMF2) deployed on the Horizon Lines cargo container M/V *Spirit* provided nearly 200 days of intra-seasonal high-resolution observations of clouds, precipitation and marine boundary layer (MBL) structure on multiple legs between Los Angeles, California, and Honolulu, Hawaii. During the deployment, MBL clouds exhibited a much higher frequency of occurrence than other cloud types and occurred more often in the warm season than in the cold season. MBL clouds demonstrated a propensity to produce precipitation, which often evaporated before reaching the ocean surface. The formation of stratocumuli is strongly correlated to a shallow MBL with a strong inversion and a weak transition, while cumuli formation is associated with a much weaker inversion and stronger transition. The estimated inversion strength (EIS) is shown to depend seasonally on the potential temperature at the 700 hPa. The location of the commencement of systematic MBL decoupling (DE) always occurred eastward of the locations of cloud breakup (CBs), and the systematic decoupling showed a strong moisture stratification. The entrainment of the dry warm air above the inversion appears to be the dominant factor triggering the systematic decoupling, while surface latent heat flux, precipitation and solar radiation did not play major roles. MBL clouds broke up over a short spatial region due to the changes in the synoptic conditions, implying that in real atmospheric conditions, the MBL clouds do not have enough time to evolve as is in the idealized models.

Title: A Comparison of Algorithms for Determination of Marine Boundary Layer Height

Presenter/First Author: Ernie R Lewis, Brookhaven National Laboratory, Upton, NY

Presenter/First Author Email: elewis@bnl.gov

Published Material: Some of this analysis was presented at the 2014 AGU fall meeting

Abstract Body:
The MAGIC field campaign, funded and operated by the ARM (Atmospheric Radiation Measurement) Climate Research Facility of the US Department of Energy, occurred between September 2012 and October, 2013 aboard the Horizon Lines cargo container ship Spirit making regular trips between Los Angeles, CA and Honolulu, HI. Along this route, which lies very near the GPCI (GCSS Pacific Cross-section Intercomparison) transect, the predominant cloud regime changes from stratocumulus near the California coast to trade-wind cumulus near Hawaii. During MAGIC, radiosondes were routinely launched four times daily, and during one round trip in July, 2013, radiosondes were launched eight times daily. In total, more than 550 soundings were made. Boundary layer heights were calculated from the radiosonde data using several different algorithms. Some of these algorithms gave values that correspond to the abrupt decrease in the relative humidity with height that occurs above a well-mixed boundary layer, but others routinely underestimated the boundary layer heights and appeared to occur at heights at which no obvious transitions are occurring. Heights determined by the various algorithms are compared and reasons for the differences are examined.

Title: Thermally-driven circulation and convection over a mountainous tropical island

Presenter/First Author: Chun-Chih Wang, McGill University, Montreal,

Presenter/First Author Email: wang.monsoon@gmail.com

Co-authors: Daniel J Kirshbaum, McGill University, Montreal, QC, Canada

Published Material: The findings from this study were presented during the 16th AMS Mountain Meteorology Conference in San Diego, CA (Aug. 18-22, 2014). A manuscript reporting the results was also submitted to Journal of the Atmospheric Sciences in November, 2014. The manuscript is currently undergoing minor revisions to address the reviewers' comments for future publication.

Abstract Body: Observational data from the 2011 Dominica Experiment (DOMEX) and cloud-resolving numerical simulations are exploited to gain a better understanding of controlling parameters of thermally-driven convection over a mountainous tropical island. A "golden" case from DOMEX with a clear diurnal cycle in cumulus convection and quasi-steady large-scale conditions is studied using observations and cloud-resolving numerical simulations. The simulations are quasi-idealized in that they use full model physics and the real Dominica terrain, along with a horizontally homogeneous initial flow based on a single observed sounding. Simulations at different grid resolutions reveal that large-eddy resolution (~100 m) provides the most accurate representation of the in-situ measurements from DOMEX and the radar-derived island precipitation. However, regardless of grid resolution, the simulations robustly under-predict the island diurnal cycle and over-predict the precipitation, which stem from biases in land-surface and subgrid microphysics parameterizations. Sensitivity tests reveal the importance of key factors including island terrain height, land-surface type, cloud-radiative feedbacks, moist stability, and background wind velocity in controlling the thermally-driven convection.

Title: Velocity and Length Scales for Moist Convection: Estimation of Scale-Aware Convective Adjustment Timescale

Presenter/First Author: Kiran V Alapaty, US EPA Library, Research Triangle Park, NC

Presenter/First Author Email: alapaty.kiran@epa.gov

Abstract Body: One of the most uncertain parameters in some of the cumulus convection parameterization (CCP) schemes is the convective adjustment time scale (τ). Yet there exists no generalized τ formulation that can be used in these CCP schemes for regional and global models as well as with measurements. To address this critical research need, for continental convection I have developed a generalized and scale-aware dynamic formulation to estimate convective adjustment time scale for CCP schemes as well as for observational studies. First, appropriate length and velocity scales for subcloud and cloud layers are identified. For subcloud layer, its depth is considered as the length scale and the velocity scale is based on turbulent kinetic energy. For cloud layers, the depth of a cumulus cloud is used as length scale while a simplified form of Arakawa and Schubert's cloud work function is used to derive the velocity scale. Then, a scale-aware convective adjustment time scale (τ) formulation for cumulus convection for shallow and deep clouds is developed as a turn-over timescale that depends on the ratio of length scale and velocity scale (simplified cloud work function). Key features of the τ formulation are: (1) it can be used in any mass flux or convective adjustment type of CCP schemes; (2) it has scale-awareness; and (3) it responds to the stabilization of subcloud layer as well as cloud layer. Various measurement data available from the TWP-ICE and MC3 experiments are used for the estimation of τ. It is found that τ can vary from about 30 minutes to about 3 hours depending on the depth of a shallow/deep convective cloud observed during the TWP-ICE and MC3 experiments' periods. Further, results obtained from a regional climate model simulations using the proposed τ formulation also indicated similar range of τ variability. Pertinent climate parameters as well as simulated surface precipitation are evaluated using corresponding observations and these results will be presented.

Title: Observational estimates of entrainment rate in convective clouds

Presenter/First Author: Michael P Jensen, Brookhaven National Laboratory, Centerport, NY

Presenter/First Author Email: mjensen@bnl.gov

Co-authors: Tami Toto, Brookhaven National Laboratory, Upton, NY; Pavlos Kollias, McGill University, Montreal, QC, Canada; Chunsong Lu, NUIST Nanjing University of Information Science and Technology, Nanjing, China

Published Material: Some of the initial results were reported at 2014 ASR PI meeting

Abstract Body: The mixing of environmental air across the cloud interface plays a significant role in the lifecycle of the convective cloud system and subsequent influences on the hydrological and energy cycles. Despite its importance, the entrainment process remains poorly understood and its measurement and its quantification is extremely difficult. We present a remote sensing technique that builds upon previous aircraft in-situ based techniques (Lu et al. 2012) in order to estimate the vertical profile of entrainment rate. The profile of vertical velocity observed by the Ka-band ARM Zenith Radar (KAZR) is used with an adiabatic parcel model that incorporates conservation of total water and energy in the retrieval algorithm. This initial study concentrates on five years of non-precipitating cumulus observations over the ARM SGP site, where radar-based observations of mean Doppler velocity are a reasonable proxy for the in-cloud air motion. A preliminary application of the methodology has shown reasonable agreement with simple bulk entrainment estimates using an entraining plume model (Jensen et al. 2006).

Title: Climatology of Boundary Layer Depth over the US Southern Great Plains

Presenter/First Author: Virendra P Ghate, Argonne National Laboratory, Argonne, IL

Presenter/First Author Email: vghate@anl.gov

Co-authors: Pavlos Kollias, McGill University, Montreal, QC, Canada; Richard Coulter, , ,

Abstract Body: The boundary layer (BL) is an important link between the surface and free troposphere that heavily modulates the transport of energy and momentum between them. In a convective environment clouds often form on the top of the mixed layer providing a constraint on the radiative heating of the surface and the energy transport. The BL over land also exhibits considerable changes (in structure, depth etc.) on diurnal, seasonal and annual timescales. In this study we have used long-term (~20 years) data collected at the Atmospheric Radiation Measurement (ARM)'s Southern Great Plains (SGP) observational facility near Lamont, Oklahoma that has been operational since October, 1993. The Radar Wind Profiler (RWP) operating at 915 MHz frequency made observations of the raw Doppler spectrum and its moments continuously (>80% uptime) at a 60 m and 30 second resolution. These observations were used to deduce BL depth on hourly time-scales from which it's diurnal, seasonal and annual cycles were deduced. The data collected by collocated instruments like the ceilometer, microwave radiometer, flux suite and met system were also used to characterize environmental conditions.

We will present the diurnal, seasonal and annual cycle of the RWP derived BL depth in the context of the environmental conditions as observed over the US Southern Great Plains.

Title: Characterizing Long-Term Observations of Convective Clouds from Combined ARM Profiling Radar and Lidar Measurements

Presenter/First Author: Karen L Johnson, Brookhaven National Laboratory, Upton, NY

Presenter/First Author Email: kjohnson@bnl.gov

Co-authors: Michael P Jensen, Brookhaven National Laboratory, Centerport, NY; Shannon Baxter, SUNY at Geneseo, Geneseo, NY; Tami Toto, Brookhaven National Laboratory, Upton, NY; Meng Wang, Brookhaven National Laboratory, Upton, NY; Pavlos Kollias, McGill University, Montreal, QC, Canada; Eugene Edmund Clothiaux, Penn State, University Park, PA

Abstract Body: The U.S. Department of Energy's Atmospheric Radiation Measurement (ARM) program has continuously operated profiling cloud radars and micropulse lidars at five fixed sites, for periods ranging from eight to nineteen years. The sites include the U.S. southern Great Plains, the Alaska North Slope and three Tropical Western Pacific locations. The radar and lidar observations, along with ceilometer and precipitation measurements, have been synthesized using ARM's Active Remote Sensing of Clouds (ARSCL) value-added product, which provides cloud boundaries and best-estimate radar reflectivities, mean Doppler velocities and spectral widths. The product's time resolution ranges from 10 seconds down to 4 seconds, with height resolution of 45 meters or better. Through its use in retrievals of cloud microphysics and dynamics, this high-resolution, long-term data set has the potential to make major contributions toward improved cloud representations in climate models and the understanding of cloud processes. However, it is essential that data set quality and accuracy be assessed and made available to data users in order to maximize utility and reliability.

In this study, we apply a variety of approaches to characterize observation quality throughout the ARSCL data record at each site with a particular emphasis on the characterization of convective cloud types. We describe instrument availability and radar operating status and possible issues. Radar sensitivity is tracked as a function of time through cirrus detection statistics as well as changes in radar signal saturation level over time. We also examine noise and insect clutter reflectivity levels as possible surrogates for radar calibration changes. We assess the impacts of changes in radar sensitivity and proxy calibration changes on convective cloud property statistics and provide valuable guidance to potential data users, for both case-study research and long-term climatological applications.

Title: Organization of subcloud layer for different cloud regimes

Presenter/First Author: Arunchandra Chandra, University of Miami, Miami, FL

Presenter/First Author Email: arun.acsharma@gmail.com

Co-authors: Pavlos Kollias, McGill University, Montreal, QC, Canada; Chidong Zhang, Univ Miami-RSMAS/MPO, Miami, FL

Abstract Body: Convective boundary layer acts as an interface for transporting fluxes of scalars (heat, moisture, pollutants, etc.) and momentum from the surface into the depth of the atmosphere. Most of the transport in the CBL takes place through the large eddies (coherent structures). The spatial structure and growth of eddy length scales in the sub cloud layer influence the cloud layer and vice-versa. Some of the cloud parameterizations utilize length scales in the sub cloud layer to parameterize various cloud variables. Most of these parameterizations are based on the LES model data and they have hard time capturing the realistic cloud regimes. Recent model studies have suggested that the organization of the sub cloud layer is different for various cloud-topped conditions. These studies aimed test these model results and to further understand the role of sub cloud layer organization under different cloud regimes. Long-term statistics of the sub cloud layer length scales and their variability are documented for various cloud regimes using the observations at the DOE ARM sites.

ABSTRACT:

Atmospheric particles have great impacts on different scales spanning from regional to global climate change (Watson et al., 2002). Aerosol plays an important role as the cloud condensation nuclei based on their composition and complex mixing states. Most of the observations pertaining to aerosol physico-chemical characteristics are limited to ground level observations. The altitude variation of the same (balloon based) is extremely limited (Zhang et al., 2012; Hara et al., 2013). The aged aerosols show enhanced ability of serving as nuclei for droplet formation and finally affect the radiative properties of clouds (Moteki et al., 2007).

To the best of our knowledge, there is no detailed study of aerosol aging information with varying altitude over India. To study the physico-chemical properties of aerosols with varying altitude, a tethered balloon based field campaign have been organized in National Physical Laboratory campus (28° 38′ 10′′N, 77° 10′ 17′′E) from 21-27 Feb, 2014 (Mishra et al., 2014). TOF-SIMS (Time of Flight-Secondary Ion Mass Spectrometry) was used to study the aging chemicals of aerosols collected at various altitudes. Samples were collected from ground level to 700m (total six altitudes). At 200m altitude, the particles were found to be heavily aged with aliphatic hydrocarbons which are fragments of tails of aliphatic amide group. Peterson and Tyler (2003) have already shown that the aging of aerosol with aliphatic amides may be of critical importance for cloud droplet formation. Together with hydrocarbons, particles were also found to be aged with $HSO4^-$, $SO3^-$ and Cl^- at 200 m altitude. The strong temperature inversion and air parcel movement from IGP (Indo Gangetic Plain) are the probable reason for enhanced aging of aerosols at this altitude. Implications of the observed aging with varying altitude to the cloud microphysics will be discussed during presentation.

ACKNOWLEDGEMENTS

Title: Covariability in the monthly mean convective and radiative diurnal cycles in the Amazon

Presenter/First Author: Jason Brant Dodson, NASA Langley Research Center, Hampton, VA

Presenter/First Author Email: jason.b.dodson@nasa.gov

Co-authors: Patrick C Taylor, NASA Langley Research Center, Hampton, VA

Abstract Body: The diurnal cycle of convective clouds greatly influences the radiative energy balance in convectively active regions of Earth, through both direct presence and the production of anvil and stratiform clouds. Previous studies show that the frequency and properties of convective clouds can vary on monthly timescales as a result of variability in the monthly mean atmospheric state. Furthermore, the top-of-atmospheric radiative budget in convectively active regions varies by up to 7 Wm^{-2}. These facts suggest that convective clouds connect atmospheric state and radiation variability beyond clear sky effects alone.

Previous research has identified monthly covariability between the diurnal cycle of CERES-observed top-of-atmospheric radiative fluxes and multiple atmospheric state variables (ASVs) from reanalysis over the Amazon region. ASVs that enhance (reduce) deep convection, such as convective available potential energy (lower tropospheric stability), tend to shift the daily outgoing longwave radiation and cloud albedo maxima earlier (later) in the day by 2-3 hr. We first test the analysis method using multiple reanalysis products for both the dry and wet seasons to investigate the robustness of the previous results. We find general qualitative agreement between multiple reanalysis products, though the amplitude of the effect can vary by 50%. The seasonal results show the importance of both the cloud and clear-sky effects in determining the shift in the radiative diurnal cycle.

We then use CloudSat as an independent cloud observing system to further evaluate the relationships of cloud properties to variability in radiation and ASVs. While CERES can decompose OLR variability into clear sky and cloud effects, it cannot determine what variability in cloud properties (e.g. cloud cover, height, and microphysics) lead to variability in the radiative cloud effects. CloudSat observes these cloud properties, as well as the presence and variability of deep convective cores responsible for anvil clouds. While CloudSat cannot sample the full diurnal cycle, it can observe changes between early morning and early afternoon, such as the higher convective intensity of daytime versus nighttime. We use these capabilities to determine the covariability of convective cloud properties, ASVs, and the radiative diurnal cycle.

Title: Insights Into Precipitation Processes As Revealed By Profiling Radar, Disdrometer and Aircraft Observations During The MC3E Campaign.

Presenter/First Author: Scott E Giangrande, Brookhaven National Laboratory, Upton, NY

Presenter/First Author Email: sgrande@bnl.gov

Co-authors: Tami Toto, Brookhaven National Laboratory, Upton, NY; Aaron Bansemer, National Center for Atmospheric Research, Boulder, CO; Matthew Kumjian, Pennsylvania State University Main Campus, University Park, PA; Alexander Ryzhkov, Cooperative Institute for Mesoscale Meteorological Studies, Norman, OK

Published Material: 2014 AGU Fall Meeting Poster; However, was unable to attend;

Abstract Body: The Midlatitude Continental Convective Clouds Experiment (MC3E) was a collaborative campaign led by the National Aeronautic and Space Administration's (NASA's) Global Precipitation Measurement (GPM) mission and the U.S. Department of Energy (DOE) Atmospheric Radiation Measurement (ARM) program. This campaign was held at the DOE ARM Southern Great Plains (SGP) Central Facility (CF) in north-central Oklahoma, with the programs joining forces to deploy an extensive array of airborne, radiosonde and ground-based instrumentation towards an unprecedented set of deep convective environment and cloud property observations. An overarching motivation was to capitalize on the wealth of aircraft observations and new multi-frequency dual-polarization radars to provide insights for improving the treatments of cloud processes in convective models.

This study considers a coupled aircraft, radar and surface disdrometer approach for identifying key cloud processes and linking those to possible radar-based microphysical fingerprints and/or cloud properties. Our emphasis is on the MC3E observations from April 27th, 2011 and collected during successive aircraft spirals over the column of the ARM CF. We investigate the usefulness of radar to inform on processes including aggregation and riming as viewed by vertically-pointing ARM wind profiler (915 MHz) and cloud radar Doppler spectral observations (35 GHz). Corresponding dual-polarization radar signatures from the nearby cm-wavelength radar are also consulted for complementary insights. For this event, the successive Citation II aircraft spirals through the melting layer and associated ground observations indicate a fortunate capture of the transition from a region of weak embedded updrafts and riming to one favoring aggregation processes more typical of the trailing stratiform shield of this event.

Title: A Summary of Convective Cloud Updrafts Observed during the MC3E by the ARM SGP Precipitation Radar Network

Presenter/First Author: Kirk North, McGill University, Westmount, QC

Presenter/First Author Email: kirk.w.north@gmail.com

Co-authors: Pavlos Kollias, McGill University, Montreal, QC, Canada

Abstract Body: Our understanding of convective clouds and their associated updrafts is vital to the progress and improvement of numerical weather and climate models. To this date, cloud resolving models (CRMs), which have recently been used as a benchmark for global circulation models (GCMs), are known to have nontrivial issues with their treatment of convection, including the significant overestimation of updraft strength in the upper 7-15 km of the atmosphere. However, there is a noticeable measurement gap in convective cloud observations, in particular the vertical air motion of these systems. Historically, in situ aircraft and profiling radars have been regarded as the most robust observational data sets for convective clouds, but these data sets offer only a limited footprint of the convective system being sampled. The U.S. Department of Energy's Atmospheric Radiation Measurement (ARM) Program's network of scanning Doppler precipitation radars at its Southern Great Plains (SGP) site can help bridge this measurement gap by providing coordinated, high resolution radial velocity observations of convective clouds over a large area (e.g., 10,000 km^2). A 3D variational (3D-VAR) algorithm is then used to estimate the 3D wind field through the minimization of a cost function defined by these radial velocity observations, mass continuity, and other a priori constraints. Using a data set covering roughly 15 hours worth of observations from the Midlatitude Continental Convective Clouds Experiment (MC3E), we map individual convective updraft cores in three dimensions and document important properties such as their depth, projected area, volume, aspect ratio, and mass flux. This type of analysis can be reproduced on numerical model output, the results of which can be compared with their observational targets as a means to provide further constraints on convective parameterization schemes.

Abstract: Sources of methane (CH_4) become highly variable for countries undergoing a heightened period of development due to both human activity and climate change. An urgent need therefore exists to budget key sources of CH_4, such as wetlands and lakes , which are sensitive to these changes. For this study, references in relation to CH_4 emissions from rice paddies, natural wetlands, and lakes in China were first reviewed and then re-estimated based upon the review itself. Total emissions from the three CH_4 sources were 11.25 Tg CH_4 yr^{-1}. Among the emissions, 8.11 Tg CH_4 yr^{-1} derived from rice paddies, 2.69 Tg CH_4 yr^{-1} from naturalwetlands, and 0.46 Tg CH_4 yr^{-1} from lakes Plentiful water and warm conditions, as well as it large rice paddy area make rice paddies in southeastern China the greatest overall source of CH_4, accounting for approximately 55% of total paddy emissions. Natural wetland estimates were slightly higher than the other estimates owing to the higher CH_4 emissions recorded within Qinghai-Tibetan Plateau peatlands. Total CH_4 emissions from lakes were estimated for the first time by this study, with three quarters from the littoral zone and one quarter from lake surfaces. Rice paddies, natural wetlands, and lakes are not constant sources of CH_4 but decreasing ones influenced by anthropogenic activity and climate change. A new progress-based model used in conjunction with more observations through model-data fusion approach could help obtain better estimates and insights with regard to CH_4emissions deriving from wetlands and lakes in China.

Title: CH_4 flux changes with permafrost thaw in a subarctic peatland

Presenter/First Author: Zheng Wang, McGill University, Montreal, QC

Presenter/First Author Email: wzhwangzheng@gmail.com

Co-authors: Nigel T Roulet, McGill University, Montreal, QC, Canada; Tim R Moore, McGill Univ, Montreal, QC, Canada

Abstract Body: To assess peatland CH_4 flux changes with permafrost thaw, intensive field research was conducted across transect from intact palsas, through thawed internal lawns, to pond sedges and thawed ponds in a subarctic peatland in north Quebec in the growing seasons of 2013 and 2014. From dry to wet areas, shrub and herb abundance and biomass declined, but sedges increased. Pore water pH increased, and N supply rates decreased (PRS™-probe), but K increased and P was similar along the transect. Chamber measurements showed that the palsa was the only CH_4 sink, and CH_4 emissions significantly increased in thaw areas, correlated with dissolved CH_4 concentrations in 10 cm pore water. Seasonal CH_4 efflux of each site could be modeled by 10 cm temperature, water table and sedge biomass. Seasonal average CH_4 exchange rates ranged from -0.23 mmol m^{-2} d^{-1} at the dry palsa to 13.32 mmol m^{-2} d^{-1} at sedges sites, with the largest emissions in the later part of growing season. The contribution of CH_4-C to net ecosystem exchange significantly increased from dry to wet sites, which greatly enforced radiation effect to atmosphere in thaw areas, and even changed the sedges sites from "cooling to heating". The thaw area with more sedges had much stronger gross ecosystem production, more liable fatty acid in root exudates, more labile pore water DOC, and emitted more CH_4. The effects of DOC mass and biodegradability, labile exudates and gross ecosystem production rather than net ecosystem exchange were correlated with CH_4 effluxes across the transect. This link suggests that vegetation activity and composition change with permafrost thaw dominates changes in CH_4 emission in subarctic peatland.

Title: Ecosystem-scale Methane Fluxes at Mer Bleue Bog

Presenter/First Author: Elyn Humphreys, Carleton University, Ottawa, ON

Presenter/First Author Email: elyn_humphreys@carleton.ca

Co-authors: Peter Lafleur, Trent University, Peterborough, ON, Canada; Tim R Moore, McGill Univ, Montreal, QC, Canada; Nigel T Roulet, McGill University, Montreal, QC, Canada

Published Material: The first two years of this four-year dataset are published: Brown, M. G., E. R. Humphreys, T. R. Moore, N. T. Roulet, and P. M. Lafleur. 2014. Evidence for a nonmonotonic relationship between ecosystem-scale peatland methane emissions and water table depth, J. Geophys. Res. Biogeosci., 119, doi:10.1002/2013JG002576.

Abstract Body: The relationship between water table position and methane emissions in a wetland is a result of a complex interaction between methane production, storage and transport processes. After two years of growing season eddy-covariance methane flux measurements at Mer Bleue, a temperate ombrotrophic bog, we made a number of key observations. Methane fluxes were small at Mer Bleue with average daily fluxes of ~ 20 mg CH_4-C m^{-2} d^{-1} but with considerable day-to-day variability. Fluxes generally increased as the water table fell to 47 cm depth (just past the long-term average water table position for the bog at 43 cm), there was hysteresis in the relationship between methane fluxes and water table position, and after a long mid-summer dry period in 2012, methane fluxes dropped and did not recover that year. Since that original analysis, an additional two years of measurements have been collected. Methane fluxes in 2013 did recover after the 2012 drought and continued to follow the patterns observed from the previous two years . 2014 however was an exceptionally wet summer and the water table remained above 43 cm. Summer methane emissions were greater than in previous years presumably due to conditions that enhanced both methane production and transport.

Title: Mitigation Options for CH_4 and N_2O Emissions from Rice Field in China : A Meta Analysis

Presenter/First Author: Shengwei Shi, University of Quebec at Montreal UQAM, Montreal,

Presenter/First Author Email: weiweishi848@gmail.com

Co-authors: Changhui Peng, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Yu'e Li, , ,

Abstract Body: The planted paddy in China is a critical source of CH_4 and N_2O emissions to the atmosphere. Implement practices to reduce CH_4 and N_2O emissions will benefits for not only grain productivity and yield stability but also climate change mitigation. Here we performed a meta-analysis of CH_4 and N_2O emissions to quantify the mitigation potential of each management practice (water management, organic fertilizer, N input ratio etc.). The results showed that the CH_4 emissions under water management of flooding-drainage-reflooding(F-D-F), flooding-drainage-reflooding-moist intermittent irrigation(F-D-F-M) and moister irrigation (M) was reduced by 45%, 59% and 83%, respectively, comparing with that under continuously flooded (CF). The water status of non-growing season also significantly enfluenced on CH_4 emission, e.g. the CH_4 emission was reduced by 42% for short drainage, by 51% for long drainage, and by 56% for tow drainage compared to containable flooded in non-growing season, respectively. The ability of organic fertilizer to produce CH_4 emission followed an order of crop straw > farm manure > green manure > biogas digestion. The CH_4 emission was decreasing gradually with increasing chemical nitrogen fertilizer ratio. The water management regimes in rice growing period and the non-growing season, and total nitrogen fertilizer input both influenced N_2O emission. Compared to CF, the N_2O emission was increased by 12% under F-D-F, by 140% under F-D-F-M and by 48% under M. The mean N_2O emission fluxes was increased by 40% ~110% under water status of short drainage, long drainage and tow drainage in the non-rice growing season A trade-off relationship between emission of CH_4 and N_2O in rice field appeared as water management regimes in rice growing period, water status of non-rice growing season, and the amount of synthetic nitrogen fertilizer. Mitigation measurements in rice fields should be taken into consideration for both of CH_4 and N_2O emissions comprehensively.

Title: Estimating global natural wetland methane emissions using process modeling: spatiotemporal patterns and contributions to atmospheric methane fluctuations

Presenter/First Author: Qiuan Zhu, Northwest A&F University, Yangling,

Presenter/First Author Email: qiuan.zhu@gmail.com

Published Material: some results were under review

Abstract Body: The fluctuations of atmospheric methane (CH_4) in recent decades are not fully understood, particularly regarding contributions by wetlands. Application of spatially explicit parameters has been suggested to be an effective method for reducing uncertainties in bottom-up approaches for wetland CH_4 emissions, but not being included in recent studies. Our goal was to estimate spatiotemporal patterns of global wetland CH_4 emissions using the process model of TRIPLEX-GHG and then to identify the contribution of wetland emissions to atmospheric CH_4 fluctuations. A newly developed process-based model integrated with full descriptions of methanogenesis (TRIPLEX-GHG) was applied to simulate global wetland CH_4 emissions. The simulation results showed that: Global annual wetland CH_4 emissions ranged from 155 $TgCyr^{-1}$ to 185 $TgCyr^{-1}$ between 1901 and 2012, with peaks occurring in 1991 and 2012. There is a decreasing trend between 1990 and 2010 with a rate of approximately 0.36 $TgCyr^{-1}$, which was largely caused by tropical wetlands emissions that have a decreasing trend of 0.33 $TgCyr^{-1}$ since the 1970s. Emissions from tropical, temperate, and high latitude wetlands comprised 59%, 26% and 15% of global emissions, respectively. Tropical wetlands are the primary contributors to the inter-annual variability of global wetland CH_4 emissions and atmospheric CH_4. The stable-to-decreasing trend in wetland CH_4 emissions, which resulted from a balance of emissions from tropical and extratropical wetlands, was a factor particularly for the slow-down in the atmospheric CH_4 growth rate during the 1990s. The rapid decrease in tropical wetland CH_4 emissions that started in 2000 is supposed to offset the increase in anthropogenic emissions, and resulted in a relatively stable level of atmospheric CH_4 during the period 2000–2006. Increasing wetland CH_4 emissions, particularly after 2010, are an important contributor to the resumed growth of atmospheric CH_4 since 2007 and to the expected increases in the near future.

Title: Estimates of CH_4 Emissions from Natural Wetlands in China: From 1950 to 2008

Presenter/First Author: Tingting Li, Institute of Atmospheric Physics, Chinese Academy of Science, Beijing,

Presenter/First Author Email: litingting@mail.iap.ac.cn

Co-authors: Yao Huang, , ,

Published Material: This presentation has been preciously reported in AOGS conference in 2014. It will be submitted to Global Change Biology in recent days.

Abstract Body: Natural wetland loss has been one of the potential environmental concerns in China, while less attention was paid to concomitant changes in methane (CH_4) emissions. In this paper, we developed a model framework based on a biogeophysical model $CH4MOD_{wetland}$, which was firstly modified to apply to the coastal wetland. Then it was coupled with TOPMODEL and TEM model in order to extrapolate to the regional scale. We estimated national CH_4 emissions resulting from the natural wetlands in China in 1950, 1978, 1990, 2000 and 2008 based on the model framework. Model simulations indicated that annual CH_4 emissions decreased from 4.50 Tg (3.74—5.37 Tg) in 1950 to 2.15 Tg (1.83—2.56 Tg) in 2008. Tremendous decrease of 2.33 Tg in CH_4 emissions happened before 2000, with wetland loss of 16.28 M ha. Among the reduction, 0.26 Tg (0.24—0.28 Tg) derived from lakes and rivers, 0.17 Tg (0.13—0.20 Tg) from coastal wetlands, and 1.92 Tg (1.54—2.33 Tg) from the inland wetlands, including marshes, floodplains, peatlands and swamps. The wetlands in northeastern China contributed ~71% to the total CH_4 reduction. Slight wetland loss happened in the Qinghai Tibet Plateau, where contributed only ~6% of total CH_4 reduction. Climate warming increased CH_4 fluxes, especially in the inland wetlands of northeastern China between 1950 and 2008. Our study implies that the increase of CH_4 fluxes will be different between Regions in future.

Title: Predicting the impacts of repeated El Niño Southern Oscillation (ENSO) on the methane emissions of tropical wetlands

Presenter/First Author: Changhui Peng, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: peng.changhui@uqam.ca

Abstract Body: Methane emission from tropical/subtropical wetlands contributed about 78% methane emissions of global nature wetlands. Decreased wetland CH_4 emissions could act as a negative feedback to future climate warming and vice versa. Recent study suggested that powerful warming events in the eastern equatorial region, known as El Niños, are likely to double as greenhouse-gas emissions rise this century. However, the impact of ENSO on wetland emission variability has been paid less attention and remained poorly quantified at both regional and global scales. Here, we used an improved global greenhouse gases dynamic model of TRIPLEX-GHG to investigate the impacts of interannual variations on CH_4 emissions in tropical wetlands during the period 1950 to 2010. Our modeled results suggest that CH_4 emissions from tropical wetlands respond strongly, with larger negative anomalies during El Niño years and larger positive anomalies in La Niña years, to repeated ENSO events throughout 1950s- 2000s, which has probably contributed to the recent decrease in the atmospheric growth rate of CH_4 concentration during 1980s-1990s and stabilized observed atmospheric CH4 concentrations during 1999-2006.

Title: Communicating Climate Risk to Natural Resource Managers

Presenter/First Author: Richard N Palmer, , Amherst, MA

Presenter/First Author Email: palmer@ecs.umass.edu

Abstract Body: The Northeast Climate Science Center (NECSC) is one of eight centers funded by the Department of Interior through the USGS to work with regional stakeholders to evaluate the impacts of climate change on natural resource management. The NECSC in housed at the University of Massachusetts Amherst and is composed of a consortium of institutions including the University of Wisconsin Madison, University of Minnesota, University of Missouri, Columbia University, the College of Menominee Nation, and the Marine Biology Laboratory. The geographic extent of the Center ranges from Maine to Virginia to Missouri to Minnesota. The goal of the center is to provide scientific information, tools, and techniques that managers and other parties interested in land, water, wildlife and cultural resources can use to anticipate, monitor, and adapt to climate change in the Northeast region.

Essential to this goal is the delivery climate projections that allow resource managers to make decisions at local and regional levels that are well-informed relative to future climate conditions. This challenge is complicated by a variety of uncertainties including those associated with future greenhouse gas levels, the current limitations and biases of general circulation and regional climate models, the relationship of climate change to species and ecosystems of interest, and limitation on our ability to model complex biological systems.

This paper discusses how the NECSC has approached these challenges in our efforts to support regional nature resource management. A combination of regional climate projections, stakeholder engagement, and improved science communication has been applied to ensure that the results generated provide users with management relevant variables, that recent historic trends as well as climate projects inform our understanding, and that the uncertainties associated with all stages of impact analysis are clearly understood by stakeholders.

Title: Evaluating Statistical Downscaling Performance Under Changing Climatic Conditions

Presenter/First Author: Keith W Dixon, NOAA, Princeton, NJ

Presenter/First Author Email: Keith.Dixon@noaa.gov

Co-authors: John R Lanzante, NOAA, Princeton, NJ; Carlos F Gaitan, University of Oklahoma Norman Campus, Norman, OK; Katharine Hayhoe, Texas Tech University, Lubbock, TX; Anne Marie K Stoner, Texas Tech University, Lubbock, TX

Published Material: The introduction & experimental design will be similar to work presented at an AMS meeting and an NCPP workshop, but that info has not appeared in a journal or in the media. Results are mostly new.

Abstract Body: A broad range of empirical statistical downscaling (ESD) methods of varying levels of complexity exist, all of which may be used to refine Global Climate Model (GCM) projections via processes that glean information from a combination of observations and GCM-simulated climate change responses. ESD output files are viewed as value-added products – deemed to be more suitable for downstream applications than the raw GCM results from which they are derived. Yet, different ESD methods have different performance characteristics, indicating that ESD processing introduces uncertainties of its own. Often, assumptions that may limit the suitability of statistically downscaled projections for specific decision-support applications are not well-conveyed to researchers interested in incorporating high resolution climate projections into regional climate change impacts studies. We are developing a framework to systematically evaluate performance characteristics of ESD methods. For example, there is an inherent stationarity assumption that presumes ESD techniques perform as well in the future as during the observed period – a difficult to evaluate assumption, given the lack of future observations. A "perfect model" experimental design quantifies aspects of ESD method performance both for a historical period and for late 21st century climate projections, thereby quantitatively assessing how well the stationarity assumption holds. Results illustrate how ESD performance varies geographically, by time of year, variable of interest, amount of climate change, and is dependent upon the specific ESD method used. By revealing sensitivities, strengths and weaknesses, these evaluations contribute to inform ESD method improvements and can provide guidance regarding aspects of the confidence one should attribute to different statistically downscaled climate projections used for regional climate change impacts studies.

Title: Quantifying Climate Change Impacts on Infrastructure: A Statistical Downscaling Application

Presenter/First Author: Anne Marie K Stoner, Texas Tech University, Urbana, IL

Presenter/First Author Email: anne.stoner@ttu.edu

Co-authors: Katharine Hayhoe, Texas Tech University, Lubbock, TX

Abstract Body: Over the coming century, climate change has the potential to impact infrastructure in many different ways, particularly in population-dense areas that depend on transportation and built environments. Many of these impacts may occur via changes in the frequency and magnitude of extremes: high and low temperature, precipitation, coastal flooding, and storm events.

In some cases, it is not yet possible to quantify how global change will affect local extremes, and/or how climate change might impact society. At the same time, resilience can be built into planning through preparing for conditions that already occur: tornadoes, derechoes, or even extreme thunderstorms. For other applications, simply the direction of change is sufficient to inform future planning: will hurricanes become stronger, or winter storms more or less frequent? For some impacts, though, particularly those that show significant historical trends as well as consistent future change and quantifiable impacts, it is possible to resolve both projected changes as well as impacts under a given scenario.

In this presentation, we describe a framework for developing and implementing future projections using the example of a set of infrastructure-relevant climate indices for the state of Delaware, USA. The indices are based on mean and extreme temperature, precipitation, humidity, and combinations thereof calculated from GCM simulations from nine models corresponding to a lower and a higher scenario, statistically downscaled to 14 individual station records using the ARRM model. We also describe the process of selecting an appropriate subset of GCMs and future scenarios, as well as how to extract useful information from a large selection of downscaled output with associated uncertainties. The results highlight the importance of including future climate projections into infrastructure planning, as opposed to using the past as a guide when planning for the future.

Title: From range retraction to population cycling: How spatially-explicit demographic models can inform climate change vulnerability

Presenter/First Author: Benjamin Zuckerberg, University of Wisconsin Madison, Madison, WI

Presenter/First Author Email: bzuckerberg@wisc.edu

Co-authors: Ilona Naujokaitis-Lewis, , , ; Lars Pomara, , ,

Published Material: Midwest Fish and Wildlife ConferencePomara, L.Y., O.E. LeDee, K.J. Martin, and B. Zuckerberg. 2014. Demographic consequences of climate change and land cover help explain a history of extirpations and range contraction in a declining snake species. Global Change Biology 20: 2087-2099

Abstract Body: Adaptation to climate change requires understanding species vulnerabilities in terms of demographic sensitivity and exposure to climatic and other environmental factors across full life cycles and in diverse landscapes. As part of an ongoing project, we present findings from two case studies using spatially-explicit demographic modeling to assess the vulnerability of Eastern Massasauga Rattlesnake (*Sistrurus catenatus*) and Ruffed Grouse (*Bonasa umbellus*) to climate change in the upper Midwest and Great Lakes region of the United States. Results from multiple survival and reproductive success studies were used to identify demographic sensitivities to several climatic and land use factors. We then used these relationships to parameterize demographic simulations with dynamic climate and land use from 1960 to 2012, and evaluated the resulting population models by comparison to long-term and spatially extensive monitoring datasets. Our modeling framework is implemented in a region showing marked variation in habitat connectivity and climatic conditions; allowing for a quantitative assessment of the relative influence of these factors on long-term population dynamics and geographic distributions. We highlight several important findings demonstrating the role of climate and land use on long-term range contraction in massasauga rattlesnakes and altered dynamics of population cycling in ruffed grouse. Both analyses are critical examples of the role of variation in temperature and precipitation extremes, synergistic effect of climate and land use change, and the importance of considering the full life cycle of vulnerable species. Climate change vulnerability assessment provides a framework for linking demographic and distributional dynamics to environmental change, and can provide unique information for conservation planning.

Title: Reconciling scales for modeling the effects of climate change on wildfire

Presenter/First Author: Uma Shankar, University of North Carolina, Chapel Hill, NC

Presenter/First Author Email: ushankar@unc.edu

Co-authors: Donald McKenzie, US Forest Service, Pacific Wildland Fire Sciences, Seattle, WA; Jared Heath Bowden, University of North Carolina at Chapel Hill, Chapel Hill, NC; Kevin Talgo, , , ; Limei Ran, University of North Carolina at Chapel Hill, Chapel Hill, NC; Bok Haeng Baek, , , ; Zachariah Adelman, Institute for the Environment, Chapel Hill, NC; Aijun Xiu, , , ; Mohammad Omary, , , ; Elizabeth A Adams, , Cary, NC; Dongmei Yang, , ,

Published Material: A review article co-authored by the first and second authors was published under the title "Smoke consequences of wildfire regimes driven by climate change" in the AGU online journal Earth's Future (McKenzie et al., Earth's Future, 2, 35-59, 2014). It describes the issues of scale associated with earth system models that are used to study the effects of climate change on wildfires. However it did not present the results of the modeling study described in this submission; the study began after that publication.

Abstract Body: Smoke from wildfires has adverse biological and social consequences, and various lines of evidence suggest that smoke from wildfires in the future may be more intense and widespread, demanding that methods be developed to address its effects on people, ecosystems, and the atmosphere. Projecting smoke consequences of future wildfires requires a multidisciplinary approach that involves reconciling complex physical and biological processes at widely different scales in space and time. We review the most difficult scaling issues, which include: (1) reconciling regional-scale atmospheric processes with fine-scale fire-spread dynamics and variation in fuel loadings, (2) translating contagious disturbance (fire) across landscapes in varying topography into estimates of regional smoke transport, and (3) identifying the feasibility of coupled modeling that incorporates important feedbacks vs. a simpler approach that may be less error-prone for integrating modules at different scales. We illustrate model linkages and tradeoffs with results from an ongoing study of climate change, wildfire, and air quality in the Southeastern US. This study dynamically downscales general circulation model (GCM) output to model the regional climate, and includes vegetation from coupling land cover to the GCMs; empirical fuel loadings at fine scales, projected into the 2040s with a delta method; a stochastic coarse-scale fire generator, and regional air quality assessments of the fire emission impacts with the Community Multiscale Air Quality (CMAQ) model. There are considerable challenges in representing future climatic variability important for fire while keeping computations feasible, but also in two efforts associated explicitly with reconciling processes across scales. First, how can coarse-scale carbon pools generated by the global model be translated into the fine-scale fuel characteristics that are critical for modeling fire? Second, how can fine-scale variation in fire activity associated with the spatial patterns of topography and vegetation (fuels) be aggregated meaningfully to produce regional projections?

Title: *Cross Site Analysis of Projections of the Biogeochemical Responses of Forested Watersheds in the Northeastern U.S. to Future Climate Change and Increasing CO_2 over the 21st Century Using a Dynamic Model (PnET-BGC)*

Presenter/First Author: Charles T Driscoll, Syracuse Univ, Syracuse, NY

Presenter/First Author Email: ctdrisco@syr.edu

Co-authors: Afshin Pourmokhtarian, Boston University, Boston, MA; John L Campbell, USDA Forest Service, Vallejo, CA; Anne Marie K Stoner, Texas Tech University, Urbana, IL; Katharine Hayhoe, Texas Tech University, Lubbock, TX

Abstract Body: A cross-site analysis of seven diverse, intensive study watersheds was conducted to evaluate how northeastern U.S. forests might respond to future changing climate. We used outputs of four AOGCMs; CCSM4, HadGEM2, MIROC5, and MRI-CGCM3 coupled with RCP8.5 and RCP4.5 emissions scenarios to represent possible higher- and lower-emission futures, respectively. These outputs were statistically downscaled using ARRM trained on meteorological observations from watershed stations. Meteorological projections were applied as inputs to the hydrochemical model PnET-BGC to evaluate the response of watershed attributes of management-relevant ecosystem services (NPP, soil C, stream water quantity and quality). Evapotranspiration (ET) is projected to increase across all sites under potential future conditions of warmer temperature and longer growing season. Spruce-fir forests are more susceptible to temperature stress due to their lower optimum temperature for photosynthesis and may be replaced in the future with more tolerant hardwoods. Some hardwood forests are projected to experience water stress due to early loss of snowpack, longer growing season and associated water deficit. This response is counter-intuitive to the anticipated increase in precipitation. The streamflow projections are highly variable with some sites showing significant increases in annual water yield, while others decrease. This variability in hydrologic response could challenge the future management of the Northern Forest. Following increases in temperature, ET and water stress associated with future climate change scenarios, a shifting pattern in carbon allocation in plants was evident causing significant changes in NPP. The soil humus C pool is projected to decrease with increases in temperature. This analysis suggests that dominant vegetation type and historical land disturbances coupled with climate variability will influence responses of forest ecosystem services to future changes in climate.

Title: Simulating Pacific Northwest Forest Response to Climate Change: How We Made Model Results Useful for Vulnerability Assessment

Presenter/First Author: John B Kim, US Forest Service Corvallis, Corvallis, OR

Presenter/First Author Email: jbkim@fs.fed.us

Co-authors: Becky K Kerns, US Forest Service Corvallis, Corvallis, OR; Jessica Halofsky, University of Washington Seattle Campus, Seattle, WA

Published Material: This was presented as a poster at AGU 2014 annual meeting.

Abstract Body: GCM-based climate projections and downscaled climate data proliferate, and there are many climate-aware vegetation models in use by researchers. Yet application of fine-scale DGVM based simulation output in national forest vulnerability assessments is not common, because there are technical, administrative and social barriers for their use by managers and policy makers. As part of a science-management climate change adaptation partnership, we performed simulations of vegetation response to climate change for four national forests in the Blue Mountains of Oregon using the MC2 dynamic global vegetation model (DGVM) for use in vulnerability assessments. Our simulation results under business-as-usual scenarios suggest a starkly different future forest conditions for three out of the four national forests in the study area, making their adoption by forest managers a potential challenge. However, using DGVM output to structure discussion of potential vegetation changes provides a suitable framework to discuss the dynamic nature of vegetation change compared to using more commonly available model output (e.g. species distribution models). From the onset, we planned and coordinated our work with national forest managers to maximize the utility and the consideration of the simulation results in planning. Key lessons from this collaboration were: (1) structured and strategic selection of a small number climate change scenarios that capture the range of variability in future conditions simplified results; (2) collecting and integrating data from managers for use in simulations increased support and interest in applying output; (3) a structured, regionally focused, and hierarchical calibration of the DGVM produced well-validated results; (4) simple approaches to quantifying uncertainty in simulation results facilitated communication; and (5) interpretation of model results in a holistic context in relation to multiple lines of evidence produced balanced guidance. This latest point demonstrates the importance of using model out as a forum for discussion along with other information, rather than using model output in an inappropriately predictive sense. These lessons are being applied currently to other national forests in the Pacific Northwest to contribute in

vulnerability assessments.

Title: Status of our understanding about legacy mercury, its role in the global biogeochemical cycle, and implications for forecasting environmental change

Presenter/First Author: Helen Marie Amos, Harvard University, Somerville, MA

Presenter/First Author Email: hamos@hsph.harvard.edu

Co-authors: Elsie M Sunderland, Harvard University, Cambridge, MA

Published Material: I will be presenting a critical review on legacy Hg, including results from Amos et al. (2013) in Global Biogeochemical Cycles, Amos et al. (2014) in Environmental Science & Technology, and Amos et al. (2015) in reivew in Environmental Science & Technology.

Abstract Body: Humans have been releasing mercury (Hg) to the environment since antiquity, resulting in a significant accumulation in the ocean, atmosphere, and terrestrial ecosystems. A large fraction of anthropogenic Hg accumulated in surface ecosystems can be re-emitted to the atmosphere, re-entering an active global cycling. This recycled portion is referred to as legacy Hg. It plays a central role in the present-day global cycle influences future trajectories of environmental Hg concentrations. We present a critical synthesis of the current state of the science regarding legacy Hg and discuss implications for our ability to anticipate future responses to regulatory action. The synthesis includes perspectives from the atmosphere, ocean, and terrestrial systems as well as primary sources of Hg (natural + anthropogenic) to the environment. There has been considerable debate in recent literature in particular about the importance of historical anthropogenic Hg emissions from early large-scale precious metal mining. We present a combined analysis using models, natural archives (sediment, peat, ice), and direct observations (atmosphere, soil, seawater) to examine anthropogenic impacts on the global Hg cycle. The weight of evidence from this analysis suggests early anthropogenic Hg emissions contribute significantly to present-day enrichment. Lastly, we use measurements and models to identify key processes driving the uncertainty in legacy Hg and anthropogenic enrichment. We also identify key uncertainties affecting future projections, providing results in a global context as well as a case study from the North Pacific Ocean. The need for aggressive future reductions of global anthropogenic Hg emissions in order to stabilize Hg concentrations in the top 1000 m of the ocean is robust to uncertainties in Hg cycling and emissions, and is due to the intrinsic timescales involved. In the atmosphere, there will be a rapid (<1 year) benefit if future anthropogenic emissions are curbed.

Title: Distribution of Hg and Pb in peatlands of Ontario

Presenter/First Author: Julie Talbot, University of Montreal, Montreal, QC

Presenter/First Author Email: j.talbot@umontreal.ca

Co-authors: Tim R Moore, McGill Univ, Montreal, QC, Canada; Meng Wang, , Montreal, QC, Canada; John L Riley, , ,

Abstract Body: While considerable attention has been given to the measurement of Hg and Pb concentrations and accumulation in a few detailed peat cores in central Canada, the geographic distribution and density of sampling is weak. Here we use the Ontario Peatland Inventory to examine broad patterns of Hg and Pb concentration with depth, based on over 400 peat cores (containing ~1500 analyzed samples) in southeastern, northeastern and northwestern sections of Ontario. Overall, Hg concentrations averaged 0.052 $\mu g\ g^{-1}$ and that of Pb averaged 11.1 $\mu g\ g^{-1}$. When samples were binned by 10-cm increments in the profile, Hg concentrations fell from 0.06-0.08 $\mu g\ g^{-1}$ in the top 30 cm to 0.03-0.05 $\mu g\ g^{-1}$ below 50 cm. The pattern was more pronounced for Pb, with concentrations falling from 20-25 $\mu g\ g^{-1}$ in the top 30 cm and 5-10 $\mu g\ g^{-1}$ below 50 cm. With average organic C:Hg and C:Pb ratios of $14.9*10^6$ and $0.18*10^6$, respectively, below 50 cm and assuming an average long-term C accumulation rate of 30 g $m^{-2}\ yr^{-1}$, these results suggest average long-term accumulation rates of 1-2 μg Hg $m^{-2}\ yr^{-1}$ and 125-150 μg Pb $m^{-2}\ yr^{-1}$.

The spatial pattern of Hg concentration in the surface layers (0-30 cm) shows small values < 0.05 $\mu g\ g^{-1}$ in remote locations, increasing to 0.10 to 0.50 $\mu g\ g^{-1}$ in SE Ontario and around population and industrial centres. Pb concentration shows a similar pattern, with values < 25 $\mu g\ g^{-1}$ in remote locations rising to 30 – 120 $\mu g\ g^{-1}$ particularly in SE Ontario and around population and industrial centres.

Title: Spatial and Temporal Trends in Mercury Accumulation in Laurentian Great Lakes Fish: Are Global Mercury Inputs Affecting the Great Lakes Ecosystem?

Presenter/First Author: Thomas Holsen, Clarkson University, Potsdam, NY

Presenter/First Author Email: holsen@clarkson.edu

Co-authors: David P Krabbenhoft, USGS Wisconsin Water Science Center, Middleton, WI; Hao Zhou, , , ; Timothy Johnson, , , ; Bernard Crimmins, , ,

Abstract Body: Lake Trout (*Salvelinus namaycush*) and walleye (*Sander vitreus*) are collected from two sites within each lake, every other year, and total mercury (HgT) is measured as part of the Great Lakes Fish Monitoring and Surveillance Program (GLFMSP). Previous analyses of Hg concentration trends at these locations were inconsistent, with concentrations at some locations increasing, some decreasing and some not changing. This updated trends analysis indicates that at nearly all sampling locations, HgT concentrations are decreasing with the exceptions of the shallow (nearshore) site in Lake Michigan and the deep (offshore) site in Lake Huron, which showed increasing Hg concentrations. Apparent increasing trends at these two locations are likely the result of older fish present in the size class collected as well as possible localized deposition emanating from nearby industrial centers. These results in conjunction with significant reductions in water column Hg; decreases in Hg(0) concentrations in air over the lakes over the past 7-10 years, and declining trends in Hg wet deposition at most locations near the Great Lakes over the past 10 years

suggest that environmental regulations enacted by U.S. and Canada are having positive effects in the Great Lakes ecosystem and that increasing global anthropogenic emissions are not overwhelming regional controls and significantly impacting mercury concentrations in the Great Lakes. Analysis of stable Hg isotope results, which is a new tool in Hg research

Title: A cross-ecosystem comparison of mercury accumulation in Canadian lakes and aquatic food webs along a 30º latitudinal gradient

Presenter/First Author: Murray Richardson, Carleton University, Ottawa, ON

Presenter/First Author Email: murray_richardson@carleton.ca

Co-authors: John Chetelat, Environment Canada Ottawa, Ottawa, ON, Canada; Gwyneth Anne MacMillan, Universite de Montreal, Montreal, QC, Canada; Marc Amyot, Universite de Montreal, Montreal, QC, Canada

Abstract Body: A cross-ecosystem study was initiated in 2012 to test a conceptual model of aquatic ecosystem sensitivity to atmospheric mercury (Hg) pollution along a climatic gradient spanning 30° of latitude, from southern Quebec to the Canadian high Arctic. The overarching goal of the study was to quantify local (physiographic, hydrogeomorphic) and regional (climatic) factors that limit or enhance mercury bioaccumulation in aquatic food webs, including both biotic and abiotic pathways. This presentation will report on inter- and intra-regional differences in water-column concentrations of total mercury (THg), methyl-mercury (MeHg) and dissolved organic carbon (DOC), and MeHg concentrations in zooplankton among 26 lakes in four different regions: Gatineau Park, QC (45.63°, 75.81° W), Kuujjuarapik-Whapmagoostui, QC (55.27° N, 77.76° W) Iqaluit, NU (63.75° N, 68.52° W) and Resolute Bay, NU (74.70° N, 94.83° W).

Surface water concentrations of MeHg were strongly and positively correlated to THg concentrations (R^2=0.72, p<0.001) in lakes across the latitudinal gradient, implying strong control of inorganic mercury supply on MeHg concentrations. THg was strongly correlated to DOC in surface waters after pooling arctic and subarctic lakes ($R^2 = 0.67$, $p < 0.001$). Surface water concentrations of both THg and MeHg decreased logarithmically ($r^2 = 0.48$ and 0.60, for THg and MeHg, respectively, $p < 0.001$) as a function of lake residence times (derived through watershed morphometry and available climate normals), suggesting that in-lake processing of THg and MeHg may reduce their concentrations within the water column. This effect was observed at both inter- and intra-regional scales. Moreover, we found water column concentrations of MeHg to explain some of the inter-lake variations in zooplankton MeHg concentrations across the latitudinal gradient (R^2= 0.47, p<0.001). These results point to an interaction between watershed and lake morphometry (i.e. watershed area to lake-volume ratio) and regional climate (mean annual runoff) that can explain large variations in Hg concentrations in northern freshwater ecosystems. Changing temperature and precipitation regimes will alter hydrologic residence times of lakes across Canada, with important implications for biogeochemical cycling and food web bioaccumulation of Hg.

Title: Climate Change Impacts on Mercury Mobility in Peatland Ecosystems

Presenter/First Author: Kristine Haynes, University of Toronto, Toronto,

Presenter/First Author Email: k.haynes@utoronto.ca

Co-authors: Carl P J Mitchell, University of Toronto, Toronto, ON, Canada; Evan S Kane, Michigan Technological University, Houghton, MI; Lynette Potvin, USDA Forest Service, Northern Research Station, Houghton, MI; Erik Lilleskov, USDA Forest Service, Northern Research Station, Houghton, MI; Randy K Kolka, USDA Forest Service, Grand Rapids, MN

Abstract Body: Mercury (Hg) cycling, speciation and mobility in peatlands will likely be affected by alterations in carbon cycling and redox conditions resulting from climate-induced changes in hydrological processes and shifting vegetation communities. The overall objective of this research is to assess the impacts of climate change, specifically fluctuating water tables and altered vegetation communities, on Hg cycling and mobility in northern peatlands through mesocosm-scale experimental research. This study is being conducted at the PEATcosm Mesocosm Facility at the USDA Forest Service Northern Research Station in Houghton, Michigan. Throughout the 2013 and 2014 growing seasons, pore water samples were collected at 20, 40 and 70 cm below the surface of 1 m^3 peat mesocosms, with manipulated (average control or low) water table positions and different vegetation communities (sedge only, ericaceae only or unmanipulated control) in a factorial design. Total Hg (THg) and methylmercury (MeHg) analyses revealed significant influences of both water table position and dominant plant functional group on pore water THg and MeHg concentrations and MeHg production and/or accumulation (as determined by the percentage of THg present as MeHg, %MeHg). The %MeHg was highest in mesocosms with lowered water tables and sedge vegetation with mean pore water MeHg concentrations of 1.0 ng L^{-1} accounting for approximately 7% of pore water THg. Pore water MeHg concentrations exhibit a positive correlation with dissolved organic carbon concentrations. These preliminary results suggest that climate change, inducing greater amplitude fluctuating water tables and shifting vegetation communities towards sedge-dominated systems, may have notable impacts on MeHg production and/or accumulation in peatland pore waters and these change may be influenced by organic matter dynamics.

Title: Effects of Timber Harvest on Mercury Cycling in the Pacific Northwest, USA

Presenter/First Author: Chris Eckley, Environmental Protection Agency Seattle, Seattle, WA

Presenter/First Author Email: eckley.chris@epa.gov

Co-authors: Collin Eagles-Smith, Forest and Rangeland Ecosystem Science Center, Corvallis, OR; Michael Tate, , , ; David P Krabbenhoft, USGS Wisconsin Water Science Center, Middleton, WI; Brandon Kowalski, USGS Forest and Rangeland Ecosystem Science Center, Corvallis; Leigh Woodruff, Environmental Protection Agency Idaho Operation Office, Boise

Published Material: Poster at AGU meeting in SF 2014

Abstract Body: Forested landscapes have been shown to act as a net sink for atmospheric mercury inputs which has resulted in a legacy of mercury accumulated in the soil. Timber production and harvesting (frequently via clearcutting) is a common land-use feature throughout forested regions and can influence mercury cycling through hydrological and biogeochemical alterations. The objective of our study was to understand how forest harvesting impacts key components of the mercury cycle including: mobilization in runoff, methylation, volatilization, and downstream bioaccumulation. The study was performed within an experimental forest located within the Trask River watershed in Oregon, USA. The study utilized three paired harvested and un-harvested sub-catchments plus a pair of reference catchments. Flumes were located at the outflow of each of the catchments and were continuously monitored for flow volume and other water quality parameters. Water samples for filtered and particulate total and methylmercury (as well as several

ancillary parameters) were measured approximately monthly for 1.5 years following harvest and represented the full range of hydrologic conditions. The results showed that there was no significant difference between particulate total mercury or total suspended solids between clearcut and forested catchments. However, there was a significant increase (36%) in filtered total-mercury concentrations in paired clearcut watersheds. Salamander tail mercury samples were also significantly higher in the clearcut catchments compared to the paired forest catchments. Soil-air mercury fluxes showed higher levels of net emission from the clearcut catchments compared to the forested sites, which appears to be related to increased levels of solar radiation reaching the soil. Overall, these results highlight the effects of forestry operations on several important aspects of mercury cycling in forested landscapes.

Title: Comparisons of Terrestrial Mercury (Hg) Accumulation and Dynamics across Temperate Forests and an Arctic Tundra site

Presenter/First Author: Daniel Obrist, Desert Research Institute, Reno, NV

Presenter/First Author Email: dobrist@dri.edu

Co-authors: Detlev Helmig, University of Colorado at Boulder, Boulder, CO; Yannick Agnan, Desert Research Institute Reno, Reno, NV; Christine Hedge, Desert Research Institute Reno, Reno, NV; Christopher W Moore, Desert Research Institute, Reno, NV; Jacques Hueber, , ,

Abstract Body: The patterns show that the arctic tundra site contains high levels of Hg in spite of its remote location. While atmospheric Hg is strongly retained in, and associated with, organic horizons at temperate sites, in the tundra Hg is not correlated with organic carbon and is subject to strong vertical translocation through organic layers and efficient sorption in mineral soils, possibly due to increased snow-melt induced vertical transport, freeze-thaw cycles, or frequent water-saturated conditions. Using semi-permeable Teflon wells to measure gas-phase Hg concentration and exchanges, we observe that both organic and mineral soil horizons at temperate and polar sites serve as sinks for gaseous elemental Hg, indicating a dominance of oxidation over reduction processes independent of climatic or moisture regimes. This study suggests a particularly strong role of mineral soil layers for Hg sorption and storage in tundra soils, with possible consequences of climate-induced warming which is expected to increase the active layer depth of tundra mineral soils.

Title: Mercury chemical transformation and speciation in atmospheric and aquatic media

Presenter/First Author: Parisa A Ariya, McGill University, Montreal, QC

Presenter/First Author Email: parisa.ariya@mcgill.ca

Abstract Body: Due to the toxicity and propensity for bio-magnification and bioaccumulations, mercury species are identified as among most toxic compounds in the planet. Despite the significant evolution of our knowledge in understanding mercury cycling, particularly in the polar regions during the last decade, there are major key science questions in our understanding of mercury transformation, including (a) mercury chemical speciation and (b) mercury chemical reactions, particularly heterogeneous reactions, topics which will be discussed in this paper. We present our recent data surface-selective femto second spectroscopy on mercury surface, as well as heterogeneous reactions on series of environmental aerosols and on particles in aquatic media. We will also present the observation of mercury speciation that was performed during the summer 2014 in the city of Montreal using our newly developed mercury spectrometry. We will discuss the implications in the context of mercury cycling in environment.

Title: Determining microbial methylmercury production through the use of molecular probes: Insights into *hgcAB* expression and distribution in the environment

Presenter/First Author: Dwayne A Elias, Oak Ridge National Laboratory, Oak Ridge, TN

Presenter/First Author Email: eliasda@ornl.gov

Co-authors: Richard A Hurt, , , ; Eugenio F U Santillan, Smithsonian Environmental Research Center Edgewater, Edgewater, MD; Ann M Wymore, , , ; Andrew J King, , , ; Allyson Bullock, , , ; Cynthia C Gilmour, Smithsonian Institution, Edgewater, MD

Abstract Body: Biotic Hg methylation to methylmercury (MeHg) is performed through the actions of anaerobic micoorganisms, and this function is encoded by the newly discovered gene pair *hgcAB*. These genes have been identified in three clades of microorganisms: the *Deltaproteobacteria*, *Firmicutes*, and *Archaea*. Because this discovery is still recent, the functions, abundance, and distribution of these genes in relation to Hg methylation have yet to be elucidated. To address this, we have designed a set of universal PCR and clade-specific qPCR primers as molecular probes. Previous primers from other studies have been created, but are very selective in the organisms they target and do not capture the breadth of *hgcAB* diversity. Our PCR primer, designed to span the entire *hgcAB* gene pair, is universal, and can be used to compare diversity among all methylating organisms. We also developed qPCR primers, which are specific for *Deltaproteobacteria*, *Firmicutes*, and *Methanomicrobia*, the three main clades of *hgcAB*+ microbes. The qPCR primers are based on the *hgcA* gene only, and were designed for evaluation of gene copy number. Primers were designed by identifying and comparing conserved regions within the HgcA and HgcB protein between 48 methylating organisms and between specific clades. After design, primer effectiveness was determined by testing the probes on monocultures of methylating organisms from a comprehensive collection curated by the Smithsonian Environmental Research Center and Oak Ridge National Laboratories. Further validation was performed by testing the probes on mixed cultures and by combinations of DNA with sand to simulate environmental samples. Lastly, primers were validated by testing their efficiency on environmental samples ranging from Arctic soils to marshes. Of the methylating organisms tested in the laboratory, the universal *hgcAB* PCR primer amplified the gene from 90% of the all cultures. The clade-specific qPCR primers amplified 70-90% of the cultures within each targeted clade. These primers give us the tools to perform meaningful quantification and taxonomy of *hgcAB* in the environment, a significant step understanding and mitigation MeHg risk.

Abstract Body: Organisms from the Class *Methanomicrobia*, a group of methylotrophic and hydrogenotrophic methanogens, have recently been identified as the first known group of Hg-methylating *Archaea*. They are one of several newly identified clades of *hgcAB*⁺ organisms, which include *Firmicutes* and syntrophic *Deltaproteobacteria*. However, despite the expanded diversity of Hg-methylating organisms and environments, orthologues of *hgcAB* are rare among available microbial genomes.

Here we begin to evaluate how important methanogens may be in Hg methylation in the environment. As a first approach, we measured Hg-methylation rates by *hgcAB*⁺ methanogens in pure culture, using organisms from culture collections with available genomes. Based on available genomes, we identified 12 *hgcAB*⁺ methanogens, all Class *Methanomicrobia*. All of the *hgcAB*⁺ *Archaea* identified from microbial genomes fall in this specific group of methanogens. Twelve of ~25 sequenced *Methanomicrobia* genomes have *hgcAB* orthologues.

Using a standardized approach to measuring methylation, we compared methylation rates among cultures, and across different culture conditions. We found major differences in methylation rates among organisms, even when normalize to growth and culture chemistry. Sulfur complexes like cysteine and sulfide appear to be critical controls on Hg methylation by methanogens, as they are in sulfate- and iron-reducing bacteria. *Methanosphaerula palustris* E1-9c and *Methanospirillum hungatei* JF-1 are particularly able methylators, rivalling SRB and FeRB, and converting over 70% of provided Hg into MeHg under optimal conditions. These results support the idea that methanogens may be important contributors to MeHg production in certain environments.

Title: Hotspots of Methylmercury in Thaw Ponds from the Eastern Canadian Arctic: Link between Methylmercury and Nutrient Loading in the Rapidly Changing North

Presenter/First Author: Gwyneth Anne MacMillan, Universite de Montreal, Montreal, QC

Presenter/First Author Email: gwynmacmillan@gmail.com

Co-authors: Catherine Girard, Universite de Montreal, Montreal, QC, Canada; Isabelle Laurion, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, QC, Canada; John Chetelat, Environment Canada Ottawa, Ottawa, ON, Canada; Marc Amyot, Universite de Montreal, Montreal, QC, Canada

Published Material: These findings were reported at a workshop on Permafrost Thawing, THAW 2014: Thermokarst Aquatic Ecosystems Workshop, organized by the Centre d'Études Nordiques, in Québec City (QC) in an oral presentation by Marc Amyot. These findings are also ready for submission to the scientific journal Environmental Science and Technology (ES&T) (submission in the next few weeks).

Abstract Body: Permafrost thaw ponds are ubiquitous in the eastern Canadian Arctic, yet little information exists on their potential as sources of methylmercury (MeHg) to freshwaters. MeHg is a potent neurotoxin that can biomagnify to elevated concentrations in aquatic food webs. Thaw ponds are microbially-active and conducive to methylation of inorganic mercury, and are affected by changes in nutrient inputs related to Arctic warming. This multi-year study investigates thaw ponds in a discontinuous permafrost region in the subarctic taiga (Kuujjuarapik-Whapmagoostui, QC) and a continuous permafrost region in the Arctic tundra (Bylot Island, NU). MeHg concentrations in thaw ponds were well above levels measured in most freshwater ecosystems in the Canadian Arctic (> 0.1 ng L-1). On Bylot, ice wedge trough ponds showed significantly higher MeHg (0.3 - 2.2 ng L-1) than polygonal ponds (0.1 - 0.3 ng L-1) or lakes (< 0.1 ng L-1). High MeHg were also measured in the bottom waters of subarctic thaw ponds near Kuujjuarapik (0.1 - 3.1 ngL-1). High water MeHg in thaw ponds were strongly correlated with variables associated with high inputs of organic matter (DOC, a320, Fe), nutrients (TP, TN), and microbial activity (dissolved CO_2 and CH_4). Our results suggest a relationship between organic matter erosion from thawing permafrost, reducing conditions in the sediments and the production of methylmercury in these sites. Thawing permafrost due to Arctic warming will continue to release nutrients and organic carbon into these systems and increase ponding in some regions, likely stimulating higher water concentrations of MeHg. Greater hydrological connectivity from permafrost thawing may potentially increase transport of MeHg from thaw ponds to neighbouring aquatic ecosystems.

Title: Methylmercury Cycling in the Arctic: What do we need to know in the face of a changing climate

Presenter/First Author: Igor Lehnherr, University of Toronto, Mississauga,

Presenter/First Author Email: igor.lehnherr@utoronto.ca

Published Material: I will be presenting a synthesis of some of my recent work, published in Lehnherr 2014 (Environ. Rev.), Lehnherr et al. 2012 (ES&T) and other related papers.

Abstract Body: There has been increasing concern regarding mercury (Hg) – and more specifically methylmercury (MeHg) – levels in marine and freshwater organisms in the Arctic, due to the importance of traditional country foods such as fish and marine mammals to the diet of Arctic Aboriginal people. This presentation will provide a synthesis of some recent advances in our understanding of MeHg cycling and sources in Arctic aquatic ecosystems. Included in this synthesis will be a discussion of the environmental factors that impart controls on MeHg production, how climate and environmental change may impact MeHg cycling, and what key knowledge gaps need to be addressed to better predict MeHg exposure in Arctic biota. In Arctic marine ecosystems, Hg(II) methylation in the water column, rather than bottom sediments, is the primary source of MeHg, although a more quantitative understanding of the role of DMHg as a MeHg source is needed. Because MeHg production in marine waters is limited by the availability of Hg(II), predicted increases in Hg(II) concentrations in oceans are likely to result in higher MeHg concentrations and increased exposure to Hg in humans and wildlife. In Arctic freshwaters, MeHg concentrations are a function of two antagonistic processes, net Hg(II) methylation in bottom sediments of ponds and lakes, and MeHg photodemethylation in the water column. Hg(II) methylation is controlled by microbial activity and Hg(II) bioavailability, which in turn depend on interacting environmental factors (temperature, redox conditions, organic carbon and sulfate) that induce non-linear responses in MeHg production and which are sensitive to changes in climate.

Co-authors: Yuting Gu, , , ; Yashika Agarwalla, , , ; Yiwei Cheng, Lawrence Berkeley National Lab, Marietta, GA; Sopan Dileep Patil, Bangor University, Bangor, United Kingdom; Greg Turk, , ,

Abstract Body: We use two Machine Learning techniques, Decision Trees (DT) and Neural Networks (NN), to provide classified images and photorealistic renderings of future vegetation cover at three large regions in the US. The training data used to generate current vegetation cover include Landsat surface reflectance images, USGS Land Cover maps, 50 years of mean annual temperature and precipitation (1950 - 2000), elevation, aspect, and slope data. Future vegetation cover for the period 2061- 2080 was predicted using bias corrected data from the NASA GISS Global Climate Model E simulation.

The three test regions encompass a wide range of climatic gradients, topographic variation, and vegetation cover. The central Oregon site covers 19,182 sq. km. Vegetation is 50% evergreen forest and 50% shrubs-scrubs. The New Mexico site covers 5,500 sq. km. Vegetation is predominantly evergreen forest, shrubs, and grasses. The northwest Washington site covers 14,182 sq. km. Vegetation is predominantly evergreen forest. The remainder of the area includes deciduous forest, perennial snow cover, and wetlands.

Using the above mentioned data we first trained our DT and NN models to reproduce current vegetation. Land cover classified images were compared directly to the USGS land cover data. Photorealistic generated vegetation images were compared to the remotely sensed surface reflectance maps.

The three trained models were then used to explore what the equilibrium vegetation would look like for the period 2061 - 2080. The predicted mean annual air temperature change for the three sites ranged from +1.8°C to +2.3°C. For the three sites precipitation changed little. In Oregon, this resulted in a 37% shift of forested areas to shrub vegetation. In New Mexico, shrubs and evergreen vegetation increased by 18% and 5%, respectively. Deciduous and grassland vegetation decreased by 90% and 52%, respectively. In Washington, deciduous vegetation, shrubs, and grasslands increased by 25%, 15%, and 7%, respectively. Evergreen vegetation and perennial snow cover on mountain tops decreased by 4.5% and 46%, respectively.

Title: CO_2, CH_4 and N_2O Emissions from Boreal Reservoirs, 20 years of data!

Presenter/First Author: Alain Tremblay, Hydro-Québec, Montreal, QC

Presenter/First Author Email: tremblay.alain@hydro.qc.ca

Co-authors: Maryse Lambert, , ,

Published Material: This is a synthesis of 20 years of data, data have been partly presented in different scientific meeting over the years throught different aspect and angles. A part of this has also been presented at ASLO in Spain in February 2015.

Abstract Body: Eastmain 1 reservoir (Quebec, Canada) was flooded in November 2005. To increase the volume of water stored in Eastmain 1, the Rupert River was diverted. Partial flooding of the Rupert diversion bays (RD) took place in 2009 and the flooding was completed in 2011. The impoundment of organic matter is known to lead to GHG emissions at the water surface of newly created reservoirs. Remarkably, the different approaches/methods used to monitor CO_2 and CH_4 partial pressures and emissions over 7 years showed comparable results. The impact of the creation of a new reservoir upstream the Eastmain 1 Reservoir was shown to be week in term of emissions. Summer and winter system productivity was estimated from CO_2 continuous measurements; for example respiration rates from 19 to 148 $mgC.m^{-3}.d^{-1}$ were found in summer at the central station of the reservoir, which is comparable to published data using different method. Finally datasets from other boreal reservoirs were used to explore the relationship between winter and summer production rate and put in perspective the lability of the organic matter in these systems.

Title: Modelling Seasonal and Annual Variability of Carbon Fluxes in a Large Boreal Hydroelectric Reservoir

Presenter/First Author: Weifeng Wang, McGill University, Montreal, QC

Presenter/First Author Email: weifeng.wang@mcgill.ca

Co-authors: Youngil Kim, Oregon State University, Corvallis, OR; Nigel T Roulet, McGill University, Montreal, QC, Canada; Ian B Strachan, McGill University, Montreal, QC, Canada; Alain Tremblay, Hydro-Québec, Montreal, QC, Canada

Published Material: The content was presented in the AGU fall meeting, but we have more solid simulation results and new findings.

Abstract Body: Greenhouse gas emissions from hydroelectric reservoirs have attracted much attention over the past decades. To quantify CO2 emissions from reservoir surfaces we intergrate a lake carbon model, modified from the Hanson Lake Carbon Model, a newly developed 1-dimension thermal stratification model, and a terrestrial biogeochemistry model (DNDC: DeNitrification-DeComposition) that simulates vegetation litter and soil organic carbon dynamics under flooded conditions. We evaluated CO2 emissions simulated by the newly developed FAQ (Flooded AQuatic)-DNDC model using observed fluxes from an eddy covariance tower in an ~600 km2 boreal hydroelectric reservoir, Eastmain-1, in northern Quebec, Canada, for the period of 2007-2012. Simulated annual CO2 emissions generally matched the observed fluxes. The model captures well the seasonal pattern of CO2 flux from the reservoir surface, although the simulated peak emission in spring are overestimated compared to the observations. Sensitivity analysis shows that the amounts of dissolved organic carbon (DOC) input rarely affect CO2 emissions but greatly influences the DOC concentration in water column. Our analysis also suggests that warming changes the temporal pattern and magnitude of CO2 emissions. Future research on mechanisms of CO2 evasions through ice is necessary for reliable simulation for seasonal ice covered aquatic ecosystems.

Title: Predicted Releases of Greenhouse Gases from Land-use Change of a Proposed Hydroelectric Reservoir in Canada Using a Carbon Mass-balance Model

Presenter/First Author: Jean-Michel A. DeVink, Stantec Consulting Ltd, Saskatoon,

Presenter/First Author Email: jdevink@stantec.com

Co-authors: Michael C. Murphy, , , ; Karen Gillam, , , ; Malcolm Stephenson, , , ; Paul Mazzocco, , , ; Siobhan Jackson, , ,

Published Material: These results were presented in an Environmental Assessment and CEAA report, but have not been specifically presented elsewhere in the scientific community.

Abstract Body: Understanding the potential contributions of large projects to greenhouse gases (GHGs) in the atmosphere is increasingly important in the current social context of heightened awareness about climate change. Regulatory agencies are requiring greater attention to activities and projects that have long-term changes to land-use that could result in substantial releases of GHGs to the atmosphere. Here we present a site-specific carbon cycle in the form of a landscape carbon mass-balance model. This model is used to predict the net GHG emissions as part of an environmental assessment for a proposed hydroelectric reservoir located in northeast British Columbia. We based the model inputs on local biophysical and geophysical properties of the site, and modeled several hypothetical Project scenarios. The model was based on the exchange (flows) of carbon between the primary carbon stores (stocks). These stocks included atmosphere (CO_2 and CH_4), surface water, soil, sediment, terrestrial plants, wetlands, and large ruminants. A baseline model was first constructed to model existing conditions and calibrated to a long-term net-zero carbon mass-balance. The baseline model was then adjusted for post-flooding landscape parameters and results were compared to the baseline model to determine the Project's net GHG emission. Overall, the model predicted a net GHG emission of the Project in the order of 43,400 to 58,200 t CO_2e/yr for the assumed 100 yr Project lifespan as a result of the land use change. Based on the Project's anticipated 5,100 GWh energy output, this translated to between 8.5 and 11.4 CO_2e/kWh from land-use change (9.7 and 13.3 g CO_2e/kWh, including construction-related emissions), which is at the lower end of the reported range of life-cycle assessments (8 to 60 g CO_2e/kWh) for boreal hydroelectric reservoirs. These results were not surprising given the Project is a tertiary reservoir drawing hydraulic capacity from a large upstream reservoir and due to its northern latitude location where the river is narrow and the resulting hydroelectric reservoir is relatively deep.

Title: Climate and Land-Use Gradients Drive Spatially Coherent CO2 Driver-Response Relationships Across US Lakes

Presenter/First Author: Jean-Francois Lapierre, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: jfrancoislapierre@gmail.com

Co-authors: Kendra S. Cheruvelil, , , ; Sarah M. Collins, , , ; Carol Emiko Fergus, Michigan State University, East Lansing, MI; Christopher Filstrup, Iowa State University, Ames, IA; David A Seekell, University of Virginia, Charlottesville, VA; Patricia Ann Soranno, , ,

Abstract Body: Understanding how diverse environmental factors influence partial pressure of CO2 (pCO2) in lakes is challenging because local or regional relationships can rarely be generalized at continental scales. The ability to predict lake pCO2 typically decreases at larger spatial extents and with increasing environmental gradients, suggesting non-linearities in the pCO2 driver-response relationships across large and diverse landscapes. We explored spatial patterns in the response of pCO2 to several biological (chlorophyll a) and chemical (nutrients, dissolved organic carbon and alkalinity) drivers in lakes across the contiguous United States using geographically weighted regressions. Allowing the regression parameters to change spatially more than tripled our ability to predict pCO2 compared to traditional multi-linear regression models. The regression parameters formed spatially contiguous clusters, indicating that there were large-scale differences in pCO2 driver-response relationships and that these clusters were substantially different from widely used, pre-determined regionalisation frameworks. The clusters were mainly differentiated on the basis of climate and land-use. In dry and low development areas, pCO2 was primarily related to alkalinity, whereas high precipitation and intensive land use (e.g., agriculture and urban) areas were negatively related to Chl a and positively related to dissolved organic carbon. These results highlight the need to consider non-linearities in the relationships between lake pCO2 and its drivers across large environmental and spatial gradients, which may improve extrapolations based on smaller-scale studies and will improve our understanding of how the aquatic carbon cycle responds to global change.

Title: Methane Oversaturation in Boreal Lakes: Towards Process-based Understanding

Presenter/First Author: Tonya Del Sontro, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: tdelsontro@gmail.com

Co-authors: Shoji D Thottathil, , , ; Yves Prairie, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Paul del Giorgio, Groupe de Recherche Interuniversitaire en Limnologie, Montréal, QC, Canada

Published Material: Will be presented in part at ASLO meeting in Granada, Spain in February.

Abstract Body: Methane (CH4) oversaturation in lakes, particularly in the surface waters, is a common finding of limnological research on gas dynamics. A few possible explanations have been put forth to explain this ubiquitous condition of the landscape, but the interaction of these possible processes and their ability to truly explain the oversaturation remain

unresolved. In this context, 11 lakes in the Laurentian region of southern Quebec, Canada were surveyed in detail for CH4 dynamics during summer 2014. Surface sampling throughout the lakes and a cross-section of depth profiles across the deepest point of the lake revealed a persistent CH4 oversaturation in each lake at the surface, as well as at several other depths with depleting concentrations in between. No significant ebullition was found in the profundal zone of any lake, while substantially high CH4 emissions were observed from floating chamber measurements in the littoral zones. Higher dissolved CH4 concentrations in the littoral along with the floating chamber measurements, as well as submerged bubble trap surveys in the littoral zones of three of the lakes, suggest that littoral methane production is mostly responsible for the CH4 oversaturation in Laurentian lakes. Mass balance models will help in determining the CH4 contribution from the littoral zone and other possible sources as well as provide the basis for testing a lake-level process-based model at the landscape and regional level of Quebec.

Title: Methane under ice in boreal lakes

Presenter/First Author: Terhi Rasilo, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: terhi.rasilo@gmail.com

Co-authors: Paul del Giorgio, Groupe de Recherche Interuniversitaire en Limnologie, Montréal, QC, Canada

Published Material: The preliminary analysis were presented as a poster in GLEON16 meeting in Octobre 2014.

Abstract Body: Lakes are important sources of greenhouse gases (GHG) to the atmosphere, emitting both carbon dioxide (CO_2) and methane (CH_4). The extent of ice cover and changes related to mixing of water column strongly influence the seasonal variation in GHG dynamics, and without considering them, the annual estimates of GHG emissions from boreal lakes may be strongly biased. While seasonal variation of CO_2 is relatively well known, the seasonality of CH_4 has not been well described, particularly in northern lakes during the ice cover period. We conducted seasonal measurements of CH_4 and CO_2 concentrations of 13 boreal lakes in Québec over the course of an annual cycle. We observed significant under ice accumulation of CH_4 in seven out of the 13 lakes, whereas CH_4 concentrations and fluxes consistently increased during summer in almost all lakes. Winter CH_4 accumulation has been previously related to the anoxic conditions but most of our lakes remained oxic also in winter and thus the role of oxygen limitation seemed to be minor in these lakes. Lakes accumulating CH_4 under ice were in general larger than non-accumulator lakes (2985±1787 km^2 and 23±14 km^2) and had higher total phosphorous concentration (20.1 $\mu g\ L^{-1}$ and 12.9 $\mu g\ L^{-1}$) but there was no difference in the mean depth between the two groups of lakes. Higher nutrient concentrations can increase primary production increasing the amount of organic matter that sediments to the bottom and acts as a source for methanogenesis. In larger lakes the residence time can be longer than in smaller lakes, which can allow more efficient accumulation. Contrary to CH_4, the seasonal CO_2 patterns were similar across the lakes, with all the lakes accumulating CO_2 under ice and having lowest concentrations in the middle of summer. Whereas winter accumulation of CO_2 and subsequent emissions following ice melt represent a major contribution to the annual CO_2 flux, this is not always the case for CH_4, since a significant fraction of lakes did not accumulate CH_4 under the ice and peak CH_4 fluxes occurred in late summer, representing the bulk of annual emissions. Our results collectively suggest that seasonal GHG patterns vary greatly across boreal lakes, and it is therefore important to account for such seasonal heterogeneity to generate reliable annual emissions budgets for boreal lakes.

Title: Lurking Just Beneath the Surface: Antibiotic Resistance Among Fe(III)-Reducing Bacteria and Other Members of Freshwater Surface Microlayer Bacterial Communities

Presenter/First Author: Christopher Drudge, McMaster University, Hamilton, ON

Presenter/First Author Email: drudgecn@mcmaster.ca

Co-authors: Lesley A Warren, McMaster University, Hamilton, ON, Canada

Abstract Body: Bacterial communities that included Fe(III)-reducing bacteria (IRB) were enriched from the surface microlayer (SML; a trace metal, nutrient, and microbially enriched interfacial microenvironment) and at 0.5 m depth in two freshwater littoral environments (wastewater-impacted Sunnyside Beach; pristine Coldspring Lake). The presence of IRBs was permitted at these well-oxygenated depths by the availability of O_2-depleted floc-based microhabitats. Enriched communities were expected to be highly resistant to metals and antibiotics due to the ability of IRB to dissolve metal-rich Fe minerals and thus be highly exposed to metals. However, inhibition of soluble Fe(III) reduction (i.e. IRB activity) occurred at significantly lower ($P < 0.05$) concentrations of environmentally relevant trace metal or antibiotic cocktails compared to the inhibition of bulk Fe(III)-reducing enrichment community metabolic activity. Further, Cu exposure selectively inhibited Fe(II) production by solid Fe(III)-reducing enrichment community members, which were specifically expected to be highly resistant to trace metals, and was associated with a decrease in the relative abundance of known IRB genera (*Aeromonas* and *Clostridium*) in 16S rRNA gene clone libraries derived from enrichments. Interestingly, unlike trace metal resistance, antibiotic resistance was significantly higher ($P < 0.05$) among IRB in soluble Fe(III)-reducing enrichment communities from the SML relative to those from 0.5 m depth, pointing to the selective promotion of antibiotic resistance in SML communities independent of metal and antibiotic resistance co-selection mechanisms. SML soluble Fe(III)-reducing enrichment communities also possessed a greater variety of antibiotic resistance gene-carrying mobile genetic elements and opportunistic pathogens compared to enrichments from 0.5 m depth in both lakes, identifying the SML as a potential reservoir and disseminator of antibiotic resistant pathogens within aquatic systems.

Title: Cyanobacteria Dominance in the Lake Simcoe Georgian Bay Area: an Oxygen, Sulfate and Iron Approach.

Presenter/First Author: Eric McQuay, University of Waterloo, Waterloo,

Presenter/First Author Email: emmcquay@uwaterloo.ca

Co-authors: Jason J Venkiteswaran, Wilfrid Laurier University, Waterloo, ON, Canada; Sherry L Schiff, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Cyanobacteria blooms are an increasing concern for cottage owners and tourists in the Lake Simcoe and Georgian Bay area. These blooms ruin the aesthetics of lakes and can result in the production of toxins that have led to the illness of children and, in some cases, the death of animals. The near annual appearance of these blooms on some lakes has reduced property values to the point where land is unsellable. Current knowledge suggests that an excess of nutrients, such as phosphorous (P) and nitrate (NO_3), are the leading cause for algal blooms. However, it is proposed that the availability of ferrous iron (Fe^{2+}) in the water column is the key to cyanobacteria dominance due to the inability of cyanobacteria to transfer Fe^{3+} across the cell membrane. This research is focused on predicting the potential of a lake to support cyanobacteria by

observing the biogeochemical interactions of P, O_2, Fe^{2+} and sulfate (SO_4) in several lakes in the Georgian Bay and Lake Simcoe area. Excess P promotes anoxia of the hypolimnion which allows for the dissolution of Fe^{2+} making it available to cyanobacteria which can migrate into the hypolimnion. Once O_2 becomes scarce, SO_4^{2-} reducers which produce sulfide (HS^-) can dominate. HS^- binds with Fe^{2+} forming insoluble iron sulfides FeS. Three sites: Sturgeon Bay, Deep Bay and North Bay were sampled throughout the summer season for SO_4^{2-}, TP, TN, O_2, Fe, NH_4^+ and NO_3^- in 2012 when blooms where present and in 2014 when blooms where absent. It is hypothesized that in 2014 these sites had less P loading, higher SO_4^2 concentrations and lower Fe^{2+} concentrations than were present in 2012. If this is the case then it may be possible to predict which lakes are likely to become dominated by cyanobacteria based solely on their chemistry and implement preventive measures accordingly.

Title: Quantification of Gas Fluxes through Frozen Sand and Snow Cover using a Multi-Tracer Approach

Presenter/First Author: Sophie Guillon, GEOTOP-UQAM, Montréal,

Presenter/First Author Email: sophieguillon88@gmail.com

Co-authors: Florent Barbecot, UQAM, , QC, Canada; Marie Larocque, Univ du Quebec - Montreal, Dorval, QC, Canada; Daniele Luigi Pinti, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Eric Pili, CEA/DAM-ILE DE FRANCE, Arpajon, France

Abstract Body: Seasonal freezing of the vadose zone affects approximately 50% of the exposed land in the Northern Hemisphere, while 30 % has a seasonal snow cover. The occurrence and thickness of frozen soil and snow cover are directly responsible for water, energy and gas fluxes from the surface to aquifers and vice-versa. Fluxes of CO_2 and other trace gases such as CH_4 and N_2O have been shown to occur during winter and to contribute to the annual budget, but they are often not measured or considered. Microbial processes, temperature and soil permeability are involved in controlling these gas fluxes, which need to be better understood and quantified. A multi-tracer approach is used to identify gas transport mechanisms and quantify gas fluxes. The experimental site is located on a sand deposit (esker), southwest of Montreal (Canada). Radon and CO_2 dynamics are currently monitored in the first meters of soil and in the snowpack throughout the 2015 winter and spring seasons. Soil water content, frost depth, snow cover and air pressure in soil and snow are also measured. Air permeability in these porous media is determined. Radon, a non-reactive gas that is produced homogeneously in the soil, is used to identify transport processes. Biological processes controlling CO_2 production can then be discriminated. In addition to these naturally produced gases, SF_6 is injected at the soil/snow interface as a tracer to evaluate the possibility for gases to seep to the atmosphere or to the unsaturated zone during winter. Transport mechanisms of gases through frozen and thawing soil as well as through heterogeneous snow cover will be discussed, in particular the role of barometric pumping as opposed to diffusion.

Title: Disturbance legacies and paludification mediate the ecological impact of an intensifying wildfire regime in the Clay Belt boreal forest of eastern North America.

Presenter/First Author: Aurélie Terrier, University of Quebec at Montreal UQAM, Verdun,

Presenter/First Author Email: terriea0@gmail.com

Co-authors: Martin P Girardin, Canadian Forest Service, Québec, Canada; Alan Cantin, , , ; William de Groot, , , ; Kenneth Agbesi Anyomi, , , ; Sylvie Gauthier, , , ; Yves Bergeron, Industrial Chair CRSNG-UQAT-UQAM in sustainable forest management, Rouyn-Noranda, QC, Canada

Published Material: The paper is going to be published in the Journal of Vegetation Science (early view)The results were presented as a poster at: - the Wildland Fire Canada Conference 2014, Halifax, Canada- the 6th Ouranos Symposium 2014, Québec, Canada

Abstract Body: High moisture levels and low occurrences of wildfires have contributed during recent millennia to the accumulation of thick layers of organic soil and to a succession into open black spruce (Picea mariana)-Sphagnum dominated forests in the Clay Belt boreal landscapes of eastern North America. In these forests, the anticipated increase in drought frequency with climate change could lead to a shift in forest structure and composition, and to a subsequent transfer of the stored carbon back into the atmosphere via increased fire disturbance and decomposition. Herein we conducted modeling experiments using the Canadian Fire Effects Model (CanFIRE) to investigate potential changes in forest structure and composition in response to a changing fire regime. Vegetation dynamic was governed by the fire danger and behaviour that affect tree mortality and postfire recruitment of species, and by long-term successional pathways that are driven by postfire recruitment and forest age. Results from multiple scenarios suggested that fire danger will rise significantly during the 21st century in the Clay Belt forest. The burn rate was projected to change from 4.2%/decade during 1971-2000 to 18.6%/decade during 2071-2100. Stand mortality, fire intensity and areas affected by crown fires were also projected to increase significantly. A shift in forest composition did not occur over the simulation period across most of our fire regime scenarios. Moist and cool conditions in these forests prevent high depth of burn and contribute to the ecological resistance of these forests to increasing fire danger.

Title: Vegetation Continuous Fields: The Evolution of Sub-Pixel Land Cover Mapping from AVHRR, MODIS and Landsat

Presenter/First Author: Robert Allen Sohlberg, University of Maryland, College Park, MD

Presenter/First Author Email: sohlberg@umd.edu

Co-authors: Charlene DiMiceli, University of Maryland College Park, College Park, MD; Mark Carroll, NASA Goddard Space Flight Center, Greenbelt, MD; Do-Hyung Kim, University of Maryland College Park, College Park, MD; Maureen Kelly, University of Maryland, College Park, MD; John R Townshend, University of Maryland, College Park, MD

Abstract Body: Land cover is an essential parameter describing the Earth's surface. In traditional satellite-based land cover maps, each pixel is assigned a single land cover class, but this method does not capture the subpixel and within-class heterogeneity present in the landscape. Traditional land cover maps also have a limited number of *a priori* vegetation classes, which may not be well tailored for all applications.

Mapping vegetation as subpixel fractions of biophysical types addresses short-comings of traditional land cover maps. Maps of Vegetation Continuous Fields (VCFs) capture gradations of landscape variability, such as those due to disturbance or subpixel patterns of nutrient and water availability. VCFs are inherently better suited to representation of gradual spatial and temporal changes in land cover, and offer improved estimation of biophysical parameters over large areas. They allow modelers greater flexibility in constructing parameterizations that directly depict driving factors in the landscape at a range of spatial resolutions, for example surface roughness.

The VCF depictions are unique and not furnished by normalized difference vegetation index (NDVI) and leaf area index (LAI) products. VCFs describe the heterogeneity of each pixel, differentiating, for example, between a pixel covered with sparse forest and a pixel covered with a mixture of forest, crops and bare ground. VCFs also quantify the subpixel proportions of tree cover, non-tree vegetation, bare ground and water found in each pixel.

Current VCF products are generated with four fractional layers: tree cover, non-tree vegetation, bare ground and water. Vegetation is further partitioned by leaf type (broadleaf / needleleaf) and leaf longevity (evergreen / deciduous). This presentation describes the evolution, lessons learned and application of VCFs over the past two decades from AVHRR (1°, 8 km, 1 km) to MODIS (500 m, 250 m) to Landsat (30 m) as well as current advances toward an inter-calibrated, multi-sensor, 30+ year data set at 1/20º. Through the VCF development history, methods have evolved from end-member mixture modeling to multiple regression trees with dynamic hands-off automated training. This evolution is described and current applications of the products are described. Funded by NASA via NNX14AJ33G and NNX13AJ35A.

Title: Efficient Updating of Land-Cover Classifications in a Data-Rich Environment

Presenter/First Author: Jeffrey A Cardille, Universite de Montreal, Montreal, QC

Presenter/First Author Email: jeffrey.cardille@umontreal.ca

Co-authors: Julie Anne Fortin, McGill University, Montreal, QC, Canada

Abstract Body: *What was the land cover of Las Vegas, Nevada on July 10, 2014? In the view of Landsat 5, 7, and 8, how much wetland area has been lost or gained annually on the Gulf Coast since Hurricane Katrina? Given observations from both MODIS and Landsat, where has forest in Bolivia been converted to non-treed land cover since 1984?*

For many scientists interested in using interpretations of remote-sensing data such as land-cover classifications, questions like these are enticing but remarkably difficult to answer given the current state of the art for interpreting remote sensing image sequences. We developed a new algorithm designed for the continuous updating of land-cover classifications through time in large data sets. The algorithm ingests classified land-cover data from any of the wide variety of earth-resources sensors; it maintains a running estimate of land-cover probabilities and the most probable class at all time points along a sequence of events. We tested this algorithm in central Quebec with Landsat 8 data for summer 2013, when a series of large fires erupted and burned through forests. Across 10 images of widely varying quality, our algorithm detected the fires, ignored contaminated image information, and mapped fire borders consistently throughout the summer. The sequence of land-cover maps through time had producer's and user's accuracies that were better than many of the component days, which were often contaminated by fire haze and clouds but nevertheless contained useable information. As we leave remote sensing's data-poor era and enter a period with multiple looks at Earth's surface from multiple sensors over a short period of time, this algorithm may help to sift through images of varying quality to extract the most useful information for mapping.

Title: Bayesian Updating of Land Cover Classification in th Brazilian Provinces of Amazonas and Mato Grosso

Presenter/First Author: Julie Anne Fortin, McGill University, Montreal, QC

Presenter/First Author Email: julie.fortin93@gmail.com

Co-authors: Jeffrey A Cardille, Universite de Montreal, Montreal, QC, Canada

Abstract Body: Land cover classifications are extremely useful tools that can be applied to help solve issues in policy, social sciences, conservation and more. However, they only capture information on a region for a snapshot in time. Given the dynamic state of the Earth and the impact of anthropogenic changes to land use and land cover on various timescales, there is need for continuous tracking of landscape change. This is of particular relevance for areas such as the Brazilian Amazon, where the rate of landscape change, especially from deforestation, has fluctuated over the past few decades. We have developed an algorithm in R (Bayesian Updating of Land Cover Classifications, a.k.a. BULC) which is capable of performing updates on land cover classifications by applying Bayesian statistics to classified images on a pixel-by-pixel basis. We have tested it on a study area around the Roosevelt River at the border between the Amazonas and Mato Grosso states in Brazil. As inputs into the algorithm, we used satellite imagery from Orbiew, Aster, CBERS, Landsat 1, 2, 7 and 8; classified imagery from the Finer Resolution Observation and Monitoring - Global Land Cover program and MODIS; as well as aerial imagery, at spatial resolutions ranging from 5 m to 500 m. We found that our algorithm is capable of providing up-to-date classifications despite relatively poor quality input classifications, in addition to being robust to using varied input data sources. Future developments of the BULC algorithm include testing the fidelity of its updates with that of pre-existing classification updates from the National Land Cover Database (NLCD) collection in the Las Vegas area between 1992, 2001 and 2006.

Title: Organic carbon cycling in lakes: exploring the source and sink balance through process modeling

Presenter/First Author: Paul C Hanson, University of Wisconsin Madison, Verona, WI

Presenter/First Author Email: pchanson@wisc.edu

Co-authors: Hilary A Dugan, , , ; Jordan Stuart Read, USGS Wisconsin Water Science Center, Middleton, WI

Abstract Body: Understanding of the roles lakes play in the global carbon cycle will be improved through advances in ecosystem models that include major components of the lake carbon cycle. Integrating lake models with catchment models and climate re-analysis products provides opportunities to study how lakes respond to both changes in landscape characteristics and climate variability and to better understand the circumstances controlling the fate of carbon in lakes. In this study, we model organic carbon dynamics in lakes and their catchments, capturing seasonal dynamics of both allochthonous and autochthonous sources of carbon. Model results are compared with major scales of variability in observed organic carbon concentrations to identify shortcomings in model structure reflective of our knowledge gaps in carbon cycling. Uncertainty in predictions, derived from uncertainties in observations and model parameters help identify ecosystem variables that warrant better observations and processes that warrant closer study.

Title: The Role of Fe and pH in the Photolytic Decomposition of Dissolved Organic Carbon in Boreal Lakes

Presenter/First Author: Jennifer L Mead, University of Waterloo, Waterloo,

Presenter/First Author Email: jmead@uwaterloo.ca

Co-authors: Sherry L Schiff, University of Waterloo, Waterloo, ON, Canada; Jason J Venkiteswaran, Wilfrid Laurier University, Waterloo, ON, Canada; Richard J Elgood, University of Waterloo, Waterloo, ON, Canada; Ryan H.S. Hutchins, Université du Québec à Montréal, Montreal, QC, Canada; Pieter Aukes, University of Waterloo, Waterloo, ON, Canada; John Spoelstra, Environment Canada, Burlington, ON, Canada

Published Material: Preliminary results from experiments that will be presented at AGU were first presented at the CCFFR/SCL Conference in Ottawa, January, 2015.

Abstract Body: Dissolved organic carbon (DOC) is the largest input of carbon to northern shield lakes but retention of DOC within lakes is large. Photodegradation of DOC is an important abiotic process for DOC loss. Products of DOC photodegradation including particulate organic carbon (POC), dissolved inorganic carbon (DIC), and photolytically altered DOC affect the size of carbon pools in lakes. Concomitantly, lake parameters such as pH and Fe concentrations can influence the rates of carbon transformation, yet these influences are poorly understood. Stable isotope analysis has been used to provide insight into the fate of allochthonous DOC and the accumulation of POC in lake sediments. In laboratory experiments, pH and Fe concentrations of three boreal streams (2 sites from The Experimental Lakes Area, Kenora, ON and one site from Dorset, ON) were manipulated to observe the impact on DOC photodegradation and POC formation. Measurement of carbon pools before, during and after photolysis allows the determination of DOC loss (production of DIC and POC formation) and carbon mass and isotopic mass balances. A novel size exclusion method, LC-OCD, was used in conjunction with other measures of quality to identify changes in DOC composition resulting from photodegradation. Changes in $^{13}C/^{12}C$ from photolysis were measured in the DOC before and after the experiment while the evolved CO_2 was measured throughout the experiment. The data will provide insight into the mechanisms controlling the partitioning of terrestrial carbon between the atmosphere and lake sediments.

Title: Modelling the impact of increasing dissolved organic carbon load on seasonal anoxia in a boreal humic lake.

Presenter/First Author: Raoul-Marie Couture, Norwegian Institute for Water Research, Oslo,

Presenter/First Author Email: rmc@niva.no

Published Material: Under review in Journal of Geophysical Research: Biogeosciences

Abstract Body: Boreal lakes are impacted by climate change, reduced acid deposition and changing loads of dissolved organic carbon (DOC) from the catchment. We set to explore how these changes, in particular the increasing DOC load, modulate ice phenology and dissolved oxygen (DO) of a boreal humic lake located in southeastern Norway. Observed trends in daily air temperature (+0.045 $^oC\ yr^{-1}$) and weekly DOC concentration (0.1 mg C yr^{-1}, +1% annually) measured over the past 40 years at the study site were used as forcings for the lake model MyLake. The model was parametrized against year-round time-series of water temperature and DO from a high-frequency lake buoy. A backcast of ice freezing and break-up dates to 1974 reveals that ice break-up occurs on average 8 days earlier in 2014 than in 1974. An earlier ice break-up enhances water column ventilation, resulting in higher DO in the spring. Later in the season, warmer water in late summer lead to longer anoxic periods, as microbial DOC turnover increases. Long-term increase in DOC concentrations causes decline in lake DO, leading to 15% more hypoxic days (< 3 mg L^{-1}) and 10% more anoxic days (< 15 ug L^{-1}) in 2014 than in 1974. We conclude that climate warming and increasing DOC loads are antagonistic with respect to their effect on DO availability. The model suggests that DOC is a stronger driver of DO consumption than temperature. DOC increase thus has the potential to reduce the oxythermal habitat of fish and aquatic biota in boreal lakes.

Title: Ecohydrological Controls on Carbon Drainage via Groundwater in a Coastal BC Douglas-Fir Headwater Catchment During Pre- and Post-Harvest Periods

Presenter/First Author: Mark S. Johnson, University of British Columbia, Vancouver, BC

Presenter/First Author Email: mark.johnson@ubc.ca

Co-authors: T. Andrew Black, University of British Columbia, Vancouver, BC, Canada; Rachhpal Jassal, , , ; Nicholas J. Grant, , , ; Iain Hawthorne, UBC, Vancouver, BC, Canada

Abstract Body: Delivery of dissolved carbon from landscapes to streams is highly pronounced in headwater catchments where terrestrial-aquatic connectivity is high. Dissolved CO_2 is of particular interest in headwater systems since it can rapid evade from inland waters to the atmosphere, which can complicate resolution of the terrestrial carbon balance. Here we focus on groundwater as the primary flowpath for delivery of terrestrially-fixed carbon from the biosphere to the hydrosphere in a ~90 Ha managed forest catchment near Campbell River, British Columbia. We present 5 years of near-continuous in situ measurements of dissolved CO_2 in riparian groundwater at the catchment outlet. These data are compared against ecosystem respiration, as well as gross and net ecosystem productivity determined using eddy covariance within the catchment prior to and following forest harvest mid-way through this study. Ecohydrological controls on carbon drainage are considered in relation to forest harvest impacts on carbon uptake dynamics and hydrological flowpaths.

Title: Hydrological and Biogeochemical Controls on Transport, Modification and Export of Dissolved Organic Matter in Large Drainage Networks.

Presenter/First Author: Jenn B Hoyle, Yale University, New Haven, CT

Presenter/First Author Email: jennifer.hoyle@yale.edu

Co-authors: James E Saiers, Yale University, New Haven, CT; Peter A Raymond, Yale University, New Haven, CT; William V Sobczak, Holy Cross College, Worcester, MA

Abstract Body: Dissolved organic matter (DOM) is essential to the ecology and chemistry of inland waters as an energy and nutrient source, a regulator of light attenuation and a transporter of heavy metals and other pollutants. The key questions explored in this research project include the controls on DOM movement from the terrestrial landscape and modification of DOM during its transit through streams and rivers and toward the ocean in a large drainage network. We explore the riverine fate of terrestrial DOM subsidies by developing a simple model that routes water and DOM through the 1300 km^2 Passumpsic River watershed located in northern New England. The Passumpsic watershed is drained by a dendritic channel network comprised of 1,500 first- through fifth-order streams that feed the 75-km long, sixth-order Passumpsic River, a tributary to the Connecticut River. Published scaling laws are used to specify the numbers, lengths, and connectivities of the stream segments, while the routing algorithm describes the precipitation-induced delivery of terrestrial DOM to headwater reaches and the down-network changes in DOM concentrations resulting from mixing with other waters and rate-limited decomposition. Results of model simulations conducted to date underscore the dominant contribution of low-frequency precipitation events to the annual subsidy of terrestrial DOM to the drainage network and reveal that most of this DOM subsidy is utilized in large rivers, far from its source within the drainage network.

Title: Revisiting Global Riverine Carbon Export to the Oceans

Presenter/First Author: Mingfeng Li, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: limf321@gmail.com

Co-authors: Yves Prairie, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Paul del Giorgio, Groupe de Recherche Interuniversitaire en Limnologie, Montréal, QC, Canada

Abstract Body:
Riverine carbon (C) export to the oceans is recognized as a key component in the global C cycling, yet is still poorly understood, in part because most p revious studies have assessed either inorganic or organic C species separat ely, and have thus yielded a fragmented perspective of riverine C exported to oceans. In addition, differences in approach have resulted in widely vary ing estimates, for example, of global annual
DOC or TOC export, ranging from 0.03 to 1 Pg. Here we revisit the global riv erine C export, explicitly taking into account DOC, POC, DIC and PIC transpo rt to the oceans, based on the most extensive meta-
analysis of published data carried out to date covering 568 rivers draining 7 3.7% of the global exorheic area. This analysis yields a global annual riverin e C export of 1.05 Pg (somewhat higher than the widely-
accepted 0.9 Pg), of which DOC, POC, DIC and PIC account for 0.32, 0.17, 0. 48 and 0.08 Pg yr^{-1}, respectively. Our estimate of global DOC export is 45% higher than the c urrently accepted value of 0.22Pg. Our results show that, at a global scale, organic C export has a significant negative relationship with catchment are a, and that DOC and DIC exports are both significantly related to catchmen t elevation, albeit in opposite directions. There is a negative latitudinal tren d in the DIC/DOC and in the POC/DOC export ratios. Our analysis also highli ghts the impact of human activities on riverine C export: Irrigation, the deg ree of impoundment, and the level of economic activity in the watershed h ave strong negative relationships with DOC export, though none on DIC ex port. Our study
more tightly brackets global riverine C export to the oceans, and further hi ghlights the differential regulation of global inorganic and organic riverine C export, with strong implications in terms of future climate and human-induced environmental change.

Title: Quantifying carbon burial in northern forested lakes since the Anthropocene

Presenter/First Author: Adam Heathcote, Groupe de Recherche Interuniversitaire en Limnologie, Montréal, QC

Presenter/First Author Email: adam.heathcote@gmail.com

Co-authors: N John Anderson, University of Loughborough, Loughborough, United Kingdom; Paul del Giorgio, Groupe de Recherche Interuniversitaire en Limnologie, Montréal, QC, Canada; Yves Prairie, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Daniel R Engstrom, Science Museum Minnesota, Marine On Saint Croi, MN

Abstract Body: The northern forested zone is one of the most important areas for the processing of carbon (C) on an annual basis. Lakes play an important role in this carbon cycle burying large amounts of organic-C in their sediments. Estimates of organic-C burial in boreal lakes are poorly constrained and do not account for possible increases in burial rates driven by global ecosystem change during the last century. To address this issue, we used a large set of ^{210}Pb-dated sediment cores to determine spatial and temporal trends in organic-C burial over the last 180 years across the northern forests of continental North America. We found that baseline organic-C burial was negatively correlated with latitude and positively correlated with mean annual temperature. Additionally, mean post-1950 rates represent nearly a 2-fold increase over background rates and a 4- to 13-fold increase over average Holocene estimates. Up-scaling the mean lake C-burial rate observed in this study to the whole boreal forest biome could account for as much as 10% of the total organic C stored in lake sediments since the Holocene. With future disturbance regimes in the boreal forest biome, lake sediment may become an even more important site of C burial.

Title: Simulating Regional Impacts of Climate Change Mitigation Policies on the Global Timber Market: Implications for Regional Forest Management

Presenter/First Author: John B Kim, US Forest Service Corvallis, Corvallis, OR

Presenter/First Author Email: jbkim@fs.fed.us

Co-authors: Brent Sohngen, , , ; Sara B Ohrel, , Elkton, MD; James McFarland, U.S. EPA - Climate Change Division, Washington, DC; Erwan Monier, Massachusetts Institute of Technology, Cambridge, MA; Raymond J Drapek, USDA Forest Service, Vallejo, CA; Bear Pitts, College of Forestry, Oregon St, Corvallis, OR; Jefferson Cole, , ,

Published Material: The global vegetation simulation, which drives the global timber market analysis, was presented at the International Union of Forest Research Organizations (IUFRO) World Congress 2014 in Salt Lake City, UT. The proposed talk will cover the global vegetation simulation, its link to the global timber market analysis model, and the final results of the global timber market analysis.

Abstract Body: Climate change will bring different types of climate change to regions of the world, and will drive different types of responses by the various forest ecosystems of the world. In turn, the global timber market will dynamically respond to and adjust to the changing productivities of forested regions around the world. Local and regional mitigation strategies and forest management policies must take into account the not only forest responses to climate change, but the additional dynamics exerted by the global timber market.

As a part of the Climate Change Impacts and Risk Analysis (CIRA) project by the U.S. EPA Climate Change Division, we integrated climate, vegetation and timber market models to estimate regional implications of global mitigation policies. The Emissions Predictions and Policy Analysis (EPPA) model and the Integrated Global System Model (IGSM) created three socioeconomic & emissions scenarios: Business-as -usual and two mitigation policy scenarios that stabilize radiative forcing levels in 2100. NCAR Community Atmospheric Model (CAM) linked to the IGSM generated 10 future climate projections. MC2 DGVM was run using the 10 climate projections, and the biophysical results from these models were used as boundary conditions for a global forestry and land use model (GTM). The resulting integrated climate-vegetation-economic modeling system is used to assess the implications of the three socioeconomic & emissions scenarios on various forest stocks, prices, and land use. Using the model, we estimate the regional impact of global mitigation policies on regions within the United States; explore the implications on regional forest mitigation policy; and assess the economic efficiency of alternative adaptation policies for the United States.

Title: Greenhouse Gas Mitigation Potential and Timing of Forest Bioenergy in Canada

Presenter/First Author: Jerome Laganiere, Natural Resources Canada - Canadian Forest Service, Québec City, QC

Presenter/First Author Email: jerome.laganiere@hotmail.com

Co-authors: David Pare, Natural Resources Canada - Canadian Forest Service, Québec City, QC, Canada; Evelyne Thiffault, , , ; Pierre Y Bernier, Natural Resources Canada - Canadian Research Service, Quebec, QC, Canada

Abstract Body: The delay before the substitution of fossil fuel by forest bioenergy starts having a net beneficial impact on atmospheric CO_2 (referred as the carbon debt) is object of debate notably among scientists, ENGO's and policymakers. Several studies have documented a long carbon debt for some forest bioenergy uses (e.g. over a century before benefits occur). As the cost of delaying GHG emission reductions is increasingly being recognised, policies are being discussed, in Europe and elsewhere, to favour bioenergy uses with precise and specific carbon debt repayment time or parity time.

We have documented the carbon parity time of forest bioenergy sourced from different feedstocks (harvest residues, salvage wood, green trees) typical of the forest biomass production in Canada to substitute three fossil fuel types (coal, oil, gas) in heating or power generation. Each scenario includes the widest possible range of factors found in the literature for forest lands remaining forest lands that could impact the timing of atmospheric CO_2 benefits including transportation distances, wood processing and environmental characteristics.

As expected, the results indicate short-to-long ranking of parity times for residues<salvage<green trees, and for substituting the less efficient fossil fuels (coal<oil<natural gas). A sensitivity analysis indicates that silviculture and enhanced biomass conversion efficiency helps reducing time to achieve atmospheric benefits. The results show that the uncertainty around the estimate of carbon parity time is generally small and inconsequential for harvest residues options, but generally large for the other feedstocks, indicating that some options present reasonable parity times with respect to current policy timeframes, while others do not.

These results illustrate that meeting specific parity time for bioenergy options using salvage or green trees is possible but under restricted conditions that would require a good tracking system. They also point out that the carbon parity time may be prone to a large uncertainty that should be taken into account when evaluating the GHG mitigation performance of particular bioenergy uses.

Title: Integrating Carbon Price Trajectories Into Canadian and California Forest Sector Mitigation Scenarios

Presenter: Matthew D Potts, University of California Berkeley, Berkeley, CA

Presenter Email: mdpotts@berkeley.edu

First Author: William Stewart, University of California Berkeley, Berkeley, CA

First Author Email: billstewart@berkeley.edu

First Author Student?: No

Co-authors: Chi-chung Tsao, , , ; Carolyn Smyth, Natural Resources Canada - Canadian Forest Service, Edmonton, AB, Canada; Mark Hafer, , , ; Werner Kurz, Canadian Forest Service, Victoria, Canada

Abstract Body: Forest policies in Canada and California are increasingly interlinked through the wood products trade as well as evolving integration between state and provincial carbon markets. While California only has 2% as much forest area as Canada, it has more end-users of wood products. Our goal is to use a rigorous systems perspective for both wood exporting regions and wood importing regions. We add price driven scenarios to recent forest management and product utilization scenarios developed with the Carbon Budget Model of the Canadian Forest Sector

(CBM-CFS3) and a harvested wood products (HWP) model. In addition, we develop plot based yield curves for California's forests to simulate the same scenarios for Canada and California.The first scenario is an increase in the global-level adoption of the current methane capture practices common to the upper quartile of the European Union's economies. The second is the substitution of bioenergy for the most polluting, rather than the average polluting, units of energy in regional energy grids. The third is the reallocation of a greater percentage of the chip-based harvest from paper products to engineered wood products. For California, we add an additional forest management option based on silvicultural thinning to reduce mortality in water limited Mediterranean climate forests. We then test whether increasing carbon price trends change the relative rank order of scenarios in terms of cumulative mitigation impacts as carbon pollution in later years will be more expensive per ton than carbon pollution in the earlier years. We use the social cost of carbon from William Nordhaus's DICE2013 model that starts at $17.7 per tCO2e in 2015 and increases 3% annually. We then explore situations where increasing carbon prices drive a more rapid diffusion of best current technologies that could significantly improve overall mitigation benefits.

Title: Long-Term Impacts from Mountain Pine Beetle Outbreaks on Merchantable Biomass, Ecosystem Carbon, Surface Albedo, and Net Radiative Forcing: The Major Role of Vegetation Response

Presenter/First Author: Jean-Sébastien Landry, McGill University, Montreal, QC

Presenter/First Author Email: jean-sebastien.landry2@mail.mcgill.ca

Co-authors: David T Price, Natural Resources Canada - Canadian Forest Service, Edmonton, AB, Canada; Navin Ramankutty, McGill University, Montreal, QC, Canada; Lael Parrott, , , ; Damon Matthews, Concordia University, Montreal, QC, Canada

Abstract Body: Although field-based studies have highlighted the role of non-target vegetation following mountain pine beetle (MPB) outbreaks, the range of possible growth release responses has not been systematically assessed in model-based studies. The potential for the spatial distribution of mortality to modulate by itself the effects from MPB outbreaks has also been overlooked heretofore, while only one study has combined the albedo-induced cooling with the CO_2-based temperature change in order to estimate the net impact of MPB on the global climate. And even if MPB outbreaks have been recurring for millennia in western North American forests, previous studies have often spanned a few decades or less, and have never gone beyond two centuries. The main objective of our study was to contribute to the understanding of MPB consequences on forestry, ecosystem carbon cycling, and climate by modifying an existing model that computes land–atmosphere exchanges of carbon, energy, and water, and simulates dynamic changes in vegetation state and distribution. We performed various long-term simulations over different locations in British Columbia, Canada, in order to address the issues identified above and a few additional ones. We found that the growth release from the non-target vegetation can indeed play a dominant role in the strength, and even the direction, of MPB-induced changes. We also observed strong non-linearities in MPB mean effects for different outbreak severities or return intervals, along with major changes in these effects through time. Our results also support the idea that the spatial distribution of mortality may explain part of the high variability in MPB effects revealed by satellite-based studies. All these complicating factors imply that extrapolating the knowledge gained from short-term or localized studies to larger spatiotemporal scales might be misleading, so that the actual impact of the ongoing MPB outbreak cannot be estimated with confidence yet over its entire domain. For example, our results suggest that the feedback to climate change from the current MPB outbreak over British Columbia could be positive or negative. Despite this uncertainty, a simple analysis nevertheless shows that the magnitude of this impact is probably much smaller than one month of current anthropogenic CO_2 emissions.

Title: Economic feasibility of conifer afforestation in North America using a process-based growth model

Presenter/First Author: Jung meng Lee, NCHU National Chung Hsing University, Taichung,

Presenter/First Author Email: mark60872000@gmail.com

Co-authors: Muhammad Altaf Arain, McMaster University, Hamilton, ON, Canada; Dan McKenney, Kyungpook National University, Daegu, South Korea; Suo Huang, McMaster Centre for Climate Change, Hamilton, ON, Canada

Abstract Body: Anthropogenic emission of carbon dioxide is one of the most significant contributions to the global climate change. One potential option to reduce atmospheric CO_2 is to make use of forest growth. Afforestation and reforestation could be a cost-effective option to sequester atmospheric carbon. The Canadian Forest Service developed an investment analysis model, the Canadian Forest Service-Forest Bioeconomic Model (CFS-FBM) to examine the carbon sequestration potential of fast growing poplars as a substitute for fossil fuels. Unfortunately despite their fast growth, poplars are costly to establish and manage which affects their economic attractiveness. There is a need to examine other species and develop forest growth curves that better account for climate variability. Our objective is to develop spatial productivity estimates that better incorporate climate variability by examining and integrating long-term eddy covariance measurements and a process-based C and N coupled model, CLASS-CTEM+N, simulated fluxes in a spatially explicit productivity and economic model (e.g. CFS-FBM). The aim is to better depict the economic potential of conifer afforestation across North America. Preliminary results indicate that there is a strong correlation between net primary productivity and minimum temperature. Biological productivity is projected to increase in all future climate scenarios. It is also projected that net ecosystem productivity is expected to grow which constitutes for the increase in atmospheric carbon sequestration. Ultimately the study will examine the economic attractiveness of conifer afforestation with and without carbon sequestration as an economic value. By incorporating a growth process model directly tied to possible future climate pathways, it better depicts yield potential and helps determine what carbon would have to be valued at to make this type of afforestation attractive.

Title: The Impact of Open-Water Pools on the Net Ecosystem CO_2 Exchange of a Boreal Peatland

Presenter/First Author: Luc Pelletier, McGill University, Montreal, QC

Presenter/First Author Email: luc.pelletier@mail.mcgill.ca

Co-authors: Ian B Strachan, McGill University, Montreal, QC, Canada; Nigel T Roulet, McGill University, Montreal, QC, Canada; Michelle Garneau, GEOTOP-UQAM, Montréal, QC, Canada

Published Material: Part of the findings presented have been published in Pelletier et al., (2014-*JGR Biogeosciences*) while others have been submitted for publication in *Biogeochemistry* and *Environmental Research Letters*

Abstract Body: Peatland open-water pools are a common feature on temperate, boreal and subarctic peatlands but their impact on the net ecosystem carbon dioxide exchange (NEE-CO_2) is poorly understood. A limited number of studies using measurements made solely during the growing season have shown pools to represent net sources of CO_2 to the atmosphere. To date, the evaluation of the CO_2 budget of peatlands with pools has only been explored through spatial extrapolation and temporal interpolation of point measurements made using static chambers; the errors introduced can be larger than the fluxes. In this study, we evaluated the annual CO_2 exchange from peatland open-water pools using a combination of methods (headspace technique and non-dispersive infrared CO_2 sensor) to obtain a complete annual surface to atmosphere CO_2 exchange from pools, including ice melt emissions. Simultaneously, we assessed if the presence of pools has a measurable impact on the peatland NEE-CO_2 using a combination of eddy covariance (EC) measurements and source area analysis. Our results confirm that the peatland open-water pools are a significant source of C to the atmosphere, with an annual release of 99 g CO_2-C m^{-2}, of which 15% was released during the ice-met period. The source area analysis performed on the EC tower data shows that an increase in pool contribution to the ecosystem CO_2 fluxes results in a reduction in both ecosystem level maximum gross photosynthesis and respiration. Despite significant CO_2 loss from the pools, we found the overall peatland to be a net sink for CO_2 for the measurement period.

Title: Understanding uncertainties in net ecosystem CO_2 exchange measurements by open-path gas analysers

Presenter/First Author: Manuel Helbig, University de Montreal, Montreal, QC

Presenter/First Author Email: manuel.helbig@yahoo.com

Co-authors: Karoline Wischnewski, University of Montreal, Montreal, QC, Canada; Elyn Humphreys, Carleton University, Ottawa, ON, Canada; Ivan Bogoev, Campbell Scientific, Inc., Logan, UT; George G Burba, LI-COR Biosciences, Lincoln, NE; Oliver Sonnentag, University of Montreal, Montreal, QC, Canada

Published Material: Parts of this study are intended to be presented at the EGU Annual Assembly in Vienna in April 2015.

Abstract Body: Open-path (OP) infrared gas analysers (IRGAs) are often used to estimate net ecosystem CO_2 exchange (NEE) using the eddy covariance technique. A main focus of this research is to better understand the variability of NEE dynamics across contrasting ecosystems. A sophisticated understanding and documentation of potential uncertainties inherent to the use of OP IRGA is necessary to ensure inter-site comparability.

In contrast to closed-path (CP) IRGAs, OP IRGAs are exposed to high-frequency temperature and humidity variations affecting CO_2 density fluctuations not related to biological sources or sinks of CO_2. The Webb-Pearman-Leuning (WPL) term accounts for these gas density fluctuations. However, the application of the WPL term introduces different sources of uncertainty compared to NEE estimates based on CP IRGAs. Potential sources of such errors in NEE are uncertainties in the measurements of sensible and latent heat fluxes, biases in absolute gas density measurements, sensor surface heating, and non-sufficient corrections for high-frequency band-broadening effects.

With this contribution, we present results from a sensor inter-comparison study conducted at the Mer Bleue peatland near Ottawa, Ontario. Eddy covariance systems with a CP IRGA (LI7000) and with an OP IRGA (EC150) were compared between September 2012 and January 2013, whereas the same CP IRGA system was compared to a second OP IRGA (LI7500) between January and April 2006. The results indicate significant biases in NEE estimates obtained with the OP IRGAs compared to CP IRGA NEE estimates. For both OP IRGAs, the differences in NEE scaled with the magnitude of the sensible heat flux. Since the absolute magnitude of the bias seems to be directly related to the magnitude of the sensible heat flux rather than to the magnitude of NEE, the relative error is likely larger at sites with small NEE. Preliminary results indicate multiple error sources for the OP IRGAs and highlight the importance of site-specific uncertainty analyses.

Title: Using Ground Penetrating Radar (GPR) to Investigate Greenhouse Gas Releases from Peatland Ecosystems: from boreal to subtropical systems

Presenter/First Author: Xavier Comas, Florida Atlantic University, Boca Raton, FL

Presenter/First Author Email: xcomas@fau.edu

Co-authors: Lee D Slater, Rutgers Univ, Newark, NJ; Neil Terry, , Newark, NJ; Andrew Parsekian, University of Wyoming, Laramie, WY; William J Wright, Florida Atlantic University, Boca Raton, FL; Matthew D McClellan, Florida Atlantic University, Boca Raton, FL

Published Material: Some of the materials that will be introduced as overview on applications of the method have been already published in several scientific journals

Abstract Body: As concerns grow over the effect that greenhouse gas releases to the atmosphere from natural sources have on Earth's climate, studies investigating the contribution from freshwater peatlands have increased largely over the last few decades. Freshwater peat soils are considered important carbon (C) reservoirs and sources of greenhouse gases such as methane (CH_4) and carbon dioxide (CO_2); it is therefore important to better understand how changes in environmental variables (such as temperature) may affect biogenic gas releases from these soils. Most studies investigating such dynamics have mainly focused on discrete point measures (such as gas chambers) or invasive techniques (such as probe insertion and/or sampling) that may provide little information on spatial and temporal patterns in gas flux variability whilst directly disturbing the gas regime. Although the use of eddy covariance methods has helped to better understand temporal patterns of gas release, the method may not resolve spatially isolated, rapid ebullition events due to the large footprint. Hydrogeophysical methods such as ground penetrating radar (GPR) can be used to non-invasively investigate the spatial and temporal variability in gas releases from freshwater peat at a spatial scale that is intermediate between the footprints provided by chamber and eddy covariance methods. The method has now been used for over a decade to target small contrasts in volumetric gas content (both in time and space) within peat soils (i.e. approximately >1%). In this study we use case studies at multiple scales of measurement (i.e. from field to laboratory scales) to show the potential of GPR to (1) better understand the spatial distribution of biogenic gases in a variety of freshwater peatlands over a wide latitudinal gradient, and (2) monitor in situ gas dynamics driven by environmental forcing. Previously unreported datasets will also be presented to further demonstrate the value of GPR for investigating biogenic gas dynamics in peat soils and highlight the potential of the method to overcome some of the limitations imposed by traditional methods.

Title: Controls on below ground free phase gas dynamics in a Northern peatland inferred from field-scale electrical resistivity tomography (ERT)

Presenter/First Author: Neil Terry, , Newark, NJ

Presenter/First Author Email: ncterry@buffalo.edu

Co-authors: Lee D Slater, Rutgers Univ, Newark, NJ; Xavier Comas, Florida Atlantic University, Boca Raton, FL; Karina V Schafer, Rutgers University Newark, Newark, NJ; Yu Zhongjie, Rutgers University, Harrison, NJ; Andrew S Reeve, Sen. George J. Mitchell Center, Orono, ME

Abstract Body: Northern peatlands act as sources of methane and both sources and sinks of carbon dioxide, but the mechanisms that control subsurface free phase gas (FPG) cycling within peatlands, and therefore estimates of past, present, and future gas flux remain unclear. In particular, the spatiotemporal variability of FPG production and release within peatlands is uncertain. While chamber-based measurements provide a direct estimate of FPG flux, these methods measure only at the surface over a small footprint (< 1 m^2). We collected one hundred and twenty-seven 3D electrical resistivity tomography (ERT) datasets during July and August of 2013 in Caribou Bog, Maine to investigate changes in FPG at a unique spatiotemporal scale. Our setup consisted of 72 electrodes placed in the surface of the peat in a 28 by 10 m array configured to sample from the entire peat volume (7 m deep). Water levels, soil temperature, atmospheric pressure, and other environmental parameters were simultaneously acquired at a minimum of 1 hour sampling interval. Methane fluxes were also measured using a flow-through gas chamber and fast methane analyzer located within the ERT array over a limited time period. Although gas flux cannot be directly quantified through ERT measurements, we assume that resistivity and FPG content are directly related due to the well-known dependence of resistivity on water content and use information from our other sensors to support this assumption. Our results indicate that water table variation exhibits the strongest control on FPG changes, but that soil temperature and atmospheric pressure are also somewhat correlated with FPG changes throughout the peat. In the shallow and middle peat (0.2 to 4.4 m depth), we witness evidence for mobility-driven ebullition in responses to changes in atmospheric and/or hydrostatic pressure. In the deep peat (> 4.4 m) we infer that buoyancy-driven migration of FPG to upper layers or the atmosphere is the dominant mechanism resulting from changes in atmospheric and hydrostatic pressure.

Title: Time-lapse geophysical measurements targeting spatial and temporal variability in biogenic gas distribution and releases from peat soils in a hydrologically controlled wetland in the Everglades

Presenter/First Author: William J Wright, Florida Atlantic University, Boca Raton, FL

Presenter/First Author Email: wwrigh19@gmail.com

Co-authors: Thomas Shahan, , , ; Nathan Sharp, , , ; Xavier Comas, Florida Atlantic University, Boca Raton, FL

Abstract Body: Peat soils are known to release globally significant amounts of methane (CH_4) and carbon dioxide (CO_2) to the atmosphere. However, uncertainties still remain regarding the spatio-temporal distribution of gas accumulations and triggering mechanisms of gas releasing events. Furthermore, most peatland gas dynamics research has historically been focused on high latitude peatlands, while recent works have suggested that gas production rates from low-latitude peat soils may be higher than those from colder climates. Therefore, understanding gas dynamics in low-latitude peatlands (*e.g.* the Florida Everglades) is key to global climate research. Recent studies in the Everglades have demonstrated that biogenic gas flux values may vary when considering different temporal scales of measurements (*i.e*. hourly vs. daily averages). The work presented here mainly targets spatial variability in gas production and release at the plot scale in an approximately 85 m^2 area. The study was conducted during two separate field campaigns in the Loxahatchee Impoundment Landscape Assessment (LILA), a hydrologically controlled, landscape scale (30 Ha) model of the Florida Everglades. Ground penetrating radar (GPR) has been used in the past decade to non-invasively investigate the release of biogenic gases from peat soils. A grid of GPR profiles was collected to image biogenic gas distribution over the study area and estimate biogenic gas production and flux from its temporal variability. Also, gas flux chambers outfitted with time-lapse cameras captured high resolution gas flux measurements in order to constrain GPR data.

Title: Methane dynamics in a montane fen: Factors controlling production, accumulation and emissions

Presenter/First Author: Kisa E Mwakanyamale, University of Calgary, Elizabeth, NJ

Presenter/First Author Email: kisa010@gmail.com

Co-authors: Heather Yeung, University of Calgary, Calgary, AB, Canada; Maria Strack, University of Calgary, Calgary, AB, Canada

Abstract Body: Characterization of methane dynamics in peatlands is essential to improve understanding of peatlands contribution to carbon balance and interaction with climate. Of the two peatland types, natural fens are known to be a larger contributor of methane emissions to the atmosphere than natural bogs. This study uses geophysical methods integrated with in-situ direct measurements and chamber fluxes to improve understanding of temporal and spatial variation in methane production, accumulation and emissions from natural montane fen in Alberta Canada. Meteorological data and peat cores (~150 cm) were collected to study factors affecting methane production, accumulation and emissions from the Sibbald Research Wetland, a montane fen in the Rocky Mountains in southern Alberta.

Our results show a direct correlation between methane accumulation and degree of peat humification, substrate quality and porosity. Changes in temperature, pressure and water table position were shown to relate to ebullition events, with the highest number of ebullition events occurring from late August to early November. The geophysical results indicate a small spatial variation in free phase biogenic gas accumulation within the studied area. Diffusive methane fluxes were correlated to plant productivity on both daily and seasonal time scales with patterns varying between plots dominated by Juncus sp. and Carex spp. These results highlight the interacting ecological and physical controls on peatland methane dynamics.

Title: SUGARCANE CARBON SEQUESTRATION POTENTIAL UNDER THE CLEAN DEVELOPMENT MECHANISM THE CASE OF KAKIRA SUGAR ESTATES-UGANDA

Presenter/First Author: John Sekajugo, Busitema University, Kampala,

Presenter/First Author Email: sekajugo@gmail.com

Published Material: It was presented as a poster on the 28th of March 2014 in Brussels- Belgium and was reviewed and accepted for presentation in the African Green Revolution Conference 2014: BRIDGING THE GAP BETWEEN SCIENCE, SOCIETY AND INDUSTRY: Building a new generation of African Soil Scientists and Agronomists Kenyatta University, Nairobi, Kenya, 1st – 5th December, 2014 but was not presented due to lack of sponsorship

Abstract Body: Abstract

Soils, and managed agricultural soils in particular, represent a potentially significant low cost sink for greenhouse gases (GHGs) with multiple potential co-benefits to farm productivity and profitability (Jonathan, Ryan and Jeffrey, 2010). Since agricultural soils can store more carbon, a modest increase in carbon stocks across the large land areas used for agriculture would represent a significant GHG mitigation. Sugarcane accompanied with good farming practices has the potential to sequester considerable amounts of carbon and so contribute to climate change mitigation. However, little has been done to provide relevant information concerning carbon sequestration in crop lands and sugarcane in particular. This research analyzed the performance of four different sugarcane varieties to sequester carbon in the soil at Kakira sugar works in Uganda. Results show that sugarcane grown in Kakira estates has the potential to sequester carbon of about 239.4Tc/ha for plant crop and 2 ratoons. Therefore, with proper agronomic practices, carbon sequestration in sugarcane can contribute to clean development mechanism in sugar milling and processing.

Key Words: Carbon sequestration, sugarcane varieties, soil organic carbon, phytoliths, Bulk density.

Title: Investigating the Landscape Scale Carbon Implications of 100 Years of Land Management in the Sooke Lake Water Supply Watershed, Victoria, British Columbia

Presenter/First Author: Byron P. K. Smiley, University of Victoria, Saanich, BC

Presenter/First Author Email: byrons@uvic.ca

Co-authors: John A Trofymow, Natural Resources Canada - Canadian Forest Service, Edmonton, AB, Canada

Published Material: Approximately 50% of this research was presented at the AGU 2014 Fall Meeting December 15-19 in San Francisco. Specifically, the baseline carbon budget and dissolved organic carbon parameterization was presented in poster form. This research has not yet been submitted to a scientific journal.

Abstract Body: To address how natural disturbance, forest harvest, and deforestation from reservoir creation affect landscape-level carbon (C) budgets, a retrospective C budget for the 8595 ha Sooke watershed from 1911-2012 was developed using historic spatial inventory and disturbance data. A baseline C budget was prepared using a spatially-explicit version of the C Budget Model-Canadian Forest Sector (CBM-CFS3), an inventory-based model used to simulate forest C dynamics at multiple scales. To examine management effects, two alternate management scenario C budgets were developed in CBM-CFS3: (S1) no reservoir raising (flooding) or sustained yield forestry and (S2) reservoir raising but no sustained forestry. In 1911 the watershed was dominated by mature/old Douglas-fir forests with aboveground biomass C (ABC) of 262 Mg C/ha and net biome production (NBP) of 0.38 Mg C/ha/yr. Successive dams were built, land cleared, and reservoir area expanded from 370 to 450 ha in 1915, 610 ha in 1970, 670 ha in 1980 and 810 ha in 2002. Early fires and logging from 1911-1953 were followed by sustained forestry from 1954 -1998, with a minimum ABC of 148 Mg C/ha in 1991. By 2012 ABC (177 Mg C/ha) had increased though still less than in 1910. Cumulative NBP (ΣNBP) for the baseline recovered from a low of -167 Mg C/ha in 1994 to -142 Mg C/ha in 2012. In contrast, the minimum ΣNBP for S1 was -85 Mg C/ha in 1956 and recovered to -35 Mg C/ha by 2012. Minimum ΣNBP for S2 was also in 1956 (-88 Mg C/ha) and increased to -49 Mg C/ha by 2012. Even with elimination of sustained forestry, deforestation alone did temper the ability of the landscape to recoup C losses earlier in the century. Over 100 years in the baseline run, 2430 ha of forest was cut and replanted, 640 ha deforested and 882,746 Mg C exported as harvested wood products (HWP). Total HWP export was decreased by 46% and 60% in S2 and S1, respectively, from the baseline. The effects of accounting for storage of C in HWP will be discussed.

Title: Environmental Controls on Tree-Ring Growth in an Age-Sequence of Planted Pine Forests

Presenter/First Author: Shawn M McKenzie, McMaster University, Hamilton,

Presenter/First Author Email: mckenzsm@mcmaster.ca

Co-authors: Muhammad Altaf Arain, McMaster University, Hamilton, ON, Canada; Michael FJ Pisaric, Brock University, St Catharines, ON, Canada; Michelle Kula, McMaster University, Hamilton, ON, Canada

Abstract Body: The objective of this study was to assess the effect of regional climate patterns and forest management on growth rates of an age-sequence of three white pine (*Pinus strobus* L.) plantation forests established in 1939 (TP39), 1974 (TP74) and in 1989 (TP89) in southern Ontario, Canada. These sites are a part of the Turkey Point Flux Station and global Fluxnet. To evaluate the effects of climate and land management on annual biomass accumulation, surface area of growth rings was measured on 15 white pine discus (tree slices at DBH) cut in 2004 and compared to historical climate records from 1939 to 2004 (temperature and precipitation) for each of the three sites. The combination of annual climate variability and decadal scale climate oscillations such as the Arctic Oscillation and El Niño Southern Oscillation show relatively strong correlation in growth. Forest response to annual temperature changes show strongest correlation ($r^2 = 0.37$) with a 2-year lag in growth, as compared to growth year ($r^2 = 0.29$) and 1-year lag ($r^2 = 0.33$). Decreased growth was observed across the chronosequence in 1975, 1989 and 1999, corresponding to decrease annual temperatures and shortened growing seasons accompanying strong La Niña years. Precipitation does not show a strong correlation with growth except during extreme drought years. As expected, plantations on former agricultural land (TP89) approach maximum growth rate much faster (at 11 yrs of age) due to nutrient residue, as compared to stands planted on former oak savannah (TP39 and 74) (at 13 yrs of age). Impacts of canopy closure begin 25 years after afforestation as shown by decreased growth rates. Thinning at the oldest site (TP39) in 1983 enhanced annual biomass accumulation for 20 years following the treatment.

Title: Carbon Dynamics of a Young White Pine Plantation Forest

Presenter/First Author: Felix C.C. Chan, McMaster University, Hamilton, ON

Presenter/First Author Email: chanfc@mcmaster.ca

Co-authors: Muhammad Altaf Arain, McMaster University, Hamilton, ON, Canada; Rachel Skubel, , , ; Myroslava Khomik, , , ; Jason J Brodeur, McMaster University, Hamilton, ON, Canada

Abstract Body: This study assesses the effects of seasonal and annual climate variability on the growth and carbon dynamics of a temperate white pine (*Pinus strobus* L.) plantation established in 2002 in southern Ontario, using CO_2 fluxes measured by the eddy covariance technique. It is rare to have continuous long-term flux measurements in a young forest since its planting. The plantation became a carbon sink after 4 years of its establishment. Drought events resulted in reduction in net ecosystem productivity (NEP). In 2005, an early growing season drought and heatwave caused the stand to become a net carbon source. Water use efficiency consistently increased over the study period with a mean value of 3.0 g C uptake per kg of water loss in 2013. Quantum yield, α (0.01 to 0.07) and maximum photosynthetic capacity, A_{max} (4.0 to 25.1 µmol $m^{-2}s^{-1}$) increased steadily as the size and density of the canopy increased over the stand age. A linear stepwise regression analysis found that growing season mean soil water content, photosynthetically active radiation and soil temperature explained 67% of the variability in NEP. This study will be a significant contribution to our understanding of the carbon dynamics of young plantation forests and their environmental controls. It will also help to determine how young plantation forests may be affected by climate variability and extreme weather events.

Title: An Analysis of Soil CO_2 Emissions in a Temperate Deciduous Forest Ecosystem

Presenter/First Author: Katelynn Michelle Daly, McMaster Center for Climate Change, Hamilton, ON

Presenter/First Author Email: dalykm@mcmaster.ca

Co-authors: Muhammad Altaf Arain, McMaster University, Hamilton, ON, Canada; Myroslava Khomik, Clark Labs, Worcester, MA

Abstract Body: The production and emission of carbon dioxide (CO_2) from soils, referred to as soil respiration (Rs), has a significant influence on the global carbon balance. Carbon is acquired by vegetation from the atmosphere through photosynthesis and stored on the surface and in soils as organic matter. This stored organic matter is returned to the atmosphere as CO_2 through belowground decomposition of organic matter by microbial communities (heterotrophic respiration) and metabolic activity of roots and mycorrhizae (autotrophic respiration). In this study, we explore temporal and spatial dynamics of Rs in a temperate deciduous forest located in Southern Ontario and how it is influenced by climatic controls. The site is a 90-year-old managed hardwood forest (Carolinian species). It is part of the Turkey Point Flux Station and global Fluxnet network. An automated soil CO_2 flux system (LI-8100A) was utilized for continuous monitoring of Rs since July 2014 at our site. To better capture the spatial variability of Rs, a portable soil CO_2 flux system (LI-6400) was also used along two 50-m transects. Comparing the two chamber systems, they both measured within one standard deviation of each other indicating that the long-term automatic chamber site is representative of the surrounding area. Monthly mean Rs varied from a maximum of 12.78µmol/m^2/s in July to a low of 1.0µmol/m^2/s in December. The seasonal trend of Rs followed closely that of soil temperature. Spatially variability in the soil water content had little effect on Rs values. This study will allow us to have a better understanding of the dynamics of Rs and how it responds to its main controlling variables, soil moisture and temperature. It will also help us to determine the impact of climate change and extreme weather events on Rs in temperate deciduous forests and help in developing vegetation ecosystem models.

Title: Response of Soil Respiration to Thinning of a Temperate Pine Forest in Southern Ontario

Presenter/First Author: Robin Thorne, McMaster University, Hamilton, ON

Presenter/First Author Email: thornerf@mcmaster.ca

Co-authors: Muhammad Altaf Arain, McMaster University, Hamilton, ON, Canada; Emily Nicholas, , , ; Jason J Brodeur, McMaster University, Hamilton, ON, Canada

Abstract Body: Soil respiration (Rs) is the largest component of ecosystem respiration, and the second largest amount in ecosystem carbon budgets after gross primary production. Soil temperature and soil moisture can explain most of the temporal and spatial variations seen in soil respiration. Forest thinning can change soil temperature and water content, organic matter, root biomass and microbial activity, thus changing soil respiration. This study will investigate the impact forest thinning will have on the forest soil respiration, with the use of an automated soil CO2 chamber system, in a 75-year old temperate pine (*Pinus strobes L.*) forest, near Lake Erie in southern Ontario, Canada. The chamber system was installed and started collecting data in the summer of 2008 with four chambers operating. In the spring of 2009, another four chambers were installed.

During the winter of 2012, the forest was selectively thinned and approximately 30% of the trees were removed to improved light and water availability and stimulate growth of the remaining trees. The chamber system was removed during this winter for precautionary measures and as heavy machinery needed to access the site to remove selected trees. This disturbance of soil layer and decomposition of debris left behind is expected to increase soil respiration. Gaps, resulting from chamber malfunctions, calibrations, winter snow and ice problems, were filled using empirical models that used a Q_{10} relationship for soil temperature and soil CO_2 efflux, and a logistic relationship for soil water content of the root zone and soil CO_2 efflux.

Total annual Rs (average of 930 g C m^2 y^{-1} over seven years) accounted for the majority (approximately 76%) of the total ecosystem respiration measured from the Turkey Point Flux Station. Distinct highs and lows were observed in Rs that closely tracked soil temperature. During the winter months, variability in Rs decreases with a decrease in soil temperature and a decrease in the variability of soil moisture. In the years following the thinning, Rs shows little difference to the pre-thinning years, and is most likely influenced by both interannual climate variability and thinning effects.

Title: Quantitative, Non-destructive Estimates of Coarse Root Biomass using 3-D Ground-Penetrating Radar (GPR)

Presenter/First Author: Joe I Boyce, McMaster University, Hamilton, ON

Presenter/First Author Email: boycej@mcmaster.ca

Co-authors: Muhammad Altaf Arain, McMaster University, Hamilton, ON, Canada; Michelle Molon, , , ; Doug Blomfield, , ,

Abstract Body: Tree root biomass is an important component of carbon storage in forest ecosystems. In this study, we evaluated 3-D imaging of root structure in a temperate pine forest in southern Ontario, Canada using high-resolution (1-GHz) GPR with post-survey corrections for surface micro-topography. A MEMS (micro-electro-mechanical systems) accelerometer was used to record antenna motions and to calculate the transmit beam vector. Surveys were performed across a 2 x 3 m calibration pit (5 cm line spacing) containing reburied root segments and a 400-m^2 forested plot (12.5-25 cm line interval). Radargrams were corrected for beam angle, migrated and interpolated to a quasi-3-D volume using an inverse distance algorithm. Root volume and biomass were estimated from isosurfaces calculated on Hilbert-transformed GPR amplitudes using a marching cubes algorithm.

The forest floor micro-topography induced significant antenna tilt (pitch > 45°, roll > 28°) and yaw (up to 10°), leading to errors in the positioning of root diffraction events in 3-D radar volumes. The corrected vector migrated GPR amplitudes showed a 15.5% amplitude increase and improved imaging of root structures due to focusing of diffraction energy. Radial scanning produced superior root imaging and continuity due to the larger number of root crossings when compared to rectilinear survey grids. Isosurfaces calculated on Hilbert-transformed amplitudes provide a rapid means of quantifying the root diameter and total biomass volume. Estimation of root biomass requires high inline sampling and line density (< 5 cm). Estimates of belowground carbon using a multi-channel GPR with small inter-line spacing could provide a viable approach for surveying large test plots and could be employed to further refine and validate ecosystem models.

Title: Noble gas, carbon and nitrogen in a St. Lawrence Lowlands bedrock aquifer (eastern Canada)

Presenter/First Author: Pauline Méjean, GEOTOP-UQAM, Montreal,

Presenter/First Author Email: mejean.pauline@courrier.uqam.ca

Co-authors: Daniele Luigi Pinti, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Marie Larocque, Univ du Quebec - Montreal, Dorval, QC, Canada; Yuji Sano, University of Tokyo, Bunkyo-ku, Japan

Published Material: Mejean P., Pinti D. L., Takahata N., Wen H.Y., Sano Y., Larocque M. (2014). Helium, carbon and nitrogen in a bedrock aquifer of the St-Lawrence Lowlands, eastern Canada. 61th Annual Meeting of the Geochemical Society of Japan, Toyama (Japon), 16-18 september 2014.

Abstract Body: Flow patterns and residence times are fundamental parameters for quantifying groundwater resources, yet they are difficult to estimate and are better defined with an integrated isotopic approach. Noble gases are excellent groundwater tracers because they are inert. In order to decipher groundwater circulation and sources in one of the several watersheds providing groundwater in the vicinity of the Montreal metropolitan area, He, Ar, Ne, N_2, CO_2 and CH_4 elemental and isotopic composition were analyzed. The Vaudreuil-Soulanges watershed (895 km^2) has Cambrian sandstone and dolostone fractured aquifers confined by Quaternary clays. Fractured Cretaceous alkaline intrusions and Precambrian bedrock (Mont Rigaud) outcrop in the northwestern part of the basin, creating an important recharge area. Preliminary results from 16 wells show variable helium contents from $6.15.10^{-8}$ to $1.32x10^{-5}$ ccSTP/g. The He isotopic ratios (R), normalized to that of air (Ra = 1.386×10^{-6}), range from 0.18 to 2.33, indicating the occurrence of both radiogenic ^{4}He and tritiogenic ^{3}He excesses compared to the atmospheric composition. Tritium contents indicate pre-bomb recharge waters (^{3}H<0.8TU) and modern water infiltrated during the last decades (^{3}H = 10.8TU). The pre-bomb waters are Na-Cl type and are located in the most confined and chemically evolved water in the region. Helium components can be explained by the mixing of a freshwater tritium-rich component (from 12 to 65 TU) mixed with groundwater containing mainly crustal He, slightly contaminated by 2% of mantle helium. Interestingly, three groundwater samples suggest that they contain up to 16.7% of mantle He. N_2/Ar ratios range between 47 and 101, higher than the ASW (air saturated water) value of 37, indicating some N in excess of the atmospheric content. A relation between the CO_2/^{3}He molar ratio and the ^{3}He/^{4}He ratio indicates that both CO_2 and He derive from a mixing between a mantle source (max 25%) and crustal sources with variable CO_2/^{3}He ratios. Fossil mantle gases could be sourced by groundwater-rock interactions with the numerous intrusions buried under the Quaternary cover and related to the Cretaceous episode of the Monteregian Hills. Particularly, the carbonatite intrusion of Oka is 20 km away from the studied basin, where ^{3}He/^{4}He ratios up to 2.54 Ra have been measured.

Title: Assessing the Predictive Accuracy and Uncertainty of the CAN-DNDC Model to Simulate Water Use Efficiency in Alfalfa Crops.

Presenter/First Author: Samantha Piquette, Carleton University, Ottawa,

Presenter/First Author Email: samanthapiquette@cmail.carleton.ca

Co-authors: Andrew VanderZaag, Agriculture and Agri-Food Canada, Ottawa, ON, Canada; Elyn Humphreys, Carleton University, Ottawa, ON, Canada; Ward Smith, Agriculture and Agri-Food Canada, Ottawa, Canada; Brian Grant, Agriculture and Agri-Food Canada, Ottawa, ON, Canada

Abstract Body: Improving the sustainability of water use in agricultural crop production requires an understanding of the existing water use efficiency (WUE) of individual crops. WUE in agricultural ecosystems may be expressed as net ecosystem exchange (NEE) / evapotranspiration (ET). When accurately calibrated and validated, the Canadian agricultural ecosystem model, Denitrification-Decomposition (CAN-DNDC) provides an ideal tool for predicting WUE by providing simulations of water and carbon cycle processes, as well as the nitrogen processes, of specific crops at the site or regional level. In support of a project addressing water use in the dairy production sector, Agriculture Canada is developing crop-specific growth curves and improved algorithms of nitrogen/water uptake for Canadian alfalfa. Our objective is to assess the predictive accuracy and uncertainty of the alfalfa model through a comparison of simulated NEE and ET data with in situ eddy covariance (EC) flux measurements. Eddy covariance measurements were obtained during the 2014 growing season from two Eastern Ontario alfalfa fields using a closed-path CO_2/H_2O gas analyzer (CPEC200, Campbell Scientific, Logan UT) and an integrated CO_2/H_2O open-path gas analyzer and 3-D sonic anemometer (IRGASON, Campbell Scientific, Logan UT). To assess the predictive accuracy of the model, a Matlab statistical program is used to estimate the structural uncertainty and a Monte Carlo analysis is performed to assess uncertainties arising from input variables.

Title: Boreal forest: effects of canopy opening on the relationship between trees and the cryptogam layer

Presenter/First Author: Marine Pacé, University of Quebec Abitibi-Témiscamingue UQAT, Québec,

Presenter/First Author Email: marine.pace@uqat.ca

Co-authors: Nicole Fenton, University of Quebec Abitibi-Témiscamingue UQAT, Rouyn-Noranda, QC, Canada; David Pare, Natural Resources Canada - Canadian Forest Service, Québec City, QC, Canada; Yves Bergeron, Industrial Chair CRSNG-UQAT-UQAM in sustainable forest management, Rouyn-Noranda, QC, Canada

Published Material: This study was presented in french for a meeting in Amos (Abitibi-Temiscamingue, Québec, Colloque 2014 de la Chaire en Aménagement Forestier Durable CRSNG-UQAT-UQAM, November 27th 2014). These findings are not under review and they were not recently accepted by a scientific journal.

Abstract Body: In the boreal forest, forest productivity can vary strongly in time and space. In some conditions, a forest can move from a productive state (dense) to a stable alternative state that is not commercially productive (lichen woodland or peatland). This long-term canopy opening occurs especially on sites with extreme conditions of drainage: poorly drained sites subject to paludification and strongly drained sites on coarse-grain deposits. In each case, during the transition there is an expansion and a shift in the composition of the moss/lichen layer. Feather mosses are replaced by Sphagnum mosses on poorly drained sites, and by lichens on excessively drained sites. The present work is part of a project which aims to explore the role of the moss/lichen layer in long-term forest opening, especially through its effects on forest soil. The objectives of this study are: (i) to determine the relationship between the degree of forest canopy openness and the composition of the moss/lichen layer; (ii) to determine the relationship between the composition of the moss/lichen layer and tree root development. Sampling was carried out in the summer of 2014 in lichen-pine and mosses-spruce woodlands of the boreal forest of Nord-du-Québec. First, we observed that Sphagnum and lichen communities, unlike feather mosses, are associated with open canopy forests. Furthermore, we observed that the presence of lichen or Sphagnum corresponded to a change in tree fine root development. These results demonstrate a non negligible relationship between the composition of the moss/lichen layer and tree fine roots production in the soil surface and suggested that while causal relationships have not been verified, canopy opening, cryptogam communities and tree root production do not vary independently. These preliminary results emphasize the potential negative effects of canopy opening on forest regeneration and the potential implications for forestry practices (partial cut and planting).

Title: Vision-driven Land Use Scenario and Its Implications to Biogeochemical Interaction in The Columbia Basin, Pacific Northwest

Presenter/First Author: Mingkai Jiang, Lehigh University, Bethlehem, PA

Presenter/First Author Email: mij212@lehigh.edu

Co-authors: Benjamin S Felzer, Lehigh University, Bethlehem, PA

Abstract Body: Land management decision is the fundamental driving factor determining biogeochemical interactions between ecosystem and climate. In Earth system models, scenarios of emissions shape how land use change occurs, which is implicitly driven by socio-economic forces. Realistically speaking, natural resources are not commensurable to economic terms, and management of natural resources is ultimately a societal choice. The interaction between environment and land use management is dynamic, complex and interdependent, superimposed on top of this is the complicated decision making process that involves independent variables of socio-economic condition, public perception, and management priorities at local, national and international level. As such, comparing to a land use scenario driven by empirical economic models, visions about future projected by public may provide a more region-specific perspective that integrates both top-down socio-economic policy pressure and regional management effectiveness in fulfilling the socio-economic demand. In this study, I generated a simple but region-specific land use scenario for the year 2050 based on land manager and stakeholder perceptions in the Columbia basin, Pacific Northwest. This land use scenario is then extrapolated temporally to serve as input to a terrestrial ecosystem model (TEM-Hydro) to understand the ecosystem response to changes in climatic conditions. Preliminary land use simulation results showed that, lands under crop, urban and water coverage would likely to increase at the expenses of reductions in pasture, forest, and grassland coverages. Consequently, carbon sequestration potential reduced and the implications to ecosystem carbon exchange may be substantial. Further work will involve the comparison of ecosystem response to dynamic land use scenarios generated based on an economic model (MIT-EPPA) to highlight the uncertainties in land use simulations and the implications to regional biogeochemical interactions.

Title: Relationship Between Valley Fever Occurrence and Satellite Assessment of Climate Response

Presenter/First Author: Erika Anabel Lomeli-Uribe, University of Nevada Las Vegas, Las Vegas, NV

Presenter/First Author Email: lomelie@unlv.nevada.edu

Co-authors: Lynn Fenstermaker, Desert Research Institute, Las Vegas, NV; Edward Teets, NASA Armstrong Flight Research Center, Palmdale, CA

Abstract Body: North America and particularly the southwestern region of the United States have been experiencing record warming and drought for the past 25 years (Cook et al., 2007; Herweijer et al., 2007; Mensing et al., 2007). In addition, Coccidioidomycosis or Valley Fever onset cases in the southwest have also increased since 1998 (Centers for Disease Control and Preventions, 2013). The California Department of Public Health annual reports show a significant increase of Valley Fever cases in southern California. Here we attempt to better understand the relationship between climate and the increased incidence of Valley Fever in the Antelope Valley region of southern California. Thirteen years of public health annual reports show a particular spike of Valley Fever cases in 2005, 2010, 2011 and 2012. To classify this relationship we have characterized the Antelope Valley land surface using multi-temporal Moderate Resolution Imaging Spectroradiometer (MODIS) NDVI 16-day composite data, Advanced Spacebourne Thermal Emission and Reflection Radiometer (ASTER) NDVI and Landsat NDVI composite imagery data. These satellite data were compared with climate variability data (surface temperature and precipitation) and Valley Fever onset statistics to correlate climate change to the increased Valley Fever cases. Results show a strong correlation between precipitation events and Valley Fever estimated onset, as well as a strong correlation between warmer years and increased registered cases. A correlation between hotter years and increased reported cases were prominent in results. Temperature increases in 2005, 2006, 2007, 2010 and 2012 show correlations between Valley Fever estimated onset and reported cases.NDVI values show a slight correlation between estimated onset and total cases. Substantial spikes in reported cases in 2005 and 2010 point to increased risk of onset for the months of August-December, indicating that August through December are particularly 'at-risk' months for contraction of Valley Fever. The methods used here can be used for other climate and human health hazard correlational studies for bacterial or fungal pathogens in arid soils.

Title: From the Ground Up: Global Nitrous Oxide Sources are Constrained by Stable Isotope Values

Presenter/First Author: Jason J Venkiteswaran, Wilfrid Laurier University, Waterloo, ON

Presenter/First Author Email: jvenkiteswaran@wlu.ca

Co-authors: David M Snider, Environment Canada, Burlington, ON, Canada; Sherry L Schiff, University of Waterloo, Waterloo, ON, Canada; John Spoelstra, Environment Canada, Burlington, ON, Canada

Published Material: This work is under review at a scientific journal.

Abstract Body: Rising concentrations of nitrous oxide (N_2O) in the atmosphere are causing widespread concern because this trace gas plays a key role in the destruction of stratospheric ozone and it is a strong greenhouse gas. The successful mitigation of N_2O emissions requires a solid understanding of the relative importance of all N_2O sources and sinks. Stable isotope ratio measurements ($\delta^{15}N$-N_2O and $\delta^{18}O$-N_2O), including the intramolecular distribution of ^{15}N (site preference), are one way to track different sources if they are isotopically distinct. 'Top-down' isotope mass-balance studies have had limited success balancing the global N_2O budget thus far because the isotopic signatures of soil, freshwater, and marine sources are poorly constrained and a comprehensive analysis of global N_2O stable isotope measurements has not been done. Here we used a robust analysis of all available in situ measurements to define key global N_2O sources. We showed that the marine source is isotopically distinct from soil and freshwater N_2O (the continental source). Further, the global average source (sum of all natural and anthropogenic sources) is largely controlled by soils and freshwaters. These findings substantiate past modelling studies that relied on several assumptions about the global N_2O cycle. Finally, two independent modelling methods were used to show that the relative contributions of marine and continental N_2O sources to the total annual emissions are 24%–26% and 74%–76%, respectively.

Title: Maize Growth as Influenced by 12 Different Biochars in a Cerrado Region (Brazil) Arenosol

Presenter/First Author: Alicia B. Sperattti, University of British Columbia, Vancouver, BC

Presenter/First Author Email: alisperat@gmail.com

Co-authors: Heiriane M. Sousa, UFMT Federal University of Mato Grosso, Cuiabá, Brazil; Eduardo G Couto, UFMT Federal University of Mato Grosso, Cuiabá, Brazil; Mark S. Johnson, University of British Columbia, Vancouver, BC, Canada

Abstract Body: The climate in much of the state of Mato Grosso, Brazil, permits a year-round growing season. Maize grown during the dry season, known as *segunda safra*, currently accounts for 97% of all the maize grown in the state. However, since it is cultivated during the dry season, the segunda safra is vulnerable to changes in precipitation patterns. Therefore, improving soil water retention in the region's Arenosols is of particular interest to local farmers. The potential of biochar (charcoal derived from waste biomass by pyrolysis) to increase soil water retention and crop growth has been observed under some conditions, and so its amendment to sandy soils could potentially be beneficial in this system. The biochars used in this study were derived from four feedstocks: cotton husks, eucalyptus sawmill residue, filtercake resulting from sugarcane distillation, and swine manure. The four feedstocks were converted to biochar under three different pyrolysis temperatures: 400°, 500°, and 600°C resulting in a total of 12 biochars (4 feedstocks x 3 temperatures of pyrolysis). Biochar was mixed at 5% dry weight to 8 kg of an Arenosol and placed in pots in a greenhouse at 30°C for 6 weeks. Pots were set up in a split-plot random block design with 4 benches split into 2 rows receiving dry season rainfall and wet season rainfall, respectively. Maize seeds were planted in all pots. Preliminary results show that maize planted in soil mixed with cotton biochars produced at 500°C and 600°C had the lowest germination rates (38 and 44 %, respectively, in dry season rainfall, and 69 and 50 %, respectively, in wet season rainfall). Factors that may have contributed to the low germination rates, such as high nutrient levels in the feedstock and high soil water retention, will be discussed. Data on plant biomass and DOC and NO_3 in leachate from pots receiving wet season rainfall will also be presented.

Title: Release of Phosphorus from Crop Residue and Cover Crops Over Winter in Southwestern Ontario

Presenter/First Author: Tatianna Lozier, University of Waterloo, Waterloo,

Presenter/First Author Email: tmlozier@uwaterloo.ca

Co-authors: Merrin L Macrae, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Maintaining sufficient crop residue on fields over the non-growing season as a means to improve soil health and reduce soil erosion remains a well-implemented agricultural beneficial management practice (BMP). As the concern for sustainable agriculture increases, there has been an emphasis on the use of cover crops to improve soil health through the retention of soluble nutrients, mainly nitrogen. However, in northern climates, crop residue and cover crops exposed to freeze-thaw cycles (FTC) have been recognized as a potential source of dissolved phosphorus to runoff; yet, there are limited field studies to support these findings. The objective of this study was to quantify the changes in water extractable phosphorus (WEP) from winter wheat (*Triticum aestivum*), red clover (*Trifolium pretense*) and oats (*Avena sativa)* over the non-growing season as the result of changes in hydroclimatic conditions such as FTC. WEP was determined from crop residue and cover crops placed in litterbags (20cm x 20cm) at different topographic locations (upland, midslope, low slope) on two fields. WEP in vegetation material was determined on fresh material, dead material, and material following FTC. Concentrations of WEP in cover crops were larger than those in the wheat residue, and, differences in WEP were also found with topographic position in the field. Concentrations of WEP varied with time, and were highest in freshly harvested wheat residue in comparison to residue that had been left on the field or exposed to FTC. In contrast, WEP in cover crops increased following FTC. This study provides insight into the timing of soluble phosphorus losses from crop residue and cover crops as well as discusses their potential contribution to winter phosphorus mobilization in Ontario.

Title: The Impact of the Oasis Effect on Wind Tunnel Measurements of Ammonia Volatilization from Urea-Fertilized Agricultural Land

Presenter/First Author: Devon Watt, McGill University, Pointe-Claire,

Presenter/First Author Email: devon.watt@mail.mcgill.ca

Co-authors: Philippe Rochette, , , ; Ian B Strachan, McGill University, Montreal, QC, Canada; Normand Bertrand, , , ; Andrew VanderZaag, Agriculture and Agri-Food Canada, Ottawa, ON, Canada

Abstract Body: The average losses of nitrogen (N) in the form of ammonia (NH_3) from agricultural land treated with synthetic fertilizers are 10-19% of applied N, and urea is the most widely used synthetic fertilizer globally.[1] The lack of efficiency of urea as a fertilizer is an economic issue for producers, and the ammonia being emitted to the atmosphere can negatively impact human and ecosystem health.[1] The oasis effect can be defined as the decrease in NH_3 volatilization rate downwind from the leading edge of the fertilized plot, and is caused by the reduction of the concentration gradient of NH_3 near the emitting surface. It is a potential bias that could result in erroneously high emission factors calculated from wind tunnel NH3-flux measurements.[2] Two 24 m long wind tunnels were constructed indoors over soil plots fertilized with surface-applied urea, and measurements of NH_3 concentration taken every 2 m along the tunnel were used to test for the oasis effect. Out of the 85 periods of data collected, 58 resulted in the distance from the entrance of the tunnel having a significant linear effect on NH_3 concentration above the plot (α=0.05), indicating the absence of the oasis effect for those periods. In addition, 37 out of the 38 periods with linear regression coefficients greater than 10^{-5} show that distance from the entrance of the tunnel is a significant regression parameter for NH_3 concentration along the tunnel. Therefore during the periods when the largest losses of NH_3 occurred, the concentration profiles along the tunnel were not significantly affected by the oasis effect.

Title: Assimilation of Earth Observation leaf area index into the STICS crop model using a formal Markov Chain Monte Carlo algorithm

Presenter/First Author: Morteza Mesbah, Agriculture and Agri-Food Canada, Ottawa, ON

Presenter/First Author Email: morteza.mesbah@agr.gc.ca

Co-authors: Elizabeth Pattey, Agriculture & Agri-Food Canada, Ottawa, ON, Canada; Guillaume Jégo, Agriculture & Agri Food Canada, Québec, QC, Canada; Jiangui Liu, Agriculture and Agri-Food Canada, Ottawa, ON, Canada; Samuel Buis, , , ; Patrice Lecharpentier, , ,

Abstract Body: Assimilation of Earth observation (EO) derived crop biophysical descriptors into crop models is proven efficient to predict yield in complex agricultural ecosystems. However, the performance of crop models is affected by the accuracy of key input parameters related to soil properties and management practices, which often are not readily available at the regional scale. In this case, data assimilation could improve model performance to predict crop yield by re-initializing key model parameters. The objective of this study is to evaluate the performance of two optimization algorithms to re-initialize seeding date and density, and soil moisture at field capacity, all of which affect the yield predictions of the STICS crop model. Simulations were performed over a small region near Ottawa (ON, Canada) where soybean, corn, and spring wheat were grown. Images from multispectral satellite data (Landsat TM, SPOT and Formosat-2) and compact airborne spectrographic imager (CASI) were acquired over several growing seasons. The LAI was calculated with the modified transformed vegetation index (MTVI2). The two optimization techniques evaluated in this study were 1) the Nelder-Mead Simplex method and 2) an adaptive formal Markov Chain Monte Carlo named Differential Evolution Adaptive Metropolis (DREAM). The DREAM algorithm is expected to offer great advantages compared to the Simplex method for regional-scale predictions because: 1) its outcome is expected to be less dependent on the initial values of the optimized parameters, 2) it provides correlation coefficients between optimized model parameters, and 3) it provides uncertainties associated with model parameters and predictions. This was shown for hydrological simulations but not for yield predictions. Our preliminary results indicated that the DREAM method lead to a root mean square error of 0.7 t ha^{-1} regardless of how the initial values for the parameters were assigned, while the Simplex method showed a high level of sensitivity (root mean square error ranging from 0.5 to 2.3 t ha^{-1}) to initial values when they were taken from properly assigned pre-defined ranges.

Title: Capturing and Processing Soil GHG Fluxes in a Multi-Analyzer Gas Flux System

Presenter/First Author: Jason R Hupp, LI-COR Biosciences, Lincoln, NE

Presenter/First Author Email: jason.hupp@licor.com

Co-authors: Dayle K McDermitt, LI-COR Biosciences, Lincoln, NE; Mark Johnson, , , ; Liukang Xu, LI-COR Biosciences, Lincoln, NE; Rod Madsen, , ,

Abstract Body: The LI-COR LI-8100A Automated Soil CO_2 Flux System is designed to measure soil CO_2 efflux using automated chambers and a non-steady state measurement protocol. While CO_2 is an important gas in many contexts, it is not the only gas of interest for many research applications. With some simple modifications, many third party analyzers capable of measuring other trace gases, e.g. N_2O, CH_4, or $^{13}CO_2$ etc., can be interfaced with the LI-8100A System, and LI-COR's data processing software (SoilFluxPro™) can be used to compute fluxes for these additional gases. In this paper we describe considerations for selecting an appropriate third party analyzer to interface with the system, how to integrate data into the system, and the procedure used to compute fluxes of additional gases in SoilFluxPro™. A case study is presented to demonstrate methane flux measurements using an Ultra-Portable Greenhouse Gas Analyzer (Ultra-Portable GGA, model 915-0011), manufactured by Los Gatos Research and integrated into the LI-8100A System. Laboratory and field test (from a managed urban site and an artificial peat bog) results show that the soil CO_2 efflux based on the time series of CO_2 data measured either with the LI-8100A analyzer or with the Ultra-Portable GGA are essentially the same. This suggests that soil GHG fluxes measured with both systems are reliable.

Title: Spatial Variability in Biogenic Gas Releases from Subtropical Wetland Ecosystems is Revealed from Ground Penetrating Radar (GPR) at the Lab and Field Scale

Presenter/First Author: Matthew D McClellan, Florida Atlantic University, Boca Raton, FL

Presenter/First Author Email: mmcclellan2013@fau.edu

Abstract Body: Peatlands are key contributors of greenhouse gases into the atmosphere that are capable of producing and releasing significant amounts of free-phase biogenic gases (CO_2 ,CH_4). Over the past two decades many studies have investigated gas flux dynamics in peat soils, however the spatial distribution of these fluxes are still highly uncertain, particularly for tropical and subtropical peatlands. This study implements an array of hydrogeophysical methods to investigate the spatial variability in biogenic gas accumulation and release in three 0.027 m^3 peat monoliths from three different wetland ecosystems in central Florida (sawgrass peatland, a wet prairie, and a depressional wetland within a pine flatwood). Over a period of five months gas content variability (i.e. build-up and release) within the peat matrix was estimated using a series of ground penetrating radar (GPR) transects along each sample about three times a week using high frequency (1.2 GHz) antennas. GPR measurements were constrained with an array of gas traps (eight per sample) fitted with time-lapse cameras in order to capture gas releases at 15 minute intervals. A gas chromatograph was used to determine CH_4 and CO_2 content of the gas collected in the gas traps. A grid of surface deformation points was also collected concurrently to monitor changes in the peat surface associated with gas build up and release. The approach was further upscaled to the field within the Blue Cypress Preserve (BC) where high temporal resolution datasets were implemented. The aim of this study is to investigate the spatial and temporal variability in gas accumulation and release of biogenic gases in subtropical peat soils at the lab and field scales and how they are potentially related to structural changes within the peat matrix. This work has implications for better understanding carbon dynamics in subtropical freshwater peatlands and how climate change may alter such dynamics.

Title: Spatiotemporal distribution of DOC and DON in water after damming of the Three Gorges Reservoir

Presenter/First Author: Gang Yang, University of Quebec at Montreal UQAM, Montreal,

Presenter/First Author Email: yanggang903@gmail.com

Co-authors: Jianqing Tian, State Key Laboratory of Mycology, Institute of Microbiology, Chinese Academy of Sciences, Beijing, China; Huai Chen, Chinese Academy of Sciences, Chendu, China; Xingzhong Yuan, , , ; Qiuan Zhu, Northwest A&F University, Yangling, China; Dan Zhu, Chinese Academy of Sciences, Chendu, China; Changhui Peng, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Jianghua Wu, Memorial University of Newfoundland, Corner Brook, NF, Canada

Published Material: Most findings published on Fresenius Environmental Bulletin.

Abstract Body: Large reservoirs always influence water environment, the change of which in turn has direct impacts on biogeochemical cycles. In this study, we measured dissolved organic carbon (DOC) and dissolved organic nitrogen (DON) in the water of the Three Gorges Reservoir Region (TGRR) from February to September of 2008 at seven sites, in order to understand the spatiotemporal features of DOC and DON in this region after the dam impoundment. The concentration of DOC in water collected at all sites ranged from 0.02 to 54.48 $mg \cdot L^{-1}$ (average 3.85 $mg \cdot L^{-1}$), and for DON the range was 0.01 to 2.60 $mg \cdot L^{-1}$ (average 0.88 $mg \cdot L^{-1}$). The concentration of DOC was the highest at Sandouping, immediately before the dam, ranging from 1.65 to 54.48 $mg \cdot L^{-1}$ (average of 11.41 $mg \cdot L^{-1}$), much higher than the average value for several other reservoirs. It is probably because a large amount of organic matter from upstream erosion was accumulated at the reservoir. Through measurement of the DOC, DON and total carbon (TC) along the TGRR, we did not find vertical variation except for DON. However, we noticed a fluctuation of DOC and DON with time. Moreover, we found DOC concentration for the drawdown area was markedly lower than that of the permanently flooded sites. This was partly because the drawdown area provided a relatively long retention time for the microbial community to decompose the soluble carbon substrate. These results were consistent with our previous study reporting a high CH_4 emission in the drawdown area of the TGRR.

Title: Modelling CO_2 and CH_4 Dynamics in a Small, Eutrophic, Monomictic Lake

Presenter/First Author: Arianto Santoso, University of Waikato, Hamilton,

Presenter/First Author Email: abs11@students.waikato.ac.nz

Co-authors: David Philip Hamilton, University of Waikato, Hamilton, New Zealand; Louis A Schipper, University of Waikato, Hamilton, New Zealand; Chris Hendy, , , ; Deniz Ozkundakci, , , ; Ilia Ostrovsky, , , ; Matthew R Hipsey, University of Western Australia, Crawley, WA, Australia

Abstract Body: Lakes play an important role in processing carbon derived from the terrestrial ecosystem. This carbon can accumulate as greenhouse gases, namely CO_2 and CH_4, as a result of biological processes. The accumulated gases are potentially emitted during seasonal mixing. Nonetheless, carbon fluxes and balances are still unclear, which limits our ability to forecast future impacts such as due to climate or land use change. To better understand greenhouse gas fluxes, we investigated the dynamics of CO_2 and CH_4 in a relatively small, eutrophic lake (Lake Okaro, New Zealand). Water column concentrations of these gases were observed monthly over one-year period. In addition, peeper incubations were made in the sediment over a period of one month to estimate sediment-water fluxes of CO_2 and CH_4. Releases of CO_2 and CH_4 from the sediment into water column were 27.03 and 28.2 mmol m^{-2} d^{-1}, respectively, and corresponded to rapid enrichment of both gases in the hypolimnion in a period of stable stratification. Calculations indicated that approximately 6.6 mmol m^{-2} d^{-1} of CO_2 was taken up by the lake from the atmosphere during the stable stratification. On the other hand, in the same period CH_4 was released to the atmosphere at a rate of around 0.1 mmol m^{-2} d^{-1}. We estimated pulsed emissions were released to the atmosphere with peaks at the onset of winter mixing when 23.5 and 6.4 mmol m^{-2} d^{-1} of CO_2 and CH_4, respectively. To complicate this analysis, however, large releases of CH_4 to the atmosphere are suspected to occur via ebullition, when large bubbles suddenly occur and cannot easily be sampled. We used a one dimensional lake ecosystem model (GLM-FABM) to better understand the temporal variability of processes affecting releases and uptake of CO_2 and CH_4 between the lake and the atmosphere.

Title: Using GIS and SWAT to Model Stream Modification, Sediment and Carbon Transfer within the Grand River Drainage Network, Ontario

Presenter/First Author: Aslam Hanief, SCL, Toronto, ON

Presenter/First Author Email: ahanief@ryerson.ca

Co-authors: Andrew E. Laursen, Ryerson University, Toronto, ON, Canada

Abstract Body: The Grand River watershed (~7000 km^2) is an important agricultural area in Southern Ontario, with several large and growing municipalities. As in many watersheds, there have been historical modifications to the drainage network related to various human endeavors. ArcMap has been used to model how a natural drainage network would appear, based on digital elevation maps (DEM) to predict flow paths. Channel lengths and locations of the predicted network were compared with a ground-truthed channel inventory (Grand River

Conservation Authority and Ontario Ministry of Natural Resources) to determine efficacy of the model. Channels not anticipated by topography were mostly first-order, with low sinuosity, and were most common in areas with high agricultural land use, and are likely excavated extensions to headwater streams to facilitate drainage. Land use, in particular agricultural activity, has significantly increased the total drainage density, sediment erosion and nutrient export in the Grand. The Soil and Water Assessment Tool (SWAT) was used to evaluate sub-basin hydrology, and the transfer of sediments, organic carbon, and other nutrients (N&P) from terrestrial to aquatic systems based on land use, management practices, historical flow and meteorological data for a 10-year period (January 2000 – December 2010) from the Grand River Basin. The SWAT model predicted well the stream discharge and sediment load, along with nutrient export when compared to observed data. A modified drainage network, based on introducing natural sinuosity to excavated headwater channels, was simulated using GIS, and SWAT was applied to estimate the retention of carbon, sediment and nutrients under this new "restoration" scenario. Model results suggest that remediation efforts could target these excavated channels in the head-water catchment areas in order to improve carbon and nutrient retention.

Published Material: Data from one region of study out of five was published:Campeau, A. and del Giorgio, P. A. (2014), Patterns in CH_4 and CO_2 concentrations across boreal rivers: Major drivers and implications for fluvial greenhouse emissions under climate change scenarios. Global Change Biology, 20: 1075–1088. doi: 10.1111/gcb.12479Campeau, A., J.-F. Lapierre, D. Vachon, and P. A. del Giorgio (2014), Regional contribution of $CO_2$and CH_4 fluxes from the fluvial network in a lowland boreal landscape of Québec, Global Biogeochem. Cycles, 28, 57–69, doi:10.1002/2013GB004685.

Abstract Body: Boreal rivers are a major component of the land-water interface in a region with a significant portion of the world's soil organic matter and freshwater. Rivers are often supersaturated with greenhouse gases (GHGs), CO2 and CH4, and emit these GHGs to the atmosphere. Although rivers represent a small fraction of the surface area of the boreal region, they are responsible for a disproportionately large amount of processing and export, thus their contribution to the global carbon budget is significant. This study measures CO2 and CH4 river fluxes in five distinct regions within the boreal biome in Quebec covering 315 000 km2. Regional CH4 fluxes were significantly higher in lower sloped regions. The river networks in these regions together release carbon to the atmosphere in teragrams per year in CO2 equivalents. However, lack of current methodology for calculating the area of zero-order streams in the network may underestimate these fluxes. Zero-order streams are most connected to terrestrial landscape and have the highest CO2 and CH4 concentrations in the network but do not show up on topographic maps.

Title: High-Frequency Dynamics of Carbon Dioxide and Methane Fluxes in a Surface Flow Constructed Wetland as Affected by Discharge and Vegetation

Presenter/First Author: Sari Juutinen, University of Helsinki, Helsinki,

Presenter/First Author Email: sari.juutinen@gmail.com

Co-authors: Pasi Valkama, , , ; Anne Ojala, University of Helsinki, Helsinki, Finland; Anna I Halonen, , , ; Kukka Koskinen, , , ; Maria E Tolppanen, , , ; Harri Vasander, , , ; Outi M Salminen, , ,

Published Material: Partly same data will be presented in ASLO Aquatic Sciences Meeting in Granada, Feb 2015.

Abstract Body: Constructed wetlands (CW) are built to manage runoff and matter fluxes to aquatic ecosystems from agricultural and urban environments. Free-water surface CWs with aquatic vegetation and stilling ponds resemble eutrophic aquatic ecosystems. We have studied fluxes of carbon, nutrients, and suspended solids in a CW at the mouth of an agricultural/residential watershed in Southern Finland. We will present dissolved [CO_2], [CH_4], and [O_2] in in- and out-flow measured at 10 min frequency since December 2012 and fluxes of CO_2 and CH_4 at the air-water interface measured weekly by chambers and bubble collectors in summer 2013. We will test a hypothesis that the photosynthesis of the submerged vegetation cause diurnal variations in dissolved [CO_2], [O_2], and [CH_4], consequently affecting gas fluxes at the air-water surface. We will also analyze the impact of discharge, weather, and vegetation on the seasonal gas flux dynamics in the CW. Continuous data with high temporal resolution of dissolved [CO_2] and [CH_4] can improve our understanding of aquatic metabolism and of the impacts of weather and vegetation on the aquatic C cycling.

Title: Effects of flooding and drainage on CO_2 flux in Dongting Lake wetlands, China

Presenter/First Author: Zhengmiao Deng, Chinese Academy of Sciences, Hunan,

Presenter/First Author Email: dengzhengmiao@163.com

Co-authors: Yonghong Xie, Key Laboratory of Agro-ecological Processes in Subtropical Region, The Chinese Academy of Sciences, Changsha, China; Xinsheng Chen, Key Laboratory of Agro-ecological Processes in Subtropical Region, The Chinese Academy of Sciences, Changsha, China; Feng Li, Key Laboratory of Agro-ecological Processes in Subtropical Region, The Chinese Academy of Sciences, Changsha, China; Chen Zhang, , ,

Abstract Body: Wetlands have been recognized as a main carbon sink on the earth. However, the role of carbon sink of flooding wetlands might be weakened due to the flooding duration time changes induced by anthropic disturbances. In this study, we quantified the effects of the flooding and drainage on CO_2 flux from a *Miscanthus sacchariflorus* marsh in Dongting Lake wetlands by eddy covariance technique from 20th June to 31st October, 2014. The results showed that the mean of CO_2 flux was -2.72μmol s^{-1} m^{-2} during 20th June to 8th July (before flooding), and it was reduced significantly to -4.29μmol s^{-1} m^{-2} during 9th July to 30th September (under flooding). However, the mean of CO_2 flux was 0.69μmol s^{-1} m^{-2} during 1st to 31th October (drained after flooding). The principal component analysis (PCA) among the environmental factors (water level (WL), sensible heat flux (H), latent heat flux (LE), air heat capacity (HC), air temperature (T), air pressure (P), air molar volume (molV), evapotranspiration (ET), water vapour density (WVD), relative humidity (RH), wind speed (S), friction velocity (U^*)) indicated that the CO_2 flux was

mainly effected by WL and air properties (i.e., T, P, HC, molV, and WVD), which explained 44.78% of total variance, while the RH and energy characters (i.e., H, LE, ET) explained 24.91% of total variance and 14.58% of total variance was explained by S and U^*. Our results indicated that the flooding in wetlands can enhance the ability of carbon fixing while the drainage might accelerate the carbon loss. The artificial controlling of water level might be an effective way to fix the atmosphere carbon in flooding wetlands.

Title: Priming of terrestrially-derived dissolved organic matter: Implications for coastal carbon cycling

Presenter/First Author: Thomas S Bianchi, University of Florida, Gainesville, FL

Presenter/First Author Email: tbianchi@ufl.edu

Co-authors: Nicholas D Ward, University of Florida, Ft Walton Beach, FL; Daniel C Thornton, Texas A & M University College Station, College Station, TX; Shari Ann Yvon-Lewis, Texas A & M University College Station, College Station, TX; Gary King, , , ; Michael R Shields, University of Florida, Ft Walton Beach, FL; Timothy I Eglinton, ETH Swiss Federal Institute of Technology Zurich, Zurich, Switzerland; Jason H Curtis, University of Florida, Gainesville

Abstract Body: <span'',serif;">Although inland waters comprise a small fraction of Earth's surface, they play a critical role in the global C cycle. Global estimates of riverine flux of dissolved organic carbon (DOC) to the oceans range from about 250 to 360 Tg y^{-1}. Interestingly, only a small fraction of the roughly 2900 Tg C yr^{-1} transported through inland waters globally ever reaches the ocean. Recent observations of immense CO_2 evasion from streams and rivers thus suggest that terrestrially-derived DOC (TDOC) is not as recalcitrant as previously thought. In a lab-based experiment pine-litter leachate was converted to CO_2 at roughly the same rate in the trehalose and diatom leachate treatments, less than 1% of the diatom leachate was converted to CO_2, as opposed to ~50% of the trehalose over a few days. It is likely that a large fraction of the diatom leachate was assimilated by bacteria, whereas the trehalose was mostly respired to CO_2. Pilot field experiments in the Amazon River, with the incubation system performed during two cruises show that $\delta^{13}CO_2$ rapidly increased after adding labeled lignin; roughly 50% of the added lignin was converted to CO_2 in 10 hours. This is equivalent to a remineralization rate of ~0.021 mg C $L^{-1}d^{-1}$, or 2x the rate of FACE-only remineralization measured in the lab experiments.

Title: Tracing Fire-Derived Organic Carbon on a Global Scale

Presenter/First Author: Michael W I Schmidt, University of Zurich, Zurich,

Presenter/First Author Email: michael.schmidt@geo.uzh.ch

Co-authors: Ulrich M Hanke, , , ; Daniel B Wiedemeier, University of Zurich, Zurich, Switzerland; Timothy I Eglinton, ETH Swiss Federal Institute of Technology Zurich, Zurich, Switzerland

Abstract Body: Fire-derived carbon, is a persistent organic carbon fraction due to its aromatic nature (Wiedemeier et al., 2015). It is globally produced on large scales by biomass burning and by combustion of fossil fuel. As it is an inherently terrestrial product it has been investigated in soils and the atmosphere, then in rivers and oceans. However, different analytical approaches produced results which could not be compared directly, thus inhibiting the calculation of a combined global budget.

The question therefore remains: how much fire-derived carbon is produced, and then transported from terrestrial systems, through rivers to coastal and abyssal sediments? We need to exploit our analytical possibilities consistently on all environmental compartments in order to estimate integrated budgets.

In this presentation, we highlight the capabilities of a state-of-the-art molecular marker method (Wiedemeier et al., 2013, Gierga et al., 2014) to globally trace quantity, quality as well as ^{13}C and ^{14}C signals of fire-derived carbon. We show its use across small model lake systems, as well as major river systems of the world, e.g. to investigate size fractions of particulate suspended sediment. First results and important implications for the understanding of global carbon cycle will be discussed.

Title: Investigating Preservation of Organic Matter Through Complexation with Iron Oxides

Presenter/First Author: Azadeh Joshani, Concordia University, Montreal,

Presenter/First Author Email: joshani.azade@gmail.com

Co-authors: Karine M Lalonde, Concordia University, Montreal, QC, Canada; Andrew Barber, Concordia University, Montreal, QC, Canada; Charles Gobeil, INRS-ETE, Quebec, QC, Canada; Yves Gelinas, Concordia University, Montreal, QC, Canada

Abstract Body: The biogeochemical cycles of iron (Fe) and organic carbon (OC) are closely interconnected. The concentration of reactive Fe is tightly controlled by soluble organic ligands in oceanic waters. In sediments however, the role of Fe in the preservation of organic compounds is only starting to be explored. We recently developed an approach based on the reductive dissolution of reactive solid phase Fe to quantify the amount of OC retained in the solid phase through its interaction with Fe. This method was applied to a series of aquatic sediments of contrasting OC contents and mineralogies collected from a broad range of deposition environments. On average, 21.5 ± 8.6% of the total OC in sediments was released to the liquid phase upon dissolution of iron and was thus directly attached to reactive solid iron phases. Interestingly, the only lake sediment in our sample set, collected in the boreal forest, had the highest percentage of OC bound to Fe. We investigated Fe-OC interactions in lake sediments to verify whether the high percentage of OC bound to Fe is characteristic of lake sediments, and to assess the importance of redox conditions/interfaces in the formation of Fe-OC aggregates. We used sediments from Lake Tantaré, a system with two basins characterized by contrasting bottom water redox conditions in the summer. We found a high percentage of OC directly associated with Fe minerals (30.1 ± 6.4%), with no significant difference between the two basins, which confirmed our previous results obtained from boreal lake sediments. Total nitrogen

(TN) followed the same trend, although with lower percentages of TN associated with Fe minerals (20.7 ± 6.7%). We characterized the Fe-associated and the non-Fe-associated OC pools at the elemental (OC, TN), isotopic ($\delta^{13}C$, $\delta^{15}N$) and functional group (FTIR) levels. Differences in reducible Fe content and in OC:Fe and TN:Fe ratios were found between the two basins; they will be discussed in relation with our working hypothesis.

Title: The Role of Iron in the Diagenesis of Organic Carbon and Nitrogen in Sediments: A Long-term Incubation Experiment

Presenter/First Author: Andrew Barber, Concordia University, Montreal, QC

Presenter/First Author Email: andrew.jack.barber@gmail.com

Co-authors: Karine M Lalonde, Concordia University, Montreal, QC, Canada; Alfonso Mucci, McGill University, Montreal, QC, Canada; Yves Gelinas, Concordia University, Montreal, QC, Canada

Published Material: The bulk of the work presented here was published in Marine Chemistry in 2014 (Barber et al., 2014) and has been presented at the 2014 Goldschmidt in Sacramento California.

Abstract Body: Marine sediments have long been proposed as a major sink of organic matter (OM) on the planet with the bulk of this OM being sequestered within coastal and deltaic sediments. The long-term storage of reduced organic compounds within these environments helps maintain the global redox balance at the surface of the planet. As a dominant constituent of the sediment mineral matrix, redox-sensitive nanophase iron (Fe) oxides play an important role in the preservation of OM through the formation of metastable Fe-OM complexes that sequester approximately 20% of the total sediment OM pool upon burial. Using a long-term sediment slurry incubation approach we examined the effect of iron on the preservation and degradation of OM. The fate of freshly deposited algal dissolved OM was monitored by tracking its depleted stable carbon isotopic signature ($\delta^{13}C$) relative to the native sediment OM. We demonstrate the incorporation of the tracer's depleted $\delta^{13}C$ signature into the sediment within the first hour of the incubation; this is consistent with the timeframe for sorptive processes and co-precipitation. In the presence of iron (oxy)hydroxides we see increased incorporation of the algal tracer's depleted isotopic signature within the solid phase demonstrating a shuttling effect of OM from the sediment pore waters into sediment particles. The effect of iron oxides on the fate of organic matter was found to be twofold, showing increased preservation of organic carbon species while increasing the rate of nitrogen removal through a process known as Feammox, short circuiting traditional nitrogen removal pathways. This study is the first study of its kind that demonstrates the dual role of iron oxides, by decoupling the elemental cycles of carbon and nitrogen within sediments originating from coastal regions.

Title: Evaluation of Accelerated Solvent Extraction and Solid-Phase Micro Extraction for the Analysis of Brevetoxins in Marine Sediments

Presenter/First Author: Amanda Gabriel, GEOTOP, Montreal,

Presenter/First Author Email: amanda.gabriel.tech@hotmail.com

Co-authors: Audrey Limoges, GEOTOP-UQAM, Montreal, QC, Canada; Anne de Vernal, University of Quebec at Montreal UQAM, Montréal, QC, Canada; Yves Gelinas, Concordia University, Montreal, QC, Canada

Abstract Body: Harmful algal blooms (HAB), caused by the proliferation of certain biotoxin releasing species of algae, have increased in occurrence, cellular concentration and global distribution over the last 20 years. These toxins persist within the environments of affected areas and act as biomarkers for the spatial and temporal distribution of HAB occurrences. One such suite of biomarkers, known as brevetoxins (PbTx), are produced by the marine dinoflagellate *Karenia brevis* and are of interest for the reconstruction of the history of red tide HABs. No method currently exists to fully extract and quantify brevetoxins found within marine sediments, a prerequisite for assessment of the environmental conditions that lead to the proliferation of harmful algae using the sedimentary record and other biological proxies.

In this work, a method based on Accelerated Solvent Extraction (ASE) followed by liquid chromatography-mass spectrometry (LC-MS) was optimised for the measurement of brevetoxins in sediments. ASE uses solvents at high temperature and high pressure to maximize extraction efficiency, but also leads to the co-extraction of a large quantity of compounds with properties similar to those of brevetoxins. The result is the formation of a precipitate in the extract that leads to a decrease in brevetoxin recoveries by removing them from solution through flocculation and coagulation. A post-extraction cleaning step was thus developed using solid-phase micro extraction (SPME) fiber probes that minimize sample manipulation and maximize sample throughput. Although we believe that the accelerated solvent extraction of brevetoxins from sediments will be more efficient than conventional extraction methods, more work is required to fully assess the figures-of-merit of the complete ASE-SPME-LC-MS protocol. The preliminary findings are promising, with measured brevetoxin recoveries of 69.1 ± 1.1% for PbTx-3 and 71.9 ± 8.2 % for PbTx-2 using SPME fiber probes, and an absolute detection limit of 1 ng/ml using the optimized LC-MS method.

This newly developed ASE-SPME-LC-MS method, when combined with other sedimentary proxies used to reconstruct paleo-environmental conditions, will further our understanding of the factors that induce the onset of toxic algal blooms and aid in predicting future occurrences.

Abstract Body: With 662 GtC, the dissolved organic carbon (DOC) pool in the ocean is an important carbon reservoir for the Earth system, but the processes that control its cycling rate are poorly understood. Recent measurements have reported a possible relationship between the molecular size and radiocarbon age of the material. As a step towards exploring this relationship, we combine a random scission model and the Smoluchowski mean-field coagulation equations to derive a mathematical model for the molecular size distribution and radiocarbon content of DOC. The model allows us to predict the transient and equilibrium joint distribution for molecular size and age of DOC. We use the model to

explore the sensitivity of the equilibrium distribution to changes in the size dependent random scission and coagulation rates.

Abstract Body: Circumneutral ferrous iron-oxidizing bacteria eke out a living precariously balanced between opposing chemical gradients: the reduced iron which acts as their energy source and dissolved oxygen that, while necessary as a terminal electron acceptor for cellular metabolism, will out-compete the bacteria at atmospheric concentrations. In this study, detrended fluctuation analysis was used to quantify changes in redox potential that occurred over time in microcosms with different amounts of bacteriogenic iron oxides (BIOS); concomitant measurements of dissolved iron concentrations were used to determine accompanying rates of iron oxidation. The BIOS and water for the microcosms were obtained from a reduced anoxic groundwater seep where the microbial community consists of mat-forming iron-oxidizing bacteria, predominantly *Gallionella ferruginea* with a small amount of *Leptothrix ocrachea*. XRD analysis confirms that the iron precipitates from the live systems consist of x-ray amorphous material. Two abiotic control systems were also tested; one with killed BIOS and one consisting only of filtered creek water. SEM analyses of the live and autoclaved precipitates reveal that iron oxide precipitates were associated with bacterial cells found only in the live systems. Rates of iron oxidation in the living systems were similar to previously reported values for bacterial ferrous iron oxidation. At the same time, the microcosms were distinguished by the presence of persistent long-range correlations in redox potential that are indicative of anomalous diffusion behavior. At the beginning of the experiment, the live systems exhibited strong fractional Brownian motion and superdiffusion; however, as the bacterial consumed ferrous iron, the redox potential scaling exponents shifted to an apparent subdiffusive regime, which resembles a different dynamic state than when the microcosms started.

Published Material: As this is a work in progress, portions of this abstract were presented at the AGU conference in December 2014 in San Francisco. This abstract focusses on the advancements since then as well as on how this technique can be applied to specific situations.

Abstract Body: In extreme environments, microorganisms persist in systems characterized by low energy production, nutrient fluxes, and microbial growth. Understanding and predicting the biogeochemical dynamics within these systems necessitates an understanding of the metabolism and physiology of organisms that are often uncultured or studied *in situ* under conditions that vary greatly from those seen in low energy environments. Cultivation independent approaches are therefore important and have greatly enhanced our ability to characterize functional microbial diversity. With the capability to reconstruct thousands of genomes from microbial populations using metagenomic techniques, one needs to develop an understanding of how these metabolic blueprints influence the fitness of organisms and how populations emerge and impact the physical and chemical properties of their environment.

Here, we discuss the development of a trait-based model of microbial activity that simulates coupled guilds of microorganisms, parameterized including traits extracted from large-scale metagenomic data. Each group within a functional guild is parameterized with a unique combination of traits governing organism fitness under dynamic environmental conditions. Using a reactive transport framework, we simulate the thermodynamics of coupled electron donor and acceptor reactions to predict the energy available for cellular maintenance, respiration, biomass development, and exo-enzyme production. This presentation will address our latest developments in the estimation of trait values related to growth and the use of metagenomic data to identify and link key fitness traits associated with respiratory and fermentative pathways, macromolecule depolymerization enzymes, and nitrogen fixation. Simulations explore abiotic controls on community emergence including identification of the processes regulating aquifer oxygen concentrations during seasonally fluctuating water table regimes at the Rifle floodplain.

Title: Bioenergetic Limitations on Slow Microbial Growth in the Subsurface: What is the Burden of Maintenance on the Overall Energy Budget?

Presenter/First Author: Christina Marie Smeaton, University of Waterloo, Waterloo, ON

Presenter/First Author Email: christinasmeaton@gmail.com

Co-authors: Bijendra Man Bajracharya, University of Tübingen, Tübingen, Germany; Christine Ridenour, University of Guelph, Guelph, ON, Canada; Chris Thomas Parsons, University of Waterloo, Waterloo, Canada; Philippe Van Cappellen, University of Waterloo, Waterloo, ON, Canada

Abstract Body: In low energy environments such as the subsurface, the minimum energy required to maintain cellular integrity and function (maintenance energy) may represent a significant fraction of the total energy available to microbial communities. However, traditional kinetic and thermodynamic models incorporating key microbial processes are often developed using data collected in nutrient rich growth media. In this study, slow microbial growth in the subsurface was simulated using a flow through bioreactor system in experiments designed to determine the maintenance energy requirement of the model subsurface bacterium *Shewanella oneidensis*. An existing bioreactor system (Applikon EZ-control®, 2.4 L) was modified to include a biomass retention filtration unit (retentostat) resulting in biomass accumulation over time. An artificial low-nutrient groundwater medium was optimized for slow *S. oneidensis* growth and was supplied and removed from the reactor at flow rates on the order of 1 mL min^{-1} with a dilution rate of 0.025 h^{-1}. The retentostat was run under electron donor limited conditions with nitrate, a common groundwater contaminant, supplied at 0.025 mM h^{-1} and lactate supplied in excess at 0.125 mM h^{-1}. Respiratory ammonification of nitrate by *S. oneidensis* and cell growth was monitored over time (40 days) and compared to parallel incubations in batch reactors. Initial rates of ammonification were similar in the bioreactor and batch reactors, however, optical density and ATP measurements showed a slow yet increasing microbial growth over time (generation time = 17 days) in the retentostat. In contrast, cells in the batch reactors did not grow significantly and died within 2 weeks of inoculation. A maintenance energy demand was estimated (0.5 kJ C-mol biomass h^{-1}) by fitting the biomass data to the van Verseveld equation. The low maintenance energy demand of *S. oneidensis* as compared to typical maintenance energies reported in the literature (>10 kJ C-mol biomass h^{-1}) likely reflects its metabolic versatility and ability to persist in low energy environments. In addition to the retentostat results, we will also discuss our efforts to develop a kinetic and thermodynamic based biogeochemical model which explicitly accounts for energy used for both microbial maintenance and growth.

Title: Nitrous Oxide Emissions from Irrigated Cotton in the Southwest USA: Assessment and Mitigation Strategies.

Presenter/First Author: Kevin F Bronson, USDA Agricultural Research Service, Maricopa, AZ

Presenter/First Author Email: kevin.bronson@ars.usda.gov

Co-authors: Jarai Mon, , , ; Douglas Hunsaker, USDA/ARS, Maricopa, AZ; Steve Del Grosso, USDA-ARS Soil Plant Nutrient Research, Fort Collins, CO

Published Material: American Society of Agronomy-Soil Science Society of America-Crop Science Society of America Annual Meetings, Long Beach, CA 2-5 November 2014.

Abstract Body: Nitrogen fertilizer is an important source of the greenhouse gas nitrous oxide (N_2O) in irrigated cropping systems. However, little data exists for row crops in the desert southwest of North America, where seasonal irrigation amounts on farms can exceed 1.2 m. The objective of these studies was to assess the effect of N fertilizer rates on N_2O emissions from furrow- and sprinkler-irrigated cotton (*Gossypium hirsutum*) in Central Arizona and to test some mitigation management options. Cotton was planted from late April to May 1 from 2012 to 2014 on 1-m wide beds. Nitrogen fertilizer as liquid urea ammonium nitrate (320 g N kg^{-1}) varied from 0 to 233 kg N ha^{-1} per season. There were two split applications of N fertilizer in surface irrigation, and three splits under the sprinkler. Emissions were measured weekly with 1-L vented chambers placed for 24 minute periods in the bottom of furrows. Fifty-ml samples were taken at 0, 12, and 24 minutes and analyzed for N_2O with an ECD-GC. During the cotton growing season N_2O emissions were measured from May to August. Nitrous oxide emissions were not agronomically significant, i.e. < than 0.5 % of applied N, but increased several-fold with the addition of N fertilizer. In 2012 and 2013 with furrow irrigation, knifing-in of N fertilizer resulted in lower N_2O emissions than fertigating into the header irrigation line. In 2014 under the sprinkler, the addition of the enhanced efficiency N source Agrotain Plus to N fertilizer had inconsistent mitigation effects on N_2O emissions. Emissions were positively correlated with soil moisture and temperature. Nitrous oxide fluxes ended 2-3 d after irrigation events that were as high as 125 mm in furrow irrigation, and declined during the season, as plant N uptake progressed. Agrotain Plus apparently breaks down quickly in the desert environment, making its use an N_2O emission inhibitor not consistent.

Title: Nitrous Oxide Emissions from Cropland Soils with Different Management Regimes in Manitoba, Canada

Presenter/First Author: Aaron J Glenn, Agriculture and Agri Food Canada, Brandon, MB

Presenter/First Author Email: aaron.glenn@agr.gc.ca

Co-authors: Amal Roy, Agriculture and Agri Food Canada, Brandon, MB, Canada; Alan Moulin, Agriculture and Agri Food Canada, Brandon, MB, Canada; Henry Finnie Wilson, Agriculture and Agri-Food Canada, Brandon, MB, Canada

Published Material: Preliminary results from the 2013 growing season for one of our study sites were presented in a poster titled "Nitrous oxide flux from a clay loam under mature no-till and variable rate N fertilizer management in western Manitoba" at the 57th Annual Manitoba Soil Science Society Conference held in Winnipeg in February 2014.

Abstract Body: Globally, the agricultural sector is the largest anthropogenic source of nitrous oxide (N_2O) to the atmosphere, the majority of which can be attributed to biogeochemical transformations of nitrogen (N) added to cropland soils. The Canadian Tier II methodology used for national GHG inventory reporting implicates the application of synthetic N fertilizer to cropland soils as the largest anthropogenic source of N_2O nationally and indicates that emissions from this source have increased by more than 70% between 1990 and 2012. As synthetic N fertilizer application is the main source of anthropogenic N_2O globally and nationally, efforts to use fertilizer more efficiently have a significant potential to reduce overall emissions from this source. The objectives of this study are to identify the relative influence of environment, management and climate on soil N_2O emissions and to measure the emission per unit production for a range of cropping systems in the region. In ongoing studies beginning in 2012, soil N_2O fluxes have been measured using the static-chamber technique in various agroecosystems in southern Manitoba. The farm characteristics vary from integrated crop-livestock operations with beef cattle manure and compost applied to soil as nutrient amendments, to a mature no-till cropland with variable rate N fertilizer management. Surface soil textures are similar at the majority of the sites but the organic C content and inorganic N availability of surface soils vary considerably. Soil temperature and moisture content were monitored during the measurement periods and related to the timing and magnitude of N_2O emissions. These measurements of soil N_2O emissions from cropland in the subhumid eastern Canadian Prairies may help to refine and revise estimates for regional inventories, particularly with regards to coefficients related to hydrology, soil texture, climate, and soil management activities. Current results from the research will be shared and discussed.

Co-authors: Claudia Wagner-Riddle, University of Guelph, Guelph, ON, Canada; Anna Crolla, , , ; Chris Kinsley, , , ; Ed Gregorich, Agriculture and Agri-Food Canada, Ottawa, ON, Canada

Abstract Body: Anaerobic digestion (AD) is a manure treatment technology that reduces CH_4 emissions from manure storage and provides a nitrogen rich fertilizer for field crops. However, few studies have evaluated the environmental impacts of applying AD effluent (digestate) to agricultural soils, and interactions between soil type, climate and timing of application. In this study, N_2O fluxes and N-leaching losses were measured for 2.5 years (October 2011 to May 2014) in Alfred, Ontario. The site consisted of two nearby fields with contrasting soil textures (sandy-loam vs. clay). Treatments included: fall- and spring-applied digestate (DG), fall- and spring-applied raw dairy manure (RM), spring urea (UR) and a zero-N control. N_2O fluxes were measured using static chambers and N-leaching was estimated by sampling isolated tile drains (clay field) and zero-tension lysimeters in both fields. N_2O emissions were higher in the second year of study (wet year) compared to the first (dry year). Peak N_2O emissions occurred during spring thaw (March-April) and ~2 weeks following spring applications and tillage. There was no overall effect of timing (spring vs. fall) on annual N_2O emissions, only a change on when emissions took place (at spring thaw for fall application and in late spring after spring manure application). DG had significantly higher N_2O emissions compared to RM and UR in the sandy-loam field (pH=6.2), but there were no N source effects on N_2O emissions in the clay field (pH=7.1). DG and RM treatments showed similar annual NO_3 losses, while UR had the highest annual NO_3 mass load in both fields measured using lysimeters and tile drains As such, lower N_2O emissions from UR were potentially the result of greater NO_3 leaching. Thus, simultaneous measurements of N_2O and NO_3 provide insight into potential pollutant trade-offs. Overall, N source effects were strongly linked to interactions with soil type and climate.

Co-authors: Hannes Hegewald, , , ; Katharina Kesenheimer, , , ; Sarah Köbke, , , ; Thomas Räbiger, , , ; Teresa Suarez, , , ; Roland Fuss, Johann Heinrich von Thünen Institute, Braunschweig, Germany

Abstract Body: Biodiesel from rapeseed is one of the major renewable resources in Germany used for fuel production. According to the Renewables Directive of the European Union, biofuels have to fulfill strict sustainability requirements, such as reductions of 35% and 50% (starting in 2017) of greenhouse gases (GHG) in comparison to fossil fuels. Thus, the mitigation of field nitrous oxide (N_2O) emissions is still challenging and depends on numerous interacting factors, such as climatic (temperature and soil moisture) and management factors, e.g. fertilizer type (organic vs. mineral fertilizer) and fertilizer rate, as well as tillage practices. Since 2012, measurements were conducted at 5 study sites throughout Germany located in the major precipitation-frost classes identified as relevant for N_2O production (Jungkunst et al. 2006). A semi-randomized block design was established at each study site investigating the complex effects of i) crop rotation of winter rape - winter wheat - winter barley and ii) 5 fertilizer regimes (100% biogas residue application with and without nitrification inhibitor, 100% mineral fertilizer, 67% mineral fertilizer, non-N fertilized control) on N_2O emissions. At each study site, nitrous oxide field emissions were measured by the same approach daily for 3-5 days following fertilization and subsequently weekly using a manual *non-flow-through non-steady-state* closed chamber system and 20-minute interval sampling. We present results from cropping seasons 2012-2013 and 2013-2014, featuring two climatically contrasting winter seasons. In 2013, the weather conditions were characterized by a cold and long winter with snow until mid-spring, whereas almost no freezing events occurred in 2014. Annual N_2O emissions as well as yield-normalized N_2O emissions from rape were low in both seasons. Nevertheless, annual differences between treatments and sites occurred. For both cropping seasons, emissions were smaller than predicted by the IPCC emission factors or by the model of Stehfest & Bouwman (2006), but were still dependent on nitrogen input.

Title: Effectiveness of 4R Mitigation Practices to Reduce N_2O Emissions of Corn Production Systems: A Modelling Approach

Presenter/First Author: Diego Abalos, University of Guelph, Guelph, ON

Presenter/First Author Email: dabalosr@uoguelph.ca

Co-authors: Lianhai Wu, , , ; Anna Chemeris, , , ; Claudia Wagner-Riddle, University of Guelph, Guelph, ON, Canada

Abstract Body: Agricultural soils are the dominant source of nitrous oxide (N_2O), a potent greenhouse gas and a major cause of ozone layer depletion. Process-based models are increasingly being used to explore the impacts of management and climate in N_2O emissions from agriculture. Models used to establish emissions under current management practices can also be used to compare alternative management scenarios intended to reduce emissions.

SPACSYS is a multi-dimensional, field scale, weather-driven dynamic simulation model of C and N cycling, which operates with a daily time-step and outputs N_2O emissions (Wu, 2007). The objective of this study is to analyse the effect of different fertilizer management practices on corn as means to control N_2O emissions without incurring in yield penalties, using SPACSYS. The evaluated management practices are part of the 4R Nutrient Stewardship Program, which proposes a framework to increase agricultural production and improve environmental sustainability by maximizing fertilizer-use efficiency.

N_2O measurements were carried out at two field sites in southern Ontario with climate and soil conditions representative of the agricultural region where the sites are located (e.g. Wagner-Riddle et al., 2007). Field data covers different years from 2000 to 2010, contrasting fertilizer types (both mineral and organic) and application depths, providing suitable datasets for testing the sensitivity of SPACSYS to changes in environmental and management factors at a regional scale. Preliminary results of the statistical analysis used to test the model for cumulative N_2O fluxes showed no statistically significant total error ($RMSE_{95}$) or bias (E_{95}) when compared to measured estimates. A strong association was found between measured and simulated values (R = 0.95).

Our results will promote effective policies to achieve more sustainable corn agro-ecosystems by showing which management practices have the greatest potential to reduce N losses and how they can be prioritized.

Title: Evaluating random error in long-term, multi-plot flux-gradient measurements of N_2O emissions

Presenter/First Author: Shannon E Brown, University of Guelph, Guelph, ON

Presenter/First Author Email: shan_brow@yahoo.ca

Co-authors: Claudia Wagner-Riddle, University of Guelph, Guelph, ON, Canada; Mingshu Sun, University of Guelph, Guelph, ON, Canada

Abstract Body: The Pointe-Escuminac raised bog is located on the eastern shore of New Brunswick and is affected by coastal erosion which created a peat cliff. The bog margins display several distinct layers of thin charred bands in the peat. We selected three profiles on the southwest section of the cliff to assess fire intervals from these charred layers. The first one is 170 cm thick and has 25 charred layers; we radiocarbon dated six samples at various depth from this profile, the bottom layer being aged at 4780 yrs BP (uncalibrated). The second profile is at an eight meter distance from the first (towards the center of the bog), is 210 cm thick, has 19 charred layers and seven radiocarbon dates with the bottom peat aged at 5090 yrs BP. The third profile is 58 m from the first and is 320 cm thick. The bottom layer could not be dated, but the lowermost of the four radiocarbon dated samples is 5350 yrs BP at a depth of roughly 265 cm. We found 22 charred layers between that point and the topmost peat. Comparison between the three profiles suggests a total of 27 distinct charred layers with an average time interval of 175 radiocarbon years varying between 60 and 630 years. Five alternating periods of longer (330, 340 yrs) and shorter (110, 160 and 160 yrs) mean fire intervals are detected. Comparison with vegetation content of peat strata suggest they are not related to local vegetation changes. It is more likely that the variations in fire intervals were caused by external factors such as climate conditions or regional vegetation changes. Another study discussing micro-charcoal content in a peat profile from a bog located 70 km from Pointe-Escuminac further supports a regional signal and the possibility to use bog margins as suitable long-term regional fire records.

Title: Climate Change, Wildfire, and Landscape Homogenization in Western Canada

Presenter/First Author: Ze'ev Gedalof, University of Guelph, Guelph, ON

Presenter/First Author Email: zgedalof@uoguelph.ca

Co-authors: Lori Daniels, University of British Columbia, Vancouver, BC, Canada; Eric DaSilva, , , ; Theresa Dinh, University of Guelph, Guelph, ON, Canada; Hélène Marcoux, , , ; Vanessa Stretch, University of Guelph, Guelph, ON, Canada

Published Material: This paper brings together the work of several graduate students that were previously presented individually at meetings of the ESA, AAG, and CAG.

Abstract Body: Wildfire is the most important disturbance agent in forests of Western Canada, affecting stand structure and composition, biodiversity, biogeochemical cycling, hydrologic processes, and natural resource extraction. Despite considerable research, consensus on the frequency and severity of historical fire occurrence has been elusive in much of the Canadian Cordillera. Much of this uncertainty derives from methodological limitations. One area of particular contention has focused on the degree to which surface versus crown fires were historically important; a second relates to how disproportionately effective suppression of surface fires may have homogenized the landscape and altered the modern and future fire regimes. We have endeavored to overcome these uncertainties by employing a multiproxy approach to reconstructing fire history, and by using randomized site and sample selection. Drawing from a network of fire scar and tree cohort samples throughout western Canada we show that mixed severity fire was historically more frequent. We further show that in some forests the fire season has shifted significantly, and forests have become more homogenous. These findings have import ant implications for land management strategies that aim to restore historical conditions, or aim to mimic the natural disturbance regime.

Title: Using a multi-proxy approach in fire history studies: Some advantages and challenges from Jasper National Park

Presenter/First Author: Emma Davis, University of Guelph, Guelph, ON

Presenter/First Author Email: edavis02@uoguelph.ca

Co-authors: Michael FJ Pisaric, Brock University, St Catharines, ON, Canada; Colin J Courtney Mustaphi, , Ottawa, ON, Canada; Jesse C Vermaire, Carleton University, Ottawa, ON, Canada; Katrina Moser, , London, ON, Canada

Published Material: The results presented here have been presented in various forms at other academic conferences -AAG 2014 - Tampa, FloridaCAG 2014 - Brock University, Ontario, Canada PALS 2014 - Québec City, Québec, Canada

Abstract Body: Using a multi-proxy approach is an effective strategy for studying processes operating on multiple temporal and spatial scales such as those controlling wildfires. The research presented here uses a recently completed fire history study from Jasper National Park that incorporates lake sediment and tree ring records to exemplify some of the advantages and challenges of using a multi-proxy approach to develop and interpret fire history records.

A 3,600-year record of fire events and vegetation change was established for the area surrounding Little Trefoil Lake, Jasper, AB, using a combination of lake sediment analysis (macroscopic charcoal and pollen analyses) and fire scar and cohort establishment dates from tree-ring data. Combining macroscopic charcoal and tree-ring fire evidence enabled a thorough characterization of the local fire history that addressed aspects of both frequency and severity. Moreover, high-severity fires recorded in the tree-ring record were used to calibrate the sedimentation rates for Little Trefoil Lake and provided support for the interpretation of peaks in charcoal

accumulation as being representative of local fire events. Through a pollen analysis performed on the same sediment core, the relationship between vegetation composition and the local fire history was assessed and determined to be of secondary importance to climatic and human influences. Although integrating proxy records representative of different spatial and temporal scales is challenging, using multiple lines of evidence to understand the processes controlling fire activity inspires a greater level of confidence in the interpretation of the results.

Title: Understanding Historic Wildfire Dynamics in Jasper National Park Using Fire-Scar Dendroecology

Presenter/First Author: Theresa Dinh, University of Guelph, Guelph, ON

Presenter/First Author Email: tdinh@uoguelph.ca

Co-authors: Ze'ev Gedalof, University of Guelph, Guelph, ON, Canada; Lori Daniels, University of British Columbia, Vancouver, BC, Canada

Abstract Body: A fire-scar based dendroecological reconstruction of wildfire history was used to detect the influence of climatic variability and land-use change on wildfire dynamics in the lodgepole pine (*Pinus contorta* var. *latifolia* Engelm.) forests of Jasper National Park in the Canadian Rocky Mountains. New original analyses were performed on 170 cross-section samples collected in the 1970s from 52 fire history sites from around Jasper, Alberta. The updated fire record reveals that fire occurrence was highly variable such that mean fire return intervals ranged from 4.9 to 52.5 years. Most fires were small and locally occurring. These fires occurred under a wide range of climatic conditions; although the largest and most widespread fires (n=18, events occurring across at least 10% of sites) were primarily driven by dry and warm climate conditions (e.g. El Niño years). Large regional fires burned across almost all sites, although some remnant patches (i.e. sites) remained unburned thus providing evidence for a historically mixed-severity fire regime. Fire activity (i.e. fire size and frequency) decreased through time with fire exclusion becoming widespread during the 1950s. Along with less fire activity on the landscape, there were also shifts in fire seasonality from early human-ignited "spring burns" to more natural lightning-ignited "summer" fires. To be consistent with historic patterns, large-scale restoration via prescribed burning should be scheduled to promote a frequent, patchy, and mixed-severity wildfire regime.

Title: Historical Wildfire Variability in the Foothills of Alberta: A Dendropyrochronological Case Study

Presenter/First Author: Vanessa Stretch, University of Guelph, Guelph, ON

Presenter/First Author Email: vstretch@uoguelph.ca

Co-authors: Ze'ev Gedalof, University of Guelph, Guelph, ON, Canada; Lori Daniels, University of British Columbia, Vancouver, BC, Canada

Abstract Body: Using dendropyrochronological proxy methods, we reconstructed ~200 years of wildfire variability in the eastern foothills of the Rocky Mountains near Hinton, Alberta, Canada – an area where little fire research has been conducted but is currently at high risk of fire and is intensively managed. We combined fire scar (a low-severity fire proxy) and stand establishment records (high-severity proxy) to reconstruct the mixed-severity nature of fire history in this landscape. The record of wildfire shows no evidence of landscape-scale fire events over the last ~150 years. Instead, we found evidence of increased low-severity fire activity in the early 1900s that is not explained by climate alone. Overall, our research shows the foothills experienced variability in fire severity over both time and space. We have found evidence for intricate connections between the complex landscape characteristics (bottom-up controls) and climate trends that drive wildfire activity in this unique and understudied landscape.

Title: Nutrient Addition Leads to Higher Methane Emissions in a Boreal Bog in Response to Changes in Vegetation and Microtopography

Presenter/First Author: Jill L Bubier, Mount Holyoke College, South Hadley, MA

Presenter/First Author Email: jbubier@mtholyoke.edu

Co-authors: Tim R Moore, McGill Univ, Montreal, QC, Canada; Veronica DeJesus, , ,

Abstract Body: Atmospheric nitrogen (N) deposition has led to nutrient enrichment in wetlands globally, affecting plant community composition, carbon cycling, and microbial dynamics. Nutrient-limited boreal bogs are long-term sinks of carbon dioxide (CO_2), but sources of methane (CH_4), an important greenhouse gas. We hypothesized that CH_4 emissions would increase in response to nutrient addition owing to changes in vegetation and microtopography. We fertilized Mer Bleue Bog, a *Sphagnum* moss and shrub-dominated ombrotrophic bog near Ottawa, Ontario, for 10-15 years with N as NO_3 and NH_4 at 5, 10 and 20 times ambient N deposition (0.6-0.8 g N m^{-2} y^{-1}), with and without phosphorus (P) and potassium (K). Treatments were applied to triplicate plots (3 x 3 m) from May – August 2000-2014 and control plots received distilled water. We measured methane (CH_4) flux with static chambers from early June until the end of July 2014. Depth to water table and as well as peat/air temperature were measured concurrently with CH_4 sampling. Seasonal mean methane flux ranged from 7 to 150 mg CH_4 m^{-2} d^{-1} with emissions from the 5NPK and 20NPK treatments 3 and 11 times higher than controls, respectively. Water table position was closer to the peat surface in these treated plots owing to loss of *Sphagnum* moss and compression of the peat. Laboratory incubations of peat samples showed that the rates of potential methane production under anaerobic conditions in samples from 30 – 40 cm were three times larger under the 5NPK and 20NPK treatments than the controls. Potential rates of methane consumption under aerobic conditions showed no significant differences among fertilizer treatments nor between 0-10 and 30-40 cm depths. These results suggest that increased methane emissions are the result of a complex suite of feedbacks among vegetation change, microbial dynamics and hydrology in response to nutrient addition.

Title: Mycorrhizal Networks Inhibit Decomposition in Boreal Bogs

Presenter/First Author: Nathan R Thorp, , Villanova, PA

Presenter/First Author Email: nthorp@villanova.edu

Co-authors: Melanie A Vile, Villanova University, Villanova, PA; R. Kelman Wieder, , ,

Published Material: I gave an oral presentation at MassMyco, a mycology meeting for New England fall 2014.

Abstract Body: Nitrogen (N) deposition has resulted in the loss of mycorrhizal fungi from diverse sites around the globe. Mycorrhizal fungi are symbiotic organisms that associate with the roots of the majority of plants, providing nutrients in exchange for host plant photosynthates. N enrichment inhibits mycorrhiza formation in plants associating with fungi specialized in N acquisition, leading to a decline of the symbiosis. I hypothesized that the inhibition of mycorrhizal networks will allow saprotrophic fungi to degrade carbon (C) more freely in ombrotrophic peatlands. With ample supplies of C provided directly by host plants, mycorrhizal fungi do not need to break down complex C substrates and instead, they focus their scavenging efforts on obtaining essential nutrients. In order to assess potential repercussions of mycorrhizal decline due to N deposition, I experimentally excluded the networks of mycorrhizal fungi while simultaneously fertilizing with ammonium nitrate. This manipulative experiment was conducted in two bogs in Alberta Canada, one mature and the other recently burned. Mycorrhizal colonization responses to N fertilization and peat litter decomposition responses to mycorrhizal network exclusion were assessed *in-situ* for *Picea mariana* seedlings growing in native *Sphagnum* peat. My results agreed with the hypothesis of N-induced reductions in mycorrhizal colonization diversity. Morphotype density (number of different mycorrhizal phenotypes per tree) was reduced ($p < 0.0001$) at the highest N addition level (20 kg N ha^{-1} yr^{-1}). Mycorrhizal network exclusion resulted in 1% higher litter decomposition in the recently burned bog over two years. This research illustrates the importance of mycorrhizal symbiosis in boreal bog *Picea mariana* N acquisition and peatland C sequestration.

Title: *Sphagnum* moss enzymatic activities indicate nitrogen and phosphorus co-limitation in a pristine boreal bog and poor fen

Presenter/First Author: Natalie N Kashi, Villanova University, Villanova, PA

Presenter/First Author Email: natalie.kashi@gmail.com

Co-authors: R. Kelman Wieder, Villanova University, Villanova, PA

Published Material: A portion of this research has been presented at AGU December 2013. Not yet submitted to a journal.

Abstract Body: Emissions of NO_x associated with Alberta oil sands development are leading to increased atmospheric nitrogen deposition in a pristine region (<1kg N ha^{-1} yr^{-1}). Excess anthropogenic nitrogen deposition has the potential to alter ecosystem function, which can be manifested by changes in plant and microbial enzymatic activities. Since 2011, we experimentally added nitrogen in simulated precipitation to an Alberta bog and poor fen in order to predict future peatland ecosystem responses under high nitrogen deposition scenarios. We assessed the potential alleviation of nitrogen limitation with the addition of up to 25 kg N ha^{-1} yr^{-1} in a pristine bog and poor fen. After three years of nitrogen addition, phosphorus and nitrogen mineralization enzymatic activities of *Sphagnum angustifolium*, *Sphagnum* fuscum, and *Sphagnum magellanicum* were quantified using methylumbelliferone fluorescent detection. *Sphagnum* moss enzymatic responses to nitrogen addition were assessed with regards to season, species, and peatland type (poor fen or bog). Phosphatase activities increased from the control to the 25 kg N ha^{-1} yr^{-1} up to five-folds in all three species and in both peatlands. Chitinase activity also increased with nitrogen addition for *Sphagnum magellanicum* in the poor fen but not the bog. Increasing enzymatic activities suggest nitrogen and phosphorus co-limitation and nutrient limitations unique to specific *Sphagnum* species in bogs and poor fens. This sensitivity to increasing nitrogen addition indicates potential consequences for peatland nutrient cycling in the oil sands development area.

Title: Nutrient availability in the Mer Bleue bog as indicated by Plant Root Simulator probes

Presenter/First Author: Meng Wang, , Montreal, QC

Presenter/First Author Email: meng.wang3@mail.mcgill.ca

Co-authors: Tim R Moore, McGill Univ, Montreal, QC, Canada; Julie Talbot, University of Montreal, Montreal, QC, Canada

Abstract Body: There are a variety of methods employed to assess nutrient availability from soils, such as total analyses, differential extractions, laboratory incubations and pore-water analyses. The adsorption of nutrient cations and anions onto exchange resins placed in the soil provides an alternative approach. We used Plant Root Simulators (PRS™) at the Mer Bleue bog to provide some baseline data on nutrient availability and its variability. In particular, we focused on ammonium, nitrate, phosphate, calcium, magnesium and potassium, expressed as µg/cm^2/week. We placed PRS probes at a depth of 5 – 15 cm in the bog for 4 weeks and determined the availability of these nutrients, from spring through to fall. Probes were also placed beneath the water table in hummock and hollow and along a transect including part of the bog which had been drained through the creation of a ditch 80 years ago. Probes were placed in the long term N (P+K) fertilization experiment. The result showed the paucity of available ammonium, nitrate and phosphate in the bog, a seasonal pattern associated with rates of mineralization driven by temperature, an increase in the availability of some nutrients as a result of drainage, and the relative availability of nutrients compared to the input from fertilization. We suggest that careful placement of the probes (e.g. exposure period, depth relative to water table etc.) may provide valuable information on variations in nutrient availability within and among wetlands.

Title: Effect of Urban Developments on the Lake Simcoe Water Resources

Presenter/First Author: Stephen Kayode Oni, SLU Swedish University of Agricultural Sciences Uppsala, Uppsala,

Presenter/First Author Email: stephen.oni@slu.se

Co-authors: Martyn N Futter, Swedish University of Agricultural Science, Uppsala, Sweden; James M Buttle, Trent University, Peterborough, ON, Canada; Peter Dillon, Trent University, Peterborough, ON, Canada

Published Material: Hydrological Footprints of Urban Developments in the Lake Simcoe Watersheds, Canada: a combined paired-catchment and change detection approach. Hydrological Processes, doi: 10.1002/hyp.10290

Abstract Body: Urban sprawl and regional climate variability are major stresses on surface water resources in many places. The Lake Simcoe watershed (LSW) Ontario, Canada, is no exception. The LSW is predominantly agricultural but is experiencing rapid population growth due to its proximity to the greater Toronto area. This has led to extensive land use changes which have impacted its water resources and altered runoff patterns in some rivers draining to the lake. Here, we use a paired-catchment approach, hydrological change detection modelling and remote sensing analysis of satellite images to evaluate the impacts of land use change on the hydrology of the LSW (1994 to 2008). Results show that urbanization increased up to 16% in Lovers Creek, the most-urban impacted catchment. Annual runoff from Lovers Creek increased from 239 to 442 mm/yr in contrast to the reference catchment (Black River at Washago) where runoff was relatively stable with an annual mean of 474 mm/yr. Increased annual runoff from Lovers Creek was not accompanied by an increase in annual precipitation. Discriminant function analysis suggests that early (1992-1997; pre-major development) and late (2004-2009; fully urbanized) periods for Lovers Creek separated mainly based on model parameter sets related to runoff flashiness and evapotranspiration. As a result, parameterization in either period cannot be used interchangeably to produce credible runoff simulations in Lovers Creek due to greater scatter between the parameters in canonical space. Separation of early and late period parameter sets for the reference catchment was based on climate and snowmelt related processes. This suggests that regional climatic variability could be influencing hydrologic change in the reference catchment, whereas urbanization amplified the regional natural hydrologic changes in urbanizing catchments of the LSW.

Title: Temperature controls inter-annual variability of summer methane emission from polygonal tundra in the Lena River Delta, Siberia

Presenter/First Author: Lars Kutzbach, University of Hamburg, Hamburg,

Presenter/First Author Email: lars.kutzbach@uni-hamburg.de

Co-authors: Christian Wille, Universität Hamburg, Hamburg, Germany; Torsten Sachs, Deutsches GeoForschungsZentrum GFZ, Potsdam, Germany; Benjamin Runkle, University of Arkansas, Fayetteville, AR; Peter Schreiber, Universität Hamburg, Hamburg, Germany; Christian Knoblauch, University of Hamburg, Hamburg, Germany; Eva-Maria Pfeiffer, , ,

Published Material: We plan to present our analysis of the multi-annual CH4 flux data set from the Siberian Lena River Delta also at the General Assembly 2015 of the European Geosciences Union (12 – 17 April 2015, abstract submitted).

Abstract Body: Methane (CH_4) emissions from northern wetlands are thought to be at least partly responsible for the observed recent rise in the growth rate of atmospheric CH_4 concentrations. The suggested causal relationship between northern wetland CH_4 fluxes and atmospheric CH_4 concentrations is so far only substantiated by indirect evidence, e.g. by space-for-time approaches using compilations of chamber flux measurements across different climates or by outcome of deterministic CH_4 process models. However, empirical data covering the inter-annual variability of CH_4 emissions are still rare. Here we present multi-annual CH_4 flux data from the Lena River Delta in the Siberian Arctic (72°N, 126°E). The study site is characterized by polygonal wet tundra and a vegetation dominated by mosses and sedges. Seasonal eddy covariance CH_4 flux measurements were conducted during the period 2002-2014. CH_4 flux data overlap during 25 days (28 July - 21 August) for 9 years. Median CH_4 fluxes during the overlap periods of the 9 years ranged between 36 and 64 µmol m^{-2} h^{-1} and were found to be positively linearly correlated to the date of thaw ($r^2 = 0.57$, $p < 0.05$) and soil temperature at 10 cm depth ($r^2 = 0.66$, $p < 0.01$) in wet polygon centers. These results are in line with plot-scale measurements and stable isotope signatures of emitted CH_4, which indicate that (i) wet polygon centers contribute most to landscape-scale CH_4 emissions and (ii) the bulk CH_4 emitted from vegetated polygon centers is not significantly modified by CH_4 oxidation during soil-atmosphere transport. Together, these findings suggest that a warmer climate and longer thaw periods stimulate the production of CH_4, which is directly reflected in increased CH_4 emissions. On the other hand, warming effects on CH_4 oxidation appear limited because transport processes that bypass the soil oxidation zone, i.e. plant-mediated transport and ebullition, dominate CH_4 emission from wet polygonal tundra.

Title: Carbon and energy fluxes from a spatially heterogeneous permafrost peatland

Presenter/First Author: Silvie R Harder, McGill University, Montreal,

Presenter/First Author Email: silvie.harder@mail.mcgill.ca

Co-authors: Nigel T Roulet, McGill University, Montreal, QC, Canada; Ian B Strachan, McGill University, Montreal, QC, Canada; Patrick M Crill, Stockholm University, Stockholm, Sweden; Luc Pelletier, McGill University, Montreal, QC, Canada

Abstract Body: Various microforms, created by spatially differential thawing of permafrost, make up the subarctic heterogeneous Stordalen peatland (68°22'N, 19°03'E), near Abisko, Sweden. This results in significantly different peatland vegetation communities across short distances, as well as differences in wetness, peat temperatures, snow distribution and therefore carbon and energy fluxes. In recent decades, the permafrost extent of Stordalen has been markedly shrinking with warming air temperatures as well as differential snow distribution. When snow accumulates along the margins of the permafrost peat plateaus and palsas, the increased insulation maintains warmer ground temperatures as compared to the tops of the peat plateaus and palsas where the snow is blown clear. This insulation can advance permafrost thaw, leading to changes in vegetation communities and local hydrology as well as impacts to both the energy and carbon balances at this peatland.

Since 2012, we have been measuring the spatially integrated CO_2, energy and water vapour fluxes from this peatland complex using eddy covariance (EC). We have also been examining the CO_2 exchange from specific plant communities within the EC tower footprint (autochambers). LIDAR was used to produce a 1 m resolution digital evaluation model of the complex and the spatial distribution of plant functional types (PFTs) across the peatland was obtained from concurrent high-resolution digital colour air photography trained from vegetation surveys. The EC footprint is calculated for every half-hour and PFT based models are run with the corresponding environmental variables. These models calculate light use efficiency as well as ecosystem respiration for the different PFTs.

Our results show that the Sphagnum, palsa, and sedge PFTs have distinctly different light use efficiency models, and that the tower fluxes are dominated by a blend of the Sphagnum and palsa PFTs. We also see a distinctly different energy partitioning between the fetches containing intact permafrost and those where the permafrost has thawed: the evaporative efficiency is higher and the Bowen ration lower for the thawed fetches.

Title: Critical Changes to Peatland Carbon Biogeochemistry Following Permafrost Thaw

Presenter/First Author: Avni Malhotra, McGill University, Montreal, QC

Presenter/First Author Email: avni.malhotra@mail.mcgill.ca

Co-authors: Nigel T Roulet, McGill University, Montreal, QC, Canada; Tim R Moore, McGill Univ, Montreal, QC, Canada

Published Material: A small subset of the proposed presentation is from a manuscript that has been submitted and is currently under review. Data from this manuscript was also presented at the following conferences:

AGU fall meeting 2014 and EUCOP 2014.Majority of the presentation material is new and based on another manuscript that is currently in preparation for submission. The proposed presentation will synthesize and build upon the 2 aforementioned manuscripts, drawing big-picture conclusions on biogeochemical changes in peatlands following permafrost.

Abstract Body: Permafrost peatlands contain significant stores of soil carbon (C) and the fate of this C is uncertain in light of the warming north. With ongoing and projected degradation of permafrost, release of permafrost C is considered a highly likely positive feedback to climate change. To quantify the magnitude of C loss following permafrost thaw in peatlands, several studies have investigated changes in ecosystem structure (vegetation and hydrology) and associated function (C cycling). Based on current literature, we developed a conceptual framework to summarize key changes in structure and function after thaw. Subsequently, we tested hypotheses generated from this conceptual framework, along a wide range of permafrost thaw conditions. Data will be presented on the abiotic and biotic correlates of litter decomposition as well as carbon dioxide and methane fluxes in a thawing landscape. Our results suggest that the dominant controls on C cycling vary significantly, depending on the degree of permafrost thaw. Across the thaw gradient, indirect pathways (change in vegetation due to change in moisture and temperature) have a more pronounced effect on litter decomposition rates than direct pathways (change in temperature and moisture). We will present a revised conceptual framework of peatland C biogeochemistry following permafrost thaw and propose landscape level integrator variables of C function for these spatially heterogeneous landscapes.

Title: Dissolved Organic Carbon Concentration Affected by Warming and Water Table Lowering in a Boreal Continental Bog

Presenter/First Author: Tariq M Munir, Saint Mary's University, Calgary, AB

Presenter/First Author Email: tmmunir@ucalgary.ca

Co-authors: Bhupesh Khadka, University of Calgary, Calgary, AB, Canada; Maria Strack, University of Calgary, Calgary, AB, Canada

Abstract Body: Mid-latitude peatlands have accumulated significant carbon (C) stocks as a result of their persistent C sink function. The large C stocks are predicted to respond to global climate changes with increased C losses from these ecosystems. An increase in air and soil temperature and subsequent lowering of water level in bogs may elevate dissolved organic carbon (DOC) concentration in the pore water and can add to the ecosystem C losses in the forms of peat respiration and hydrologic export. During the growing seasons (May to October) of 2012 and 2013, we compared pore water DOC concentration across hummock-hollow microtopography among three sites situated in a continental boreal treed bog located near the town of Wandering River, Alberta. The three sites were; control, recent (2-3 years; experimental) and older drained (12-13 years; drained) with water levels on average at 38, 74 and 120 cm below peat surface, respectively. Pore water DOC concentration was significantly different among the sites with the highest at the drained site (111 mg l^{-1}) followed by 95 mg l^{-1} at the experimental and the lowest at the control site (81 mg l^{-1}). A peat surface warming of ~ 1°C significantly increased DOC concentration and interacted with microform to result in highest concentration at the drained warmed hummocks. Therefore, we conclude that warming and water table lowering may influence the concentration and chemistry of pore water DOC and feedback to carbon biogeochemical cycling both within the peatland and downstream ecosystems.

Title: Biogeochemical iron cycling in subalpine wetlands: Kinetics and impact on organic carbon transport

Presenter/First Author: Céline E Pallud, University of California Berkeley, Berkeley, CA

Presenter/First Author Email: cpallud@berkeley.edu

Co-authors: Kathrin Schilling, University of California Berkeley, Berkeley, CA; Linden Schneider, , , ; Thomas Borch, Colorado State University, Fort Collins; Charles Rhoades, US Forest Service, Fort Collins, CO

Published Material: Some preliminary data were presented at the 2014 SSSA meeting in Long Beach (Nov. 2014)

Abstract Body: Located at the interface between terrestrial and aquatic ecosystems, wetlands are key biogeochemical hotspots. The intersection of hydrologic flow paths and organic-rich, anoxic substrates create a unique array of conditions where the biogeochemical cycling of carbon (C) and nutrients differ from the surrounding ecosystems. In these environments, transformation and movement of C and iron (Fe) are closely linked. We investigated how contrasting hydrologic conditions and varying temperature influence microbial Fe(III) reduction kinetics and its consequences on the mobilization/retention of organic C in subalpine wetlands.

Within the USDA Fraser Experimental Forest in Colorado (USA), we studied a depressional wetland that provides a hydrologic gradient from constantly waterlogged soils to soils undergoing typical wetting/drying cycles. The effect of temperature on potential rates of Fe(III) reduction and dissolved organic carbon (DOC) release, as well as on the kinetics of Fe(III) reduction (maximum reaction rate, R_{max}, and affinity constant, K_m) were obtained using flow-through reactor experiments run at three temperatures (6, 12 and 18°C) mimicking field conditions.

We showed that Fe(III) reduction is a temperature sensitive and hydrology dependent process in subalpine wetland soils. R_{max} values ranged from 55.6 to 449.4 nmol cm^3 h^{-1}, with the highest values observed for the highest temperatures (Q_{10} of 1.1-2.6), the waterlogged sites, and the more C-rich shallower soil depths. K_m values ranged from 0.3 to 3.7 mM and indicated a higher affinity for Fe(III) at ~12°C, which corresponds to the yearly average field temperature. In addition, our results showed a positive correlation between rates of Fe(III) reduction and of DOC release. Such findings suggest that there is a local adaptation of microbial kinetics to temperature and that soil warming could lead to decreasing water quality in subalpine wetlands, as a result of increased Fe(III) reduction-mediated DOC release.

Title: Implications of land management practices for greenhouse gas fluxes from tropical peatland oil palm plantations

Presenter/First Author: Yit Arn Teh, University of Aberdeen, Dundee,

Presenter/First Author Email: yateh@abdn.ac.uk

Co-authors: Frances Manning, University of Aberdeen, Dundee, United Kingdom; Norliyana binti Haji Zin Zawawi, University of Aberdeen, Dundee, United Kingdom; Timothy Hill, University of St Andrews, St Andrews, United Kingdom; Melanie Chocholek, , , ; Lip Khoon Kho, , ,

Published Material: Some of these findings will also be reported at the European Geosciences Union General Assembly meeting in April 2015.

Abstract Body: Tropical peatlands are one the largest terrestrial reserves of C and are experiencing some of the most rapid rates of land-use change globally. Conversion of tropical peatlands to oil palm are one of the dominant forms of land-use change in the Southeast Asian tropics, with potentially significant implications for regional and global atmospheric budgets of biogenic trace gases. Here we report preliminary findings from a long-term, multi-scale project in Sarawak, Malaysian Borneo that aims to evaluate the impacts of oil palm conversion on ecosystem greenhouse gas budgets, and investigate how alternate management practices could mitigate the negative environmental impacts of land-use change. Flux chamber measurements indicate that soil CO_2, CH_4 and N_2O fluxes averaged 20.0 ± 16.0 Mg CO_2-C ha^{-1} yr^{-1}, 37.4 ± 29.9 kg CH_4-C ha^{-1} yr^{-1} and 4.7 ± 4.2 g N_2O-N ha^{-1} yr^{-1}, respectively. Fluxes of soil CO_2 and N_2O were spatially stratified, and linked to the distribution of palms, harvest residues and soil moisture. Soil CO_2 fluxes were most strongly influenced by the distribution of palms. On average, autotrophic respiration accounted for approximately 78 % of total soil CO_2 flux, and total soil respiration declined steeply away from palms; e.g. soil respiration in the immediate 1 m radius around palms were up to 6 times greater than fluxes in inter-palm spaces. Harvest residue placement also played an important role in modulating soil CO_2 fluxes; soil respiration rates doubled in areas where harvest residues were deposited, reflecting an enhanced input of labile organic matter for decomposition. In contrast, N_2O fluxes were best-predicted by the distribution of harvest residues, and were only weakly related to plant distributions or soil moisture. N_2O fluxes from harvest residue piles were up to twice of the overall plot-average, suggesting that N_2O fluxes were at least partially constrained by the availability of labile substrates for denitrification. In contrast, N_2O fluxes showed no clear pattern around palms; this is surprising because N fertilizers are applied near palm stems, and we predicted that N_2O fluxes would be greatest in areas of high fertilizer input. This suggests that palms may be a strong competitor for inorganic N in these ecosystems, and that fertilizer application may closely match overall plant demand.

Title: Fourteen Year Carbon Balance For A Raised Temperate Bog

Presenter/First Author: Nigel T Roulet, McGill University, Montreal, QC

Presenter/First Author Email: nigel.roulet@mcgill.ca

Co-authors: Elyn Humphreys, Carleton University, Ottawa, ON, Canada; Peter Lafleur, Trent University, Peterborough, ON, Canada; Tim R Moore, McGill Univ, Montreal, QC, Canada

Abstract Body: Continuous eddy flux measurements of water, energy and CO_2, and the export of dissolved organic carbon (DOC) have been made since May 1, 1998 on a raised, ombrogenic, oligotrophic, shrub and *Sphagnum* covered bog, the Mer Bleue peatland, near Ottawa, Ontario, Canada. Measurements of the CH_4 flux have also been made from 1998 to the present time using a combination of manual and automated chambers, and eddy covariance. In 2007 we published a six-year (1999-2006) net ecosystem carbon balance (NECB) for Mer Bleue of ~20 ± 40 g C m^{-2} yr^{-1}. The average NEE was ~40 g C m^{-2} yr^{-1} over this period and the net loss of C via the CH_4 and DOC fluxes were 4 and 15 g C m^{-2} yr^{-1}, respectively. The six-year average NECB was remarkably similar to the long-term C accumulation rate, estimated from peat cores, for the last 3,000 years. The post 2006 NEE at Mer Bleue has increased to an average of ~60 g C m^{-2} yr^{-1}. The loss of C via DOC and CH_4, while showing considerable year-to-year variable, has not been significantly different post 2006 than it was in the first six years. Hence, the proportional loss of C as CH_4 and DOC was slightly less post 2006 than it was before 2006. As a result the NECB has increased to ~ 80 g C m^{-2} yr^{-1} post 2006 yielding a 14 year contemporary NECB that is ~50% greater than the long-term accumulation rate of C.

Title: Distinctive Patterns of Carbon and Nitrogen Fractions in a Deforested and Converted Tropical Peat Dome

Presenter/First Author: Gusti Z Anshari, , Pontianak,

Presenter/First Author Email: gzanshari@live.untan.ac.id

Co-authors: Evi Gusmayanti, , , ; M Afifudin, , ,

Abstract Body: A deforested, drained and converted peat is recently common in Indonesia. This study aims at assessing patterns of Carbon and Nitrogen densities in disturbed peat dome in the equatorial Borneo of West Kalimantan Province, Indonesia. We investigated 160 peat cores samples from community oil palm (LU1); open peat dominated by ferns (LU2); and degraded forest (LU3). Research variables include Carbon, Nitrogen, bulk density, C:N ratio, and Carbon and Nitrogen densities. We categorized the samples into upper depth section (D1 = 0-50 cm); mid section (D2=50-100 cm); and bottom section (D3>100 cm). All data do not have normal distribution and unequal variances. We employed traditional single factor and Brown Forsythe Anovas prior to Welch-t comparisons. Carbon concentration distinctively decreases in the upper depth section and in oil palm. Nitrogen concentration substantially increases in the upper depth section but is lower in oil palm (*Elaeis guineensis*) than in open peats and degraded forest. C:N ratio is substantially lower in the upper depth section than in mid and bottom sections, and is slightly higher in oil palm than in other two land uses. Due to anthropogenic influence, bulk density is high in the upper depth section and in oil palm, leading to an increase of bulk, Carbon and Nitrogen densities. Results of statistical analyses indicate non-significant difference on Carbon fraction according to these depth clusters, and land uses, and significant difference on Nitrogen concentration according to depth sections only. Decline of C:N ratio in surface peats suggests rapid peat decomposition. A high C:N ratio in oil palm due to loss of Nitrogen and rapid absorption by this plant. High bulk density leads to an increase of Nitrogen availability, which enhances the breakdown of selected organic matters. We assume Carbon stock in this peat is unstable.

Title: Simulating long-term carbon dynamics in disturbed and restored peatlands

Presenter/First Author: Anne Quillet, McGill University, Montréal, QC

Presenter/First Author Email: anne.quillet@gmail.com

Co-authors: Nigel T Roulet, McGill University, Montreal, QC, Canada; Jianghua Wu, Memorial University of Newfoundland, Corner Brook, NF, Canada

Abstract Body: Around 25% of the global peatlands have been exploited either for agricultural purposes, forestry, peat extraction or infrastructure development (Parish et al. 2008). Exploitation of peatlands is still on-going. Modelling current and future carbon exchanges in peatlands thus requires further understanding of carbon dynamics in drained, exploited and restored peatlands.

This projects aims at quantifying the carbon balance in disturbed and restored peatlands. Since no long-term (i.e. > 15 years) datasets are available, the chosen approach is the development of a new model. The

developed model, suitable for disturbed and restored peatlands, is based on the millennial scale Holocene Peat Model (Frolking et al. 2010) and the centennial scale McGill Wetland Model (Wu et al. 2012), which simulates carbon fluxes (i.e. CO_2, CH_4 and DOC).

This new model simulating peatland dynamics in restored peatlands accounts for peat mining and the specific vegetation succession occurring during the restoration process. It includes a new representation of vegetation dynamics and interactions between vegetation and ecohydrology. Simulation results give an estimate of the amount of carbon accumulated in the peatland prior to its exploitation as well as the carbon loss during exploitation. This model allows the estimation of current and future carbon fluxes associated with various scenarios of restoration.

Title: Testing model assumptions in the field: peatland carbon cycling, vegetation, and water table depth

Presenter/First Author: Ellie Goud, Cornell University, Ithaca, NY

Presenter/First Author Email: emg244@cornell.edu

Co-authors: Tim R Moore, McGill Univ, Montreal, QC, Canada; Nigel T Roulet, McGill University, Montreal, QC, Canada

Abstract Body: Peatland biogeochemical models represent vegetation as plant functional types (PFTs), and carbon fluxes are calculated for each PFT as a unimodal function of water table depth. However, field data has rarely supported such unimodal relationships. Moreover, models assume single PFTs but field studies typically measure vegetation that contains a mixture of PFTs. It is uncertain whether it's reasonable to characterize a vegetation group by its dominant PFT. In order to test these assumptions, we measured species abundance and CO_2 exchange in 27 sites from May – September in 2012 and 2013 along a gradient from ombrotrophic bog to beaver pond. Plant species and PFTs fell into six vegetation groups: hummock, hollow, bog moss, bog margin, pond moss and pond margin. For each vegetation group we found unimodal relationships between weekly water table depth and gross ecosystem photosynthesis (GEP). The water table optima and range that we found for each group generally corresponded to values previously reported for that group's dominant PFT, implying that peatland vegetation groups can usually be characterized by their dominant PFT. We also found unimodal relationships between species abundance and annual water table depth. We compared the water table range from species abundance curves to the water table range of the corresponding GEP curves. For hollow, bog moss and bog margin groups, the abundance and GEP ranges were statistically indistinguishable, implying that environmental factors are the dominant controls on species abundance and carbon exchange for these vegetation groups. For hummock, pond moss and pond margin the abundance and GEP ranges were significantly different, implying that biotic factors such as physiological tradeoffs and competitive interactions are more dominant in these vegetation groups. Overall, our work helps to bridge the gap between model assumptions and field studies.

Title: Unlocking the Power of Many – Why Inter-Catchment Comparisons Can Advance Our Understanding of Forest Hydrological Resilience to Climate Warming

Presenter/First Author: Irena F Creed, University of Western Ontario, London, ON

Presenter/First Author Email: icreed@uwo.ca

Co-authors: Taehee Hwang, National Yunlin University, Touliu Yulin, Taiwan; Chris Brimacombe, , ,

Published Material: About 10% of the results were presented at the Fall AGU in 2011.

Abstract Body: A predictive understanding of forest hydrological resilience in the face of climate change is important because substantial changes to historical water yields place communities that depend of forest water supplies at risk. Hydrological resilience is the ability of a forested catchment to absorb change and maintain or quickly regain hydrological function. Capitalizing on investments into catchment monitoring from provincial/state and federal governments over the past 50+ years, we use novel techniques to explore the hydrological resilience of water yields in natural forested landscapes. In a recent study, we used the theoretical framework of the Budyko curve to explore the elasticity of water yields and changes in water yields related to climate warming – high elasticity indicates resilient water yields, and low elasticity indicates non-resilient water yields. In this study, we consider additional metrics of elasticity [e.g., incorporating stationary (natural, oscillating) vs. non-stationary (anthropogenic, trends) signals in water yields and exploring if catchments with more pronounced oscillations (indicating a system regularly exposed to larger amplitude and/or shorter duration cycles) are more or less vulnerable to climate change]. We then explore hydrological mechanisms (changes in the accessibility of water storages for evapotranspiration) and ecological mechanisms (changes in forest compositions, structure and function) that may contribute to forest expressions of elasticity in response to climate warming. We demonstrate the power of using long-term hydrological monitoring catchments across a range of scales – from a single watershed, to the temperate forest biome, to a range of forest biomes across North America – to "unpack" the complexity and help predict the potential hydrological resilience of catchment water yields to climate change.

Title: The role of long-term monitoring in meeting science and policy needs: Lessons from 35 years of research at the Turkey Lakes Watershed

Presenter/First Author: Kara L Webster, Canadian Forest Service, Sault Ste. Marie, ON

Presenter/First Author Email: kara.webster@nrcan.gc.ca

Co-authors: Paul W Hazlett, , , ; Ray Semkin, Environment Canada, Burlington, ON, Canada

Published Material: Some aspects included in a talk at Fall AGU 2014

Abstract Body: The Turkey Lakes Watershed (TLW) is located on the Precambrian Shield in central Ontario, Canada and has been the site of multi-discipline ecosystem research since 1979. The 10.5 km^2 watershed is within the Great Lakes - St. Lawrence forest region with an uneven-aged tolerant hardwood forest having 90% of the basal area as mature to over-mature sugar maple. Within the watershed, 4 lakes, 13 first-order catchments, hundreds of permanent sample plots have been monitored to elucidate spatio-temporal processes controlling hydrological and biogeochemical patterns. While acid rain was the initial focus of the watershed study it has proven to be an important outdoor laboratory to study many topics such as forest harvesting, climate change, carbon accounting, fate of nitrogen and calcium depletion, among others. The TLW study has proven effective due to its partnership between 3 federal departments (NRCan, EC and DFO) and provincial government (Ministry of Natural Resources and Forestry), which provide the core funding and Crown Land reserve to keep the facilities open and collect long-term

baseline data. Universities have contributed with shorter-term graduate student projects and provided additional funding for equipment and infrastructure for tremendous value-added research. Ongoing success of watershed studies such as TLW involve strengthening internal partnerships among government, university, local stakeholders and formalizing linkages with other watershed studies to ensure it can continue to address new and emerging scientific concepts and policy-driven hypotheses.

Title: Long-term Observations of the Recovery from Acid Deposition in Central Ontario

Presenter/First Author: S.a. Watmough, Trent University, Peterborough, ON

Presenter/First Author Email: swatmough@trentu.ca

Abstract Body: Long-term (mid-1970s – present) measurements of bulk deposition and stream chemistry by the Ontario Ministry of Environment have enhanced our understanding of the impacts of acid-rain and subsequent recovery in acid-sensitive forested catchments in central Ontario. In response to large emission reductions, sulphate concentrations in precipitation and streams have declined markedly over the past 40 years. However, sulphate levels in streams are also greatly affected by climate, with high acid and metal pulses occurring in stream water following summer droughts. A decrease in atmospheric nitrate deposition has occurred more recently (from mid-1990s) and although most N is retained in catchments, streams draining predominately upland catchments have exhibited a decline in nitrate concentration as well. Despite past decreases in acid deposition, chemical recovery (increase in pH) of surface waters has been less than expected, primarily due to losses of base cations from the shallow, base-poor soils. The combined influence of soil acidification and climate-mediated biogeochemical changes is causing acid deposition related issues to persist long after emission reductions have occurred.

Title: Long-term monitoring in Kejimkujik National Park Nova Scotia reveals increasing aluminium concentrations in rivers

Presenter/First Author: Shannon M Sterling, Dalhousie University, Halifax, NS

Presenter/First Author Email: shannon.sterling@dal.ca

Abstract Body: Elevated aluminum levels in rivers is known to be toxic for aquatic species, in particular *Salmo salar*; however it was only recently aluminium has been identified as a potential threat to *Salmo salar* populations in South Western Nova Scotia, Canada (SWNS) (Dennis and Clair 2012). Previously, it was thought SWNS rivers contained enough DOC to render the aluminium in rivers inactive. A key remaining question is whether aluminium levels are declining following atmospheric pollution reductions. Here we make a first assessment of long term (1980-2011) aluminium concentration trends in three watersheds located in SWNS, as measured by weekly grab samples. Our results show that total aluminium levels have significantly increased from 1980-2011 in all three sites. Estimates of ionic aluminium levels indicate that the ionic aluminum concentration frequently exceeds the threshold for the level of aquatic health determined by the European Inland Fisheries Advisory Commission (Howells et al. 1990). Data also indicates that calcium levels have yet to recover even with declining concentrations of riverine sulfate. This new knowledge that aluminium is at toxic levels and is worsening will have implications for policy on acidification mitigation in SWNS; this is an urgent issue as the local salmon population numbers currently are declining to near extirpation levels.

Title: Long term monitoring of forested catchments in Québec, Canada

Presenter/First Author: Daniel Houle, Ministère des Ressources Naturelles, Québec,

Presenter/First Author Email: daniel.houle@mffp.gouv.qc.ca

Published Material: Some data have been published in scientific papers, some are unpublished.

Abstract Body: Forested and aquatic ecosystems are submitted to important environmental changes. While acidic atmospheric deposition of sulfur has significantly increased from the sixties to the eighties and is now declining since, climate has been warming. At the same time, a steep decline in nitrate deposition is now observed in eastern North-America. Separating the effects of these large scale drivers on forest growth and surface water chemistry is not a simple task. Among the calibrated catchments in Quebec, the lake Laflamme catchment is one of the most intensively studied since 1981. Routine measurements of precipitation, throughfall, soil solution and stream chemistry as well as tree growth measurements and forest dynamics are being conducted. In addition, experiments of N addition and soil warming are taking place to assess specifics impacts of environmental changes on tree growth and soil chemistry. The long term data gathered at the site as well as the result of the ongoing experiment will be used to portray the impact of environmental changes on forested ecosystems and surface water chemistry.

Title: The Value of Long-term Gauged Watershed Experiments in Forest Hydrology: lessons from the South African Experience.

Presenter/First Author: David Findlay Scott, Jet Propulsion Laboratory, Pasadena, CA

Presenter/First Author Email: david.scott@ubc.ca

Published Material: A version of this presentation (without the specific South African reference) was presented at the IAHS Workshop HW05 held 6-8 July 2011 in Melbourne, Australia, 'Revisiting Experimental Catchment Studies in Forest Hydrology'.

Abstract Body: Much of what we know about the hydrology effect of forestry has come from gauged watershed experiments conducted over the last 80 years. These experiments have been enormously useful, but there are many critics who consider the paired-catchment experiment to be an out-dated technology. Their argument is based on many valid points: catchment experiments are costly, take a long time, do not provide a detailed understanding of the individual hydrological processes ("catchments are a black box"), are empirical and results are difficult to transfer (size or extrapolation issues). This paper argues that despite the problems there is a need for long-term watershed studies, and uses the South African experience to illustrate the case.

- Gauged watersheds are the ultimate integrators of all hydrological processes. The catchment experiments therefore

provide the definite answer to the study of changes in factors that influence the hydrology at a particular location.

- Catchment experiments are the proper setting for hydrological process studies, as the catchment provides the boundaries and limits within which process studies can be best tested and extended.
- Long term data from gauged watersheds provide a firm baseline for modelling studies, which are being used more and more, but are much more valuable if set within the bounds provided by a gauged watershed.
- As hydrological questions change, so the paired-catchment experiments can be adjusted to answer new questions.
- Long-term catchment experiments provide an historic reference which is needed now, and will be needed in the future, to investigate questions relating to changing climate, land use effects, and other questions which are yet to arise.

Title: The Role of Long-Term Observatories and Networks for Advancing the Frontiers of Science: Linking Networks and Promoting Scientific Engagement Nationally and Internationally.

Presenter/First Author: Charlotte L Roehm, National Ecological Observatory Network, Boulder, CO

Presenter/First Author Email: croehm@neoninc.org

Published Material: The generic information about NEON has been presented, however, the majority of this talk will focus on opportunities for interoperability specific to Canadian networks and scientific engagement models.

Abstract Body: In an era of 'Big Data', linking research networks and observatories through interoperability standards can provide a model for universal access to accurate scientific data and the tools needed to interpret data for informing new scientific discoveries. Building a community, developing discovery and interoperability solutions and supporting the community with tools are some approaches for addressing the increasing availability of and demand for Big Data. This talk will focus on the role of long term networks and observatories for pushing the frontiers of science. The National Ecological Observatory Network is poised to start operations in 2017 to provide a platform for collecting and freely distributing long term ecological data to enable the forecasting of the impacts of climate and land use change and invasive species on ecosystems across the United States. Opportunities for collaborating on national and international interoperability standards and for defining scientific engagement will also be discussed.

Title: Groundwater – Surface Water Interactions in Mountain Environments: Comprehending Heterogeneity

Presenter/First Author: Jeffrey M McKenzie, McGill University, Montreal, QC

Presenter/First Author Email: jeffrey.mckenzie@mcgill.ca

Co-authors: Ryan Gordon, Syracuse University, Syracuse, NY; Devin Cairns, University of Lethbridge, Lethbridge, AB, Canada; Laura Lautz, Syracuse University, Syracuse, NY; James M Byrne, University of Lethbridge, Lethbridge, AB, Canada; Bryan G Mark, OSU-Byrd Polar Rsrch Ctr, Columbus, OH

Published Material: A subset of the Cordillera Blanca research was presented at AGU. The Blanca research is in review with J. Hydro. The DEM analysis research is on the cusp of being submitted to a journal.

Abstract Body: In glaciated mountain catchments, groundwater is critical in maintaining surface water flows at mid- to high-latitudes during winter and in low-latitudes during the dry season. In these systems, groundwater-surface water interactions are difficult to characterize due to the complex and heterogeneous nature of the hydrogeology. We present results from two groundwater – surface water studies that quantify the magnitude of these interactions and attempt to understand the role of spatial heterogeneity.

At a headwater and mid-valley site in the Cordillera Blanca, Peru, tracer measurements of stream and spring discharge were combined with synoptic sampling of water isotopic and geochemical composition to quantify streamflow contributions from different groundwater reservoirs. At the headwater site, groundwater supplies approximately half of the dry-season stream discharge across a small meadow, with most originating from an adjacent alluvial fan and little (6%) from the meadow itself. At the mid-valley site, with more extensive meadows, groundwater is a large component of streamflow. Although, the most focused inflow of groundwater occurred across a moraine between two meadows (200 L/s or 18% of average discharge). Heterogeneous features, such as valley-crossing moraines and alluvial fans, demonstrate the heterogenous nature of groundwater – surface water interactions.

In the headwaters of St. Mary River Watershed in Glacier National Park, Montana, we have applied an automated geomorphometric model to a 10-m DEM in order to identify the approximate spatial distribution of geomorphic features, considered to represent the subsurface geology, and to delineate each of these features based on relative hydrostratigraphic differences (e.g. glacial depositional features, bedrock outcrops, periglacial landforms, etc.). The results further demonstrate the complexity of the underlying hydrogeologic system and how it may affect subsurface storage and residence times.

Title: Surface Water and Groundwater Controls on Local Lake Water Chemistry and Water Balance in a Boreal Esker Complex

Presenter/First Author: Maxime P Boreux, Queen's University, Kingston, ON

Presenter/First Author Email: m.boreux@queensu.ca

Co-authors: Scott F Lamoureux, Queen's University, Kingston, ON, Canada; Brian F Cumming, Queen's University, Kingston, ON, Canada

Published Material: Only early preliminary findings were reported in a poster session of the 2014 WATIF student meeting in May 2014. We now have a strong complete data set and hoping for an oral presentation

Abstract Body: Hydrological water balance and chemistry in lakes are critical to biogeochemical cycles and influence aquatic biota. Understanding the climatic controls on water balance and lake water chemistry is essential for ecosystem management and conservation,

especially in a time of rapid climate change from human activities. These controls were investigated in a set of 50 lakes located in an esker system near Timmins, Ontario. Water samples were collected in June 2013, June 2014 and August 2014 for stable isotopes of water (δ18O and δ2H), solutes, alkalinity, and dissolved organic carbon to assess how isotopic composition and water chemistry indicate variations in localized water balance between adjacent lakes.

Statistical analyses of the water from the studied lakes indicated a clear separation between two clusters of lakes based on water geochemistry along an elevation gradient: (1) recharge lakes located at higher elevations that were low in solutes and isotopically enriched, and (2) discharge lakes situated at lower elevations that were high in dissolved solutes and isotopically depleted. Differences in lake trophic status and primary production were also observed between these two groups of lakes. Precipitation-fed upland lakes had higher trophic status and dissolved organic carbon concentrations compared to lower elevation groundwater discharge systems presumably in relation to longer water residence times in upland lakes that contribute to local groundwater recharge.

Results suggest that upland recharge lakes will be more prone to evaporative drawdown and therefore more sensitive to short-term climate change and droughts, while discharge lakes will be buffered by groundwater inflow and affected by hydroclimatological changes of greater duration and persistence.

Title: Water and nutrient fluxes at the sediment-water ecotone of lakes: How important is exchange with groundwater?

Presenter/First Author: Donald O Rosenberry, USGS Central Region Office, Lakewood, CO

Presenter/First Author Email: rosenber@usgs.gov

Co-authors: Joerg Lewandowski, Leibniz-Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin, Germany; Karin Meinikmann, , , ; Gunnar Nuetzmann, Leibniz Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany

Published Material: Some of the results that will be presented have recently been accepted for publication in the journal Hydrological Processes.

Abstract Body: The stability and viability of the groundwater-surface-water ecotone depends largely on fluxes of water and nutrients across the sediment-water interface. Larger rates of groundwater discharge create a more stable environment at and near the interface. However, ecosystem viability suffers if groundwater delivers contaminants or excessive nutrient loads. A comprehensive literature survey was conducted to compile reported rates of water and nutrient exchange in lake settings. Exchange of lake water and groundwater is highly variable in space and time in nearly all lakes. Nutrient fluxes are further complicated by chemical processes that affect nitrogen differently from phosphorus (P) and depend on the redox state of the aquifer. Reported rates of flow from groundwater to lake water range from near 0 to 7.45 m/day. The median of 102 reported studies is 0.007 m/day. Reported flows from lake water to groundwater are far fewer and range from near 0 to 2.63 m/day with a median value of 0.006 m/day. Median discharge of phosphorus and nitrogen to lakes was 34.7 and 1310 $mg/m^2/year$, respectively. Uncontaminated groundwater approaching a sediment-water interface of a lake commonly contained less than 50 µg/L phosphate P. Reported phosphate-P values for nutrient-enriched groundwater ranged from 100 to 4900 µg/L. Nitrite, nitrate, and ammonium concentrations of groundwater approaching lakes were commonly less than 0.01, 10, and 0.2 mg/L, respectively, with nitrate having the greatest variance. Groundwater anthropogenically enriched with nitrogen had nitrite, nitrate, and ammonium concentrations approximately 2, 1, and 1 orders of magnitude larger, respectively. This comprehensive summary indicates that groundwater is an important influence for both the ecotone at the sediment-water interface and often the entire lake ecosystem.

Title: The Ubiquity of Artificial Sweeteners in the Aquatic Environment

Presenter/First Author: Kristen Alexandra Leal, University of Waterloo, Waterloo,

Presenter/First Author Email: kaleal@uwaterloo.ca

Co-authors: John Spoelstra, Environment Canada, Burlington, ON, Canada; Sherry L Schiff, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Artificial sweeteners have been used in food, beverage and pharmaceutical products for more than 30 years. Recent studies have documented relatively high concentrations of artificial sweeteners (e.g. acesulfame, saccharin, cyclamate and sucralose) in many aquatic environments including rivers, lakes, groundwater, and estuaries. The potential use of artificial sweeteners, especially acesulfame, as tracers of human wastewater in urban environments has been well documented since the first such study published in 2011, where acesulfame was found at all 8 urban sample sites investigated. There is currently minimal information regarding the toxicity of artificial sweeteners on aquatic organisms. As wastewater treatment plant effluents and leaky sewer systems are major sources of artificial sweeteners, it is not surprising that artificial sweeteners are being found in groundwater and surface waters in and near urban areas. However, in this study we demonstrate that even areas without municipal effluent sources have measureable concentrations of artificial sweeteners. In small agricultural and forested catchments, artificial sweeteners were found in 20 of the 25 catchments sampled. Acesulfame and saccharin were found in concentrations ranging from below detection limits to 117 ng/L and 390 ng/L, respectively, with sucralose and cyclamate less commonly found. Analysis of land use and spatial data suggest that both intensive livestock operations and septic systems are sources of different artificial sweeteners. As a consequence, artificial sweeteners were found in streams and rivers that do not have municipal wastewater effluent discharges. The presence of artificial sweeteners in these agricultural dominated watersheds may offer a new method of apportioning nitrogen and phosphorus loading in mixed-use watersheds.

Title: Surface water-groundwater interactions buffer seasonal changes in urban stream water quality

Presenter/First Author: Laura Lautz, Syracuse University, Syracuse, NY

Presenter/First Author Email: lklautz@syr.edu

Co-authors: Sarah Holderness Ledford, Syracuse University, Syracuse, NY

Published Material: Some elements of this presentation have been published in a paper in Hydrological Processes (accepted and in press) and presented at prior Geological Society of America and AGU meetings. Other elements of the presentation are new findings.

Abstract Body: Urban streams commonly suffer from degraded stream water quality and limited surface water-groundwater (SW-GW) interaction due to channel incision and straightening, armoring of the stream bed and banks, and degradation of riparian floodplains and wetlands. Reestablishing hydrologic connection between urban streams and their hyporheic and riparian zones may be effective for naturally attenuating nutrients and salts. To investigate the impact of SW-GW interactions on urban stream water quality, we observed longitudinal and seasonal changes in stream water quality in an urban stream in Syracuse, New York. The stream is heavily degraded (channelized, armored, no riparian floodplain) for the upper 4 km and then transitions to being hydrologically connected to a broad, intact riparian floodplain, with a meandering channel, geomorphically complex bedforms, and large woody debris for the most downstream 1.5 km. We collected grab samples of stream water every 2 weeks from May 2012 to June 2013 at 24 sites positioned longitudinally along the stream and in a transect of riparian groundwater wells in the downstream floodplain. We also quantified the discharge profile along the 5 km stream in August 2012 using a constant rate injection of Rhodamine WT. Results show water quality in the urban stream is heavily impacted by road salt runoff and groundwater discharge along the lower, connected reach buffers seasonal changes in chloride. Groundwater discharge dilutes high in-stream chloride concentrations in winter; but, chloride storage in the riparian flood plain elevates in-stream chloride concentrations in non-winter months. Nitrate concentrations in the degraded reach are highly variable seasonally. In summer, direct exposure to sunlight, elevated stream temperatures, and rapid primary productivity promote nitrate uptake. In winter, stream nitrate concentrations increase as nitrate uptake by biota and denitrification are at a minimum. Groundwater modeling illustrates the mechanisms of salt storage in and discharge from the riparian aquifer. In-stream nitrate injection experiments quantify seasonal changes in nitrate uptake rates in the degraded and connected stream sections. Results indicate intact riparian floodplains can regulate urban stream water quality and should be preserved or restored.

Title: Impact of Direct Nutrient Inputs via Groundwater on Near-shore Zones of Large Water Bodies: Regional Scale Approaches

Presenter/First Author: Hans Hermann Dürr, University of Waterloo, Waterloo, ON

Presenter/First Author Email: hans.durr@uwaterloo.ca

Co-authors: Nils Moosdorf, University of Hamburg, Hamburg, Germany; Philippe Van Cappellen, University of Waterloo, Waterloo, ON, Canada

Published Material: Approaches on tropical islands have been published recently by 'Grundwasser'. This makes up about 30% of the material to be presented.

Abstract Body: Direct groundwater discharge to near-shore zones of large water bodies (lakes and oceans) is a pathway for freshwater and associated dissolved nutrients. However, it is hard to quantify, especially at regional to continental scales. Some coastal ecosystems are at particular risk through eutrophication, hypoxia, or harmful algal blooms, and while local field methods or models are available, targeted research at larger scales is scarce. Here, we review available assessments of direct groundwater discharge and solute transport, using examples from large inland water bodies (here, the Laurentian Great Lakes), as well as coastal areas surrounding tropical islands. We demonstrate example approaches, reaching from the use of the ratio of coastline length to hinterland area as first-order approach to estimate the importance of direct groundwater discharge compared to rivers (Moosdorf et al. 2015), to the use of large-scale hydrological and hydrogeological models. Information on near-shore groundwater quantity and/or baseflow, combined with assessments of nutrient concentrations in groundwater bodies, can set an upper boundary for the potential contribution, and identify likely hotspots of nutrient delivery via this discharge pathway.

Title: Hydrologic controls on the fate of contaminants at the groundwater-lake interface at freshwater beaches

Presenter/First Author: Clare E Robinson, University of Western Ontario, London, ON

Presenter/First Author Email: crobinson@eng.uwo.ca

Co-authors: Laura Jill Vogel, University of Western Ontario, London, ON, Canada; Spencer S Malott, University of Western Ontario, London, ON, Canada; Sabina Rakhimbekova, , , ; Denis M O'Carroll, University of Western Ontario, London, ON, Canada

Published Material: This paper will present a review of field data that has been collected over the last 5 years examining the impact of dynamic groundwater-lake interactions on different contaminants along freshwater shorelines. The data related to E. coli fate was presented at the AGU Fall 2014 meeting. The data at one site (Port Stanley) that examined the fate of arsenic was published in ES&T (2014) however in the proposed presentation data will be presented from multiple beaches across the Great lakes.

Abstract Body: The role of groundwater-surface water interactions in controlling the delivery of contaminants to surface waters in freshwater beach environments is not well understood. These environments are ubiquitous on large inland lakes and nearshore water quality is often deteriorated due to fecal pollution (e.g., *E. coli*) and algal fouling. Field data obtained at sandy beaches on the Great Lakes provide important insight into the important influence of dynamic groundwater-lake interactions on the fate of contaminants, including trace elements (arsenic), nutrients, and fecal indicator bacteria (*E. coli*), in beach groundwater and subsequent fluxes to the lake. The data illustrate the role of wave-induced groundwater recirculations in accumulating *E. coli* in shallow foreshore beach sand and groundwater, and, in combination with sand erosion, later delivering *E. coli* from this reservoir back to the lake during periods of intensified wave activity. In addition, wave-induced recirculations across the sediment-water interface, which vary with wave intensity, set up sharp redox and pH gradients in beach groundwater that promote precipitation of iron (hydr)oxides and subsequent sequestration of chemical species including arsenic and phosphate. For instance, elevated dissolved arsenic below the shoreline (up to 56 μg/L) has been observed in beach groundwater at multiple beaches around the Great Lakes suggesting that this arsenic enrichment may be naturally occurring and linked with geochemical conditions set up by wave-induced recirculations. The interacting hydrologic and geochemical processes revealed have important implications for the flux of a wide range of contaminants across the groundwater-lake interface in freshwater coastal environments.

Title: Connectivity and Nitrogen Transport of Two Wetland-Rich Boreal Sites in the Athabasca Oil Sands Region

Presenter/First Author: Mikaela Lynn Cherry, University of Victoria, Victoria, BC

Presenter/First Author Email: mikaela.l.cherry@gmail.com

Co-authors: John J Gibson, University of Victoria, Victoria, BC, Canada; S Jean Birks, Alberta Innovates-Technology Futures, Calgary, AB, Canada

Abstract Body: Development of the Athabasca Oil Sands Region (AOSR) has increased atmospheric nitrogen emissions. The area surrounding development is comprised of Boreal forests and peatlands. Improved understanding of the hydrological connectivity between Boreal peatlands and uplands is needed to predict the fate and transport of atmospheric N deposited across the region. Two wetlands sites: Jack Pine High (JPH, located 45 km north of Fort McMurray) and Mariana Lakes (ML, located 100 km south of Fort McMurray) were instrumented with piezometers nests and water table wells for this study (n= 108 sampling locations). The wells were placed along transects that cover target landscape units (bog, fen, upland). Wells were sampled for water isotopes and geochemical variables during the summers of 2011-2014 to characterize the baseline geochemistry of groundwater in the different landscape units. Inorganic (nitrate, ammonium) and organic forms of nitrogen (dissolved organic nitrogen), major and minor ions and water isotope tracers (d^{18}O, d^{2}H and ^{3}H) were measured to identify the various forms of nitrogen in the different landscape units, as well as to assess connectivity and potential for nitrogen transport between the different units. At JPH the connectivity between the uplands and fens is a simple recharge from the upland to the fen. There was little (<0.1-1.5 mg/L) nitrate, ammonium, or dissolved organic nitrate (DON) found throughout JPH. Concentrations of ammonium and DON increased at depths throughout ML. The distribution of ^{3}H with depth within the peatland have shown limited connectivity between the peat and underlying mineral soils.

Title: Using Artificial Soils as Simplified Model Systems to gain insight into the effect of Mineral Composition on Microbial Community Development and Soil Organic Matter Formation

Presenter/First Author: Geertje Johanna Pronk, Lehrstuhl für Bodenkunde, Technische Universität München, Freising,

Presenter/First Author Email: pronk@wzw.tum.de

Co-authors: Doreen Babin, , , ; Franziska Ditterich, , , ; Julia Giebler, , , ; Katja Heister, , , ; Michael Hemkemeyer, , , ; Ellen Kandeler, , , ; Ingrid Kogel-Knabner, Soil Science - TU München, Freising, ; Yamuna Kunhi Mouvenchery, , , ; Christian Poll, , , ; Anja Miltner, , , ; Gabriele Schaumann, , , ; Michael Schloter, , , ; Kornelia Smalla, Institut fur Epidemiologie und Pathogendiagnostik, Braunschweig, Germany; Annelie Steinbach, , , ; Christoph Tebbe, , , ; Kai Uwe Totsche, Friedrich Schiller University of Jena, Jena, Germany; Susanne Woche, , , ; Cordula Vogel, , , ; Lukas Wick, , ,

Published Material: The findings were previously reported at the World Congress of Soil Science in Jeju, Korea, 2014. The presentation contains a syntesis of various results, which are already publised in several different journals.

Abstract Body: Soils represent a very complex materials where mineral, organic and biological components closely interact. It is difficult to gain complete understanding of biogeochemical processes in soils, as the initial conditions and development history are usually unknown and soil composition is usually not well defined. Therefore, we composed simplified artificial soils to study in particular the effect of mineral composition and charcoal presence on soil organic matter and microbial community development.

The artificial soils contained 8 different mixtures of the minerals illite, montmorillonite, ferrihydrite and boehmite, and charcoal. Sand and silt-sized quartz were used to provide texture, the mixtures were inoculated with an extract from a natural arable soil, and sterilized manure was added as a substrate. The mixtures were incubated in the dark at 20°C and constant water content, and sampled after 3, 6, 12 and 18 months incubation. They were then analysed in an extensive interdisciplinary study for e.g. microbial abundance and diversity, functionality, as determined by respiration and enzyme activity, organic matter composition, physical structure and surface properties.The mixtures quickly developed into soil-like systems with an established microbial community, macroaggregation and developing organo-mineral associations. Different microbial communities were established in the artificial soils depending on artificial soil composition. However, the development of soil organic matter and organo-mineral associations was similar for all mixtures.

Overall, the artificial soils used in this study provide a new approach to gain a mechanistic understanding of biogeochemical processes in well-defined soil-like systems. Furthermore, the combination of interdisciplinary methods illustrates how microbial communities interacted with, and were affected by, the OM, mineral and charcoal surfaces present in their habitats.

Title: Soil Oxygen Dynamics under Freeze-Thaw Cycles

Presenter/First Author: Tatjana Milojevic, University of Waterloo, Waterloo, ON

Presenter/First Author Email: t2miloje@uwaterloo.ca

Co-authors: Fereidoun Rezanezhad, University of Waterloo, Waterloo, ON, Canada; Philippe Van Cappellen, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Freezing and thawing cycles are a natural climate forcing acting on soils at middle to high latitudes. Freezing and thawing affect a soil's physical properties, biogeochemistry, microbial activity, carbon and nutrient turnover rates, and modulate gas exchanges between the soil and atmosphere, which, in turn, exerts a strong influence on oxygen (O_2) availability within soil environments. The ability to monitor changes in O_2 levels in both the gas and aqueous phase is key to understanding how changes in frequency and amplitude of freeze-thaw cycles affect a soil's geochemical conditions and microbial activity. In this study, we perform soil column experiments in a temperature-controlled environmental chamber. The air temperature of the chamber determines the soil's surface temperature, while a band-heater keeps the lower part of the column at a constant groundwater temperature. This design allows us to reproduce realistic, time- and depth-dependent temperature gradients in the soil column. High-resolution, luminescence-based, *Multi Fiber Optode* (MuFO) microsensors are used to enable continuous O_2 detection at a high degree of spatial flexibility in the column. High-resolution digital images of the sensor-emitted light are recorded and light intensity is converted to O_2 concentration via signal image-processing techniques. Headspace gas measurements are used to derive the effluxes of CO_2, CH_4 and N_2O during the experiment. In this presentation, we will present preliminary results to assess the hypothesis that freeze-thaw cycles regulate the fluxes of the greenhouse gases (GHG) not only by acting on the physical transport of gases, but also on soil microbial respiration via the variations in O_2 availability. The next step of our research will be to identify diagnostic geochemical and microbial signatures of the fluctuations in soil O_2 concentrations.

Title: Impact of precipitation intensity and riparian geomorphic characteristics on greenhouse gas emissions at the soil-atmosphere interface in a water limited North Carolina riparian zone

Presenter/First Author: Philippe Vidon, SUNY-ESF, Syracuse, NY

Presenter/First Author Email: pgvidon@esf.edu

Co-authors: Sara M Marchese, , Corning, NY; Sara K McMillan, UNC Charlotte, Charlotte, NC; Molly Welsh, , ,

Abstract Body: As greenhouse gas concentrations (GHG: N_2O, CO_2, CH_4) continue to increase in the earth atmosphere, there is a critical need to fully quantify GHG emissions from natural systems. In particular, rapidly changing moisture conditions often observed following precipitation events have the potential to create short periods (a few days) during which anaerobic conditions dominate in the riparian zone. These hot moments of denitrification and methanogenesis have the potential to significantly alter net GHG emissions at the soil-atmosphere interface in these systems. In this study, we use a combination of natural and artificial precipitation to investigate the impact of precipitation on overall GHG emission over a 3-day period in a forested riparian zone in North Carolina, USA, and characterize how GHG (CO_2, N_2O, CH_4) fluxes change as a function of location within the riparian zone. No significant differences in CO_2, CH_4, and N_2O fluxes in response to increased moisture were observed between a depression, a sand bar, and an upland forested area. However, in this well-drained site where water-limited aerobic conditions dominated before the onset of precipitation, methane oxidation decreased and aerobic respiration increased following precipitation. Although a short term burst in N_2O emission was observed 5 and 24 hours after precipitation occurred, elevated N_2O emissions did not persist long enough to turn the site from the N_2O sink to a N_2O source in the 3 days following the beginning of the experiment. Although in contrast with some previously published work where water limitation was unlikely to play a strong role on riparian biogeochemistry, our results are consistent with our current understanding of the impact of soil moisture on GHG emission at the soil atmosphere interface, and illustrate the complexity of riparian biogeochemistry and GHG dynamics. We present a conceptual model illustrating our findings in relation to previously published work.

Title: Early Diagenesis of Fe and Mn in the Laurentian Trough: Influence of Environmental Variables

Presenter/First Author: Bjorn Sundby, McGill Univ, Montreal, QC

Presenter/First Author Email: bjorn.sundby@mcgill.ca

Co-authors: Alfonso Mucci, McGill University, Montreal, QC, Canada; Qiang Chen, McGill University, Montreal, QC, Canada

Abstract Body: We determined the vertical distributions of dissolved Fe and Mn and solid phase ascorbate-extractible Fe and Mn (Fe_{asc} and Mn_{asc}) in six sediment cores recovered on a transect along the Laurentian Trough and extending from the Lower St. Lawrence Estuary through the Gulf of St. Lawrence to the edge of the continental shelf. At all sites, the sediment surface layer is enriched in both Fe_{asc} and Mn_{asc}. Manganese cycles both within the sediment column and across the sediment-water interface with a net loss of Mn to the overlying water. In contrast, Fe cycles entirely within the sediment column, without loss. The inventories of dissolved Fe and Fe_{asc} are strongly correlated to the reactivity of the sedimentary organic matter and its exposure time to oxygen. The peak concentration of dissolved Fe within a given core as well as the sum of dissolved Fe upward and downward flux (from dissolved Fe maximum at each core) show the comparable correlations. Despite a seaward increase in the relative contribution of autochthonous organic matter to the seafloor, the correlations indicate that the reducing capacity of the sediments (inferred from the strength of the Fe diagenetic cycles) nearly follow the track of the transect, as the sedimentation rate decreases and the bottom-water oxygen concentration and water depth increase seaward.

Title: Early diagenesis, methylmercury production and total mercury deposition in North American Arctic Margin sediments

Presenter/First Author: Charles Gobeil, INRS-ETE, Quebec, QC

Presenter/First Author Email: charles.gobeil@ete.inrs.ca

Co-authors: Zou Zou A Kuzyk, University of Manitoba, Winnipeg, MB, Canada; Robie W Macdonald, Institute of Ocean Sciences, Sidney, BC, Canada; Daniel Cossa, Ifremer Biblio Perouse, Grenoble, France

Published Material: Our findings have not been submitted to a journal yet. Some aspects of our mercury results were presented at a national conference but, here, we want to propose for the first time a thorough interpretation for the total mercury and methylmercury distribution in arctic margin sediments taking into account early diagenetic processes.

Abstract Body: The profiles of total Hg (HgT) and methylmercury (MeHg), i.e. the toxic form of Hg that biomagnifies in aquatic food webs and can be produced in marine sediments, were determined in sediment cores collected across the North American Arctic Margin (NAAM). To provide a diagenetic context to interpret these profiles, Mn, Fe, total S, reduced inorganic S (S-Red) and radioisotopes (Pb-210, Ra-226, Cs-137) were also determined. The cores from the Beaufort Sea, Canadian Archipelago and Baffin Bay are characterized by high levels of Mn and Fe oxyhydroxides down to several cm below the sediment-water interface and low levels of total S, S-Red and MeHg. In contrast, sediments from the Bering and Chukchi Seas contain negligible amount of Mn and Fe oxyhydroxides but high levels of S-Red and MeHg. In these highly productive regions of the NAAM, S-Red increases with depth in the sediments and reaches concentrations at the bottom of the cores (~40 cm) that are about 10 times higher than in the Beaufort Sea, Canadian Archipelago and Baffin Bay. Likewise, MeHg increases with depth in Bering and Chukchi Seas sediments to concentrations significantly higher (1-2 ng g^{-1}; 2-4% of HgT) than those measured in the other regions of the NAAM (<0.2 ng g^{-1}; 0.3% of HgT). From these results we submit 1) that the anaerobic oxidation of organic C is mainly driven by the reduction of sulfate in Bering and Chukchi shelves sediments and by that of Mn and Fe oxyhydroxides in the sediments of the others regions of the NAAM, 2) that significant accumulation of MeHg in NAAM sediments only occurs in the Bering and Chukchi Seas and 3) that sulfate-reducing bacteria are likely the key microorganisms responsible for the conversion of inorganic Hg to MeHg in the sediments from these two marginal seas. Lastly, assuming negligible post-depositional redistribution of HgT, we propose that the depositional flux of HgT in surface sediments across the NAAM is higher than in preindustrial time by 1±0.9 ng cm^{-2} a^{-1}.

Co-authors: Daniel Bourgault, University of Quebec at Rimouski UQAR, Rimouski, QC, Canada

Abstract Body: Sandy beaches are key environments of biogeochemical dynamic at the land-sea interface, where fresh and salt waters mix. Multiple physical forces that drive groundwater flows and residence times control the reaction rates and thus the chemical transformations in this active biogeochemical zone. Terrestrial drivers and marine processes interplay in a complex way to modify the subsurface transport pathway and local geochemical conditions. Understanding how these local flow regimes influence chemical transformations in subterranean estuary is important to estimating regional chemical fluxes from aquifers to coastal waters. Here, we combine physical and geochemical approaches to explore the impact of tidal oscillations on hydrogeological and biogeochemical mixing in a subterranean estuary of a microtidal beach located in Magdalen Islands (Gulf of St. Lawrence, Canada).

Tidal propagations in the beach were investigated via a harmonic analysis of piezometric level fluctuations recorded over 20 days. In addition, high-resolution depth profiles were sampled in a cross-shore transect and a suite of biogeochemically cycled elements and stable isotope tracers were analyzed. We use the abundance of δD and $\delta^{18}O$ to discriminate the mixing of nearshore fresh and saline groundwaters over tidal cycles. Tidal effect is also examined on the distribution of reactive biogenic compounds in the subterranean estuary. Preliminary results reveal that tidal oscillations decrease landward with increasing phase lags as observed in other isotropic shallow aquifers. Tides components induce water level fluctuations are completely damped 35 m landward of the shoreline. In the subterranean estuary, these piezometric level fluctuations seem to have only a limited effect on fresh groundwater – saltwater mixing. The downward transport of the saltwater and the subsequent water mixing may be mainly controlled by both the permeability of the beach aquifer and the frequency of tidal-forcing. This may also explain the temporal lag we observed between the tidal oscillation and the geochemical conditions measured in the subterranean estuary.

Title: Iron Isotope Systematics in a Eutrophic Lake

Presenter/First Author: Lingling Wu, University of Waterloo, Waterloo, ON

Presenter/First Author Email: lingling.wu@uwaterloo.ca

Co-authors: Sherry L Schiff, University of Waterloo, Waterloo, ON, Canada; Jason J Venkiteswaran, Wilfrid Laurier University, Waterloo, ON, Canada; Kai Liu, , , ; Lewis A Molot, York University, Toronto, ON, Canada; Josh D Neufeld, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Iron isotopes are a useful tracer of biogeochemical processes in a variety of environments. This study investigated the iron isotope signatures in eutrophic Lake 227 in the Experimental Lakes Area, which was experimentally fertilized with phosphorus and nitrogen for more than 45 years. The aim was to use iron isotope tools to shed light on processes such as cyanobacterial blooms and anoxygenic photosynthesis by photoferrotrophs. The iron isotope compositions of the dissolved fraction and suspended loads in lake waters are clearly different in the two thermal layers: in the upper mixed layer above the oxycline where there is a cyanobacteria bloom, dissolved Fe showed $\delta^{56}Fe$ values about 0.8‰ heavier than the suspended particles, reflecting association with colloids and organic matter and possibly uptake of isotopically light Fe by cyanobacteria; in the anoxic hypolimnion where photoferrotrophs thrive, the fractionation between dissolved and suspended Fe is reversed with dissolved Fe about 1.0 to 1.5‰ lighter than the suspended solids, consistent with results of laboratory cultures of photoferrotrophs. The uniform isotope signature of dissolved Fe with depth in the hypolimnion is consistent with diffusion of Fe(II) from complete microbial reduction in the sediments. Alternatively, the isotope fractionation between dissolved and suspended Fe in the hypolimnion may reflect microbial reduction of Fe oxyhydroxides settling down from the oxycline. Sequencing of DNA obtained from water column samples provided additional data implicating photoferrotrophs in Lake 227 biogeochemistry. More data are needed to further understand the dynamic cycling of Fe in the system.

Title: Stochastic Resonance: A New Mechanism for the Formation of Banded Patterns in Limestone-Marl Sequences

Presenter/First Author: Ivan L'Heureux, University of Ottawa, Ottawa, ON

Presenter/First Author Email: ilheureu@uottawa.ca

Published Material: I gave an one-hour long seminar on this topic at GEOMAR (Kiel, Germany) in August 2014.

Abstract Body: The origin of banded sequences in calcareous-marl deposits is not yet completely understood. Are they only due to systematic external variations in the environment (such as the 100 ka climate cycle)? Are they due to self-organized recurrent conditions generated by the nonlinearity of the diagenetic processes? Or a combination of both, as suggested by cellular automata modelling approaches available in the literature? In this contribution, a simple diagenetic reactive-transport model (RTM) is presented, following the conceptual model of Munneke et al. (Int. J. Earth Sciences (2001): 90, 795-812). This RTM differs from cellular automata approaches by explicitly considering diffusion of dissolved calcium and carbonate ions. However, no self-organized diagenetic oscillations were found in the RTM. Nevertheless, it was established that a parameter regime exists for which the system is multistable, indicating that different steady-state solutions are reached according to which initial sediment condition is chosen. When the system is driven by a weak external periodic forcing and a random external signal, it can then exhibit stochastic resonance, whereby the system undergoes noise-induced transitions from one state to another in synchronicity with the periodic external signal, even though the latter is not sufficiently strong to induce such transitions by itself. As a result, it is possible that small systematic variations in the external environment (superposed with a random component) trigger substantial transitions in the sediment sequences between a limestone-rich state and a limestone-poor one.

Title: Greenhouse Gas Exchange from Sites Used as a Source of Vegetation Donor Material for Peatland Restoration

Presenter/First Author: Kimberley Robyn Murray, University of Waterloo, Waterloo,

Presenter/First Author Email: k7murray@uwaterloo.ca

Co-authors: Andrea Borkenhagen, , , ; David J Cooper, Colorado State University, Fort Collins, CO; Maria Strack, University of Calgary, Calgary, AB, Canada

Abstract Body:

Horticultural extraction of peatlands converts them from carbon and greenhouse gas (GHG) sinks to sources. The moss layer transfer technique for peatland restoration may return the GHG sink function, but requires a source of vegetation donor material. This technique may also be incorporated into fen construction projects following oil sands extraction. Collecting this donor material creates an additional disturbance, often in a previously undisturbed peatland, and the recovery of these “donor sites” and the impact on their GHG emissions is unknown. We monitored growing season GHG fluxes and plant communities on donor sites in an ombrotrophic bog and minerotrophic fen in Alberta, Canada from which material was removed between 1-6 year prior to the study and compared results to neighbouring undisturbed peatland.

Plant recovery on both donor sites was rapid with 70% and 120% total plant cover after two growing seasons at the fen and bog, respectively. Of this, moss cover also returned, reaching 83% cover after 5 years at the bog. On the other hand, the majority of undisturbed peatlands in western Canada are treed and tree recruitment on the donor sites remained low likely due to higher water tables resulting from the removal of surface material. The strong vegetation recovery led to a growing season carbon sink at the 5-year bog donor site. However, methane emissions were higher from both donor sites than undisturbed areas due to the high water table and large cover of sedges that colonized the sites.

Title: From 10 Hz to 30 Minutes: Standardized Procedures for (Post)-Processing Eddy Covariance Measurements of the Taiga Plains Flux Tower Meso-Network in Northwestern Canada

Presenter/First Author: Karoline Wischnewski, University of Montreal, Montreal, QC

Presenter/First Author Email: Karoline.Wischnewski@gmail.com

Co-authors: Manuel Helbig, University de Montreal, Montreal, QC, Canada; Natascha Kljun, Swansea University, Swansea, United Kingdom; Laura Chasmer, Wilfrid Laurier University, Waterloo, ON, Canada; Philip Marsh, Wilfrid Laurier University, Waterloo, ON, Canada; William L Quinton, Wilfrid Laurier University, Waterloo, ON, Canada; Oliver Sonnentag, University of Montreal, Montreal, QC, Canada

Abstract Body: Warming air temperatures and widespread degradation of permafrost in the Taiga Plains in northwestern Canada potentially alters biosphere-atmosphere interactions by modifying the net exchanges of greenhouse gases and energy. To enhance our understanding of the underlying biophysical and biogeochemical ecosystem processes, we are establishing a meso-network of four micrometeorological towers along a 1000-km permafrost gradient ranging from the sporadic/discontinuous permafrost zone experiencing continental climate to the continuous permafrost zone with a coastal climate. Identical low power-low maintenance micrometeorological instrumentation and standardized procedures for processing high-frequency measurements and for post-processing half-hour flux data are crucial to ensure consistency and inter-site comparability.

The open-path flux tower at the southern margin of permafrost is located in a highly heterogeneous boreal forest-peatland landscape. Detailed footprint analyses are conducted combining a 2D-footprint model (Kljun et al. 2002), landcover classification maps, and canopy structure information derived from high-resolution LiDAR data. In addition, to better interpret the mixed signal obtained form the heterogeneous landscape, a nearby shorter nested tower collects flux data from a homogeneous footprint within the heterogeneous footprint of the taller tower. With this contribution, we outline the development of standardized (post-) processing procedures for eddy covariance measurements across the evolving flux tower meso-network, highlighting the importance to incorporate site-specific conditions characteristic to different permafrost regimes (e.g., landscape heterogeneity).

Title: Throughfall and Stemflow as Hot Phenomena of Biogeochemical Fluxes in Temperate Swamps

Presenter/First Author: Matthew Malone, University of Toronto, Mississauga,

Presenter/First Author Email: matthew.malone@mail.utoronto.ca

Abstract Body: The production of throughfall (TF) and stemflow (SF) is precipitation-driven and has been shown to acquire various plant leachates as these hydrologic fluxes pass through a tree canopy. Enrichment of TF and SF with dissolved organic carbon (DOC), nitrogen (N) and various other compounds increase the ability of these hydrological fluxes to bring chemicals, beneficial or potentially harmful, to the soils present under the vegetative canopy. TF and SF have the potential to induce hot phenomena upon reaching the soil below due to the biogeochemical pulses provided by them. This is especially true for SF, which has been proven to contain higher DOC and nutrient concentrations than precipitation (P) and TF and has preferential access to the soil matrix via the root system of the tree. This study presents the investigation of the biogeochemical fluxes of TF and SF during P events in two swamps of southern Ontario. These biogeochemical fluxes and resulting hot phenomena impact nutrient cycling, species composition and water quality in wetlands, with this study providing a unique look at these fluxes during the growing season in two temperate mixed-deciduous swamps. With the aid of this research, wetland conservation and management authorities can obtain important information regarding the fluxes of DOC and N species into temperate swamps, as well as the dissolved organic matter (DOM) character of TF and SF. The objectives for this study were to determine the quantity of DOC and N present in TF and SF and how they differ between different stands and different tree species. Additionally, an analysis of DOM character in TF and SF was performed to determine the amount of bioavailable organic material (relative molecular mass), aromaticity and fluorescence properties (fluorescence index, EEM’s, PARAFAC) of each.

Title: Spatial and Temporal Variability of CO2, CH4 and N2O Emissions from the Soils of a Subtropical Mangrove Wetland

Presenter/First Author: Derrick Yuk Fo Lai, Chinese University of Hong Kong, Hong Kong,

Presenter/First Author Email: dyflai@cuhk.edu.hk

Co-authors: Jiaxing Xu, The Chinese University of Hong Kong, Hong Kong SAR, Hong Kong

Abstract Body: The concept of "blue carbon" has received increasing attention recently, which points to the potential role of vegetated coastal wetlands in carbon sequestration. Yet, the magnitude and controls of greenhouse gas emissions from coastal wetland ecosystems, especially mangroves in the subtropical regions, are still largely unknown. In this study, we conducted chamber measurements in the Mai Po Marshes Nature Reserve of Hong Kong at monthly intervals to characterize the spatial and temporal variability of the emission of greenhouse gases, including CO_2, CH_4 and N_2O from mangrove soils, and examine the influence of environmental and biotic variables on greenhouse gas fluxes. We found the highest mean CH_4 and N_2O emissions in autumn and the highest CO_2 flux in summer. Along the tidal gradient, we observed significantly higher CH_4 and N_2O emissions from the middle zones and landward zones, respectively, while no clear spatial variation of CO_2 emissions was observed. There were significantly higher soil greenhouse gas emissions from sites dominated by *Avicennia marina* than those dominated by *Kandelia obovata*, which might be due to the presence of pneumatophores which facilitated gas transport. We found a significant, negative correlation between CH_4 flux and soil NO_3-N concentration, while CO_2 flux was positively correlation with total Kjeldahl nitrogen content. Soil temperature was positively correlated with the emissions of all three greenhouse gases, while water table depth was positively and negatively correlated with CH_4 and N_2O emissions, respectively. Our findings demonstrate the high spatial and temporal variability of greenhouse gas emissions from mangrove soils which could be attributed in part to the differences in environmental conditions and dominant plant species.

Title: Changes of carbon fluxes and major carbon sources after palsa thawed into pond

Presenter/First Author: Zheng Wang, McGill University, Montreal, QC

Presenter/First Author Email: wzhwangzheng@gmail.com

Co-authors: Nigel T Roulet, McGill University, Montreal, QC, Canada

Abstract Body: Permafrost thaw is pronounced in peatlands across the discontinuous permafrost zone. Our research assesses the carbon (C) fluxes before and after palsa peatlands thaw. The terminal point of the thaw sequence is often thawed ponds, which is believed to be a major source of C gases to the atmosphere. At our study site in northern Quebec near Kuujjuarapik, the thawed ponds (~3 m in depth) were strongly stratified with thick anoxic hypolimnias from 0.5 m to the pond bottoms. The CO_2 flux and most the CH_4 fluxes from the ponds were positive to the atmosphere, while the palsas took up CO_2 and CH_4 for most of the growing season. The average seasonal C losses from the ponds were 9.46 mmol CO_2 m^{-2} h^{-1} and 1.69 to 2.00 µmol CH_4 m^{-2} d^{-1}. Over the summer larger pond had significantly higher CO_2 efflux, while the smallest pond had significantly higher CH_4 efflux. Bubble emission accounted a large part of pond CH_4 emission, with greater ebullition at the pond edges. The dissolved CO_2 and CH_4 concentrations increased ~ 10 fold from 10 to 50 cm deep, and more than 100 fold at 230 cm depth. The $\delta^{13}CH_4$ indicated CH_4 production shifted from acetoclastic methanogenesis dominated at the surface to CO_2 reduction dominated at the bottom. DOC mass and biodegradability (SUVA/FI) strongly correlated with pond C gas effluxes, suggesting pond surface DOC may be a C source supporting pond C gas effluxes. Comparing $\delta^{13}C$ of surface dissolved CO_2 and CH_4, DOC, peat, sediments, and plant litter & exudates, we determined that plant exudates was the main source of the labile DOC that decomposed into C gas fluxes. Palsa thaw to ponds leads to large CO_2 and CH_4 emissions, supported by newly produced labile DOC from the plant communities surrounding the ponds rather than the peat and pond sediments.

Title: Methanotrophs Contribute to Peatland Nitrogen

Presenter/First Author: Tuula Larmola, University of Helsinki, South Hadley, MA

Presenter/First Author Email: tuula.larmola@gmail.com

Co-authors: Sanna M. Leppänen, University of Jyväskylä, Jyväskylä, Finland; Eeva-Stiina Tuittila, , , ; Maija Aarva, , , ; Päivi Merilä, , , ; Hannu Fritze, , , ; Marja Annika Tiirola, University of JyväSkylä, JyväSkylä, Finland

Published Material: Part of these findings were reported at AGU Annual Meeting in December 2014 and at EGU General Assembly in April 2014, and published in *Proceedings of the National Academy of Sciences USA*, but my presentation will include some new results that have not been reported previously.

Abstract Body: Atmospheric nitrogen (N_2) fixation is potentially an important N input mechanism to peatland ecosystems, but the extent of this process may have been underestimated because of the methods traditionally used inhibit the activity of methanothrophs. We examined the linkage of methane (CH_4) oxidation and N_2 fixation using $^{15}N_2$ technique. Dominant flark and hummock *Sphagnum* species were collected from twelve pristine peatlands in Siikajoki, Finland, which varied in age from 200 to 2,500 y due to the postglacial rebound. The mosses were incubated in a two-day field $^{15}N_2$ and $^{13}CH_4$ pulse labelling experiment and the incorporation of $^{15}N_2$ and $^{13}CH_4$ in biomass was measured with Isotope Ratio Mass Spectrometer. The rates of *Sphagnum*-associated N_2 fixation (0.1-2.9 g N m^2 y^{-1}) were up to 10 times the current N deposition rates. Methane-induced N_2 fixation contributed to over 1/3 of moss-associated N_2 fixation in younger stages, but was switched off in old successional stages, despite active CH_4 oxidation in these stages. Both the N_2 fixation rates and the methanotrophic contribution to N_2 fixation during peatland succession were primarily constrained by phosphorus availability. Previously overlooked methanotrophic N contribution may explain rapid peat and N accumulation during fen stages of peatland development. Reference. Larmola T., Leppänen S.M., Tuittila E.-S, Aarva M., Merilä P., Fritze H., Tiirola M. First Author Student?: No

Abstract Body: Abstract: Inorder to meet the water demand by population growth and urbanization, many countries started using untreated or partially treated wastewater for irrigation, groundwater recharge, landscaping and other purposes. On the other hand, the use of nitrogen-based fertilizers in agriculture has helped to feed millions of people but it's also disrupted the nitrogen cycle, and resulted in nitrate contamination in groundwater creating various health issues. A scientific investigation on the nitrogen dynamics in the subsurface, its sources, sinks, transformations and transport is essential to device proper wastewater reuse strategies and to ensure safe groundwater. The major nitrogen transformation process in soil like adsorption, chemical and biological transformations namely nitrification and denitrification, plant uptake and others will control the final release of nitrates into the groundwater. Therefore, it is very important to study the fate and transport of nitrogen species from fertilizer and/or wastewater irrigation in order to predict the spatial and temporal distributions of concentrations in the vadose zone and groundwater. In this aspect, experimental evidences are needed to quantify the individual reaction rates of all the processes by batch and bench scale column studies. The data from batch experiments will be used to propose a mathematical model for simulating the processes of nitrogen dynamics spatially and temporally in real scenario. Finally, a comprehensive, replicating the field conditions will be helpful in validating the model and thereby applying it for predictions, scenario analysis and guidelines development for wastewater irrigation and fertilizer management.

Abstract

Two fresh water fish species Tilapia (*Oreochromis mossambicus*) and Common Carp (*Cyprinus carpio*) were cultured to investigate the survival rate in bioremediated sewage effluent of Shehzad town, Islamabad, Pakistan. Two earthen ponds one with fresh water and second with bioremediated sewage effluent with dimension of 20×40 m were selected at Fisheries and Aquaculture Programme, NARC. Fish survival was investigated after fortnight sampling. Physicochemical parameters of bioremediated water were within permissible limit recommended for fish. Less than one percent survival was observed in bioremdiated water pond whereas 100% fish survival was recorded in fresh water pond. Further investigation and results showed the higher level of ammonical-nitrogen (NH4+-N; 31.08 mg/L), nitrate-nitrogen (NO3--N; 18.58 mg/L) and chlorides (Cl-; 39.61mg/L) in bioremediated sewage water that were main cause of fish mortality. Complete fish survival was recorded in bioremediated sewage effluent after phytoremediation with Coontail (*Ceratophyllum demersum*) plant that has potential of removing NH4+, NO3- and Cl- from sewage waste water. This study showed that this treated sewage water required further treatment for removal of NH4+-N, NO3--N and Cl- by using phytoremdiater Coontail (*C. demersum*).

Title: Effect of Water Table Fluctuations on the Fate and Distribution of *Escherichia coli* in a Freshwater Beach Environment: An Experimental Study

Presenter/First Author: Avid Banihashemi, University of Waterloo, Waterloo,

Presenter/First Author Email: a2baniha@uwaterloo.ca

Co-authors: Radmila Kovac, University of Waterloo, Waterloo, ON, Canada; Fereidoun Rezanezhad, University of Waterloo, Waterloo, ON, Canada; Danny Hyumin Oh, , , ; Christina Marie Smeaton, University of Waterloo, Waterloo, ON, Canada; Maria Mesquita, , , ; Clare E Robinson, University of Western Ontario, London, ON, Canada; Philippe Van Cappellen, University of Waterloo, Waterloo, ON, Canada

Abstract Body: To investigate the role of water table dynamics on the distribution of *E. coli* in sandy lake beaches, an automated column system was used to simulate the effect of water table fluctuations. Four undisturbed cores were collected perpendicular to the shoreline at Burlington beach site in Ontario, yielding four sand columns. The water table regime in the columns was designed to mimic the dynamic water table fluctuations observed at variable distances from the shoreline. The columns were inoculated with a naturally occurring nalidixic acid resistant *E. coli* strain every 48 hrs. A one time inoculation of 1.0µm fluorescent microspheres as bacterial surrogates was also carried out. A mini-auger system was used to periodically retrieve small amounts of sand (< 1.0 g) from the columns, hence making it possible to monitor changes in the *E. coli* concentrations. Changes in pore water composition were monitored by collecting water with micro-Rhizon samplers from different depths of the columns. The experiment ran for 35 days in total and at the end of the experiment, the columns were sliced and analysed for microspheres, *E. coli* and solid phase chemistry. High level of *E. coli* and microspheres were observed at the top of the columns. By the end of the experiment, only less than 5% of the total *E. coli* introduced to the columns reached 25cm deep below the sand surface. These results suggests that in-situ depth distributions of *E. coli* in beach environments are strongly controlled by the input and transport properties of the bacteria. Nitrification occurred more intensively at the layers of sand columns with higher *E. coli* concentrations under aerobic conditions controlled mainly by water table fluctuations. This can be explained by *E. coli* aging and subsequent die-off releasing organic N in the sand.

Title: Hydrochemistry, $^{18}O/^{16}O$ and $^{2}H/^{1}H$ Ratios of Groundwater and Surface water in Raya Valley, Northern Ethiopia.

Presenter/First Author: Merhawi GebreEgziabher GebreMichael, Addis Ababa University, Addis Ababa,

Presenter/First Author Email: meregebre@gmail.com

Published Material: Ayenew, T., GebreEgziabher, M., Kebede, S., & Mamo, S. (2013). Integrated assessment of hydrogeology and water quality for groundwater-based irrigation development in the Raya Valley, northern Ethiopia. Water International, 38(4), 480–492. doi: 10.1080/02508060.2013.821640.

Abstract Body: The uses of groundwater for irrigation, domestic supply and livestock water is increasing in the Raya Valley. Raya valley has been affected by recurrent draught and famine in few years back. Recent, study shows that the groundwater potential of the study area is high. The volcanic aquifer and alluvial aquifers are the host geological formation to hold and transmit groundwater.

In this study, we used the application of isotope hydrology and hydrochemistry to understand the possible interconnections between groundwater with surface water. A total of 128 water samples were collected from groundwater, river, swamp, lake and rainfall. Most of the groundwater samples from volcanic aquifers are characterized by fresh, low salt content and depleted isotopic composition, however, the low-lying alluvial aquifer is characterized by high dissolved chemical constituents, high salt content and enriched isotopic composition. A moderate salt content and slightly enriched groundwater samples are found from the foot of the escarpment, showing possible groundwater mixing. Almost all of the groundwater samples are plotted just below Local Meteoric Water Line, which indicates the groundwater origin is meteoric origin and undergoes significant evaporative fractionation prior to recharge.The surface water shows distinct physiochemical, hydrochemical and isotopic values. The average stable isotopes values for Lake Ashenge samples were found to be 4.27 ‰ for δ18O and from 29.23 ‰ for δ2H. Lake water sample plotted below the LMWL and shifting toward the right this shows the lake undergoes high level of evaporation.

The local evaporation line for Lake Ashenge (LEL) is constructed based on isotopic data and given as δ2H = 5.16 δ 18O + 8.5 with regression coefficient of 0.89. The LEL crosses the LMWL at the isotopic values of 1‰ in δ2H and -1.5 ‰ in δ18O. This input signal indicates the dominant groundwater inflow from the lake is from the groundwater and local rainfall. The slight enrichment of the input signal relative to the mean precipitation in the study area could be evaporation of river flowing toward lake during rainy season. The Isotopic signature for the Gerjale wampy water, which supports a lots of ecological fauna and flora, indicates the principal source from the local perched aquifer.

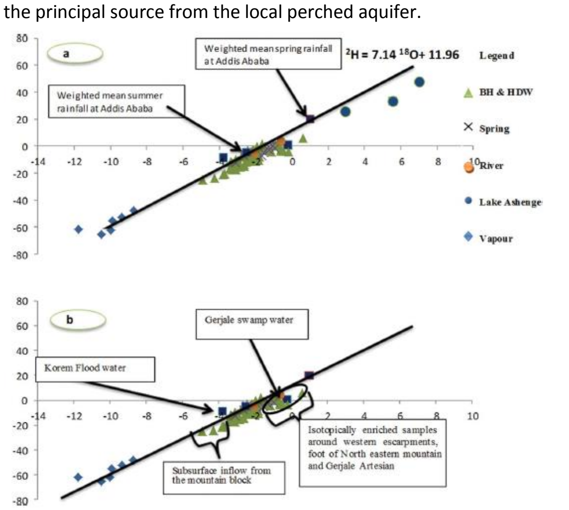

Figure 4. (a) Isotopic compositions of all water samples with weighted mean spring and summer rainfall. (b) Plot of concentrations of deuterium (δ^2H) and oxygen-18 ($\delta^{18}O$) isotopes for groundwater samples classified based on isotopic value.

Title: Temporal Redox Fluctuations in Sediments: Pulsed Phosphorus Loadings in Freshwater Marsh Systems?

Presenter/First Author: Chris Thomas Parsons, University of Waterloo, Waterloo,

Presenter/First Author Email: chris.parsons@uwaterloo.ca

Co-authors: Fereidoun Rezanezhad, University of Waterloo, Waterloo, ON, Canada; David O'Connell, University of Waterloo, Waterloo, ON, Canada; Philippe Van Cappellen, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Phosphorus concentrations in many surficial wetland sediments have increased substantially over the last century due to excessive anthropogenic loading of phosphorus to surface water. Wetland sediments are also often subject to rapidly oscillating redox conditions, driven by bioturbation or fluctuating dissolved oxygen concentrations in surface water. We used *in situ* mesocosms, alongside bioreactor sediment suspension experiments, to evaluate the effect of short temporal redox fluctuations on sedimentary phosphorus speciation and mobility in Cootes Paradise, a hypereutrophic coastal marsh which drains into Hamilton Harbour.

Results from bioreactor experiments show that repetitive re-oxidation of surficial wetland sediment (0-15cm) results in rapid degradation of organic phosphorus species (P_o) in autochthonous algal material to orthophosphate. Therefore, there is little accumulation of P_o in sediments (P_o = 13% of total sediment P). Despite enhanced extracellular phosphatase activities under oxic conditions (e.g. phosphomonoesterase activity of 2.4 mmol hr^{-1} kg^{-1}), maximum phosphorus mobilization occurs during reducing conditions due to a strong metal oxide control. Reductive dissolution of iron oxides under anoxic conditions results in the reversible redistribution of iron oxide bound P to other solid phase pools and the aqueous phase.

Preliminary *in situ* mesocosms suggest that diurnal cycling of dissolved oxygen concentrations, controlled by photosynthesis and respiration, does not exert a strong influence on internal phosphorus loading to surface water. This is due to excessive nitrate concentrations (~200 µM) in surface water which inhibit iron reduction at the sediment water interface during short periods of water column anoxia and prevent pulsed phosphorus release.

Title: Impact of soil freezing and thawing dynamics on greenhouse gas emission and nutrient fluxes

Presenter/First Author: Fereidoun Rezanezhad, University of Waterloo, Waterloo, ON

Presenter/First Author Email: frezanez@uwaterloo.ca

Co-authors: Chris Thomas Parsons, University of Waterloo, Waterloo, Canada; Christina Marie Smeaton, University of Waterloo, Waterloo, ON,

Canada; Radmila Kovac, University of Waterloo, Waterloo, ON, Canada; Tatjana Milojevic, University of Waterloo, Waterloo, ON, Canada; Philippe Van Cappellen, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Freezing and thawing is an abiotic stress applied to soils that affect the physical properties, biogeochemistry, microbial activity, and the rates of carbon and nitrogen cycling in soils. A better mechanistic understanding of how freezing and thawing influences soil respiration, greenhouse gas emissions, and leaching of nutrients to groundwater is needed to predict how soils will respond to climate change. To enhance this understanding, a highly instrumented soil column experiment was designed to realistically simulate freeze-thaw dynamics under controlled conditions. This approach combines the acquisition of integrated physical, chemical and microbial data collected periodically from different depths in which time-dependent, vertical temperature profiles are generated that mimic temperature distributions in real soils under freeze-thaw conditions. In this presentation, we focus on soil-specific physical, chemical, microbial factors (e.g. redox conditions, respiration, fermentation) and the mechanisms that drive greenhouse gases emission and nutrient cycling in soils under freeze-thaw cycles. The results indicate that changes in the soil microbial community and activity, driven by the fluctuations in temperature and oxygen availability, together with the recurrent development of a physical barrier preventing exchange of gaseous compounds between the soil and atmosphere during freezing conditions, modulate the time-dependent release of greenhouse gases from the soil surface. In other words, both physical and biogeochemical processes regulate the belowground soil carbon and nitrogen allocation and respiration during the alternating frost and thaw periods.

Title: Carbon isotope signature of CH_4 and CO_2 as a tool to unravel diagenetic pathways in lake sediments

Presenter/First Author: Francois Clayer, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Québec, QC

Presenter/First Author Email: francois.clayer@ete.inrs.ca

Co-authors: Anja Moritz, Concordia University, Montréal, QC, Canada; Yves Gelinas, Concordia University, Montreal, QC, Canada; André Tessier, , , ; Charles Gobeil, INRS-ETE, Quebec, QC, Canada

Published Material: A part of these findings were reported at the 17th Annual Chemistry and Biochemistry Graduate Research Conference at Concordia University, Montréal.

Abstract Body: In aquatic sediments, methane (CH_4), a potent greenhouse gas, is produced through the microbial breakdown of organic matter (OM) once sulfate is depleted, and can be consumed by aerobic and anaerobic oxidation (methanotrophy). It is well known that methanotrophy as well as methanogenesis, i.e. acetate fermentation (acetoclasty) and CO_2 reduction with H_2 (hydrogenotrophy), are processes that modify the carbon isotopic composition ($\delta^{13}C$) of CH_4 and CO_2 contained in the sediments. To unravel methane diagenetic pathways in the sediments of an oligotrophic and seasonally anoxic Canadian Shield lake, we determined high-resolution vertical profiles of dissolved CH_4 and CO_2, as well as their $\delta^{13}C$. The concentration profiles of CH_4 and CO_2 were modeled, using a one-dimensional transport-reaction equation, to constrain the depth-intervals (zones) where these species are produced or consumed in the first 25 cm of the sedimentary column, and to estimate their net production/consumption rates in each of the zones. The comparison of CH_4 and CO_2 net reaction rates enables us to constrain, in each zone, rates for acetoclasty, hydrogenotrophy, methanotrophy and OM fermentation. Then, fitting the measured $\delta^{13}C$ profiles with those simulated by a steady-state transport-reaction model allows us to clarify the relative contribution of acetoclasty and hydrogenotrophy. The model takes into account the constrained rates and established isotope fractionation factors reported in the literature for all the above-mentioned processes. We conclude that nearly 100% of CH_4 was produced by hydrogenotrophy following the non-fractionating fermentation of humic substances to CO_2 and H_2.

Title: Geochemical Behavior of Cadimum during Early Diagenesis in Tidal Sediment from the Shuangtaizi Estuary, China

Presenter/First Author: Baolin Liu, China University of Geosciences Beijing, Beijing,

Presenter/First Author Email: liubaolin@cugb.edu.cn

Co-authors: Yongsheng Nie, , ,

Abstract Body: A sediment core and pore-water samples were taken in the Shuangtaizi Estuary for a study on early diagenesis in sediment and its influence on geochemical behavior of cadimum. Sulfate, Fe and Mn ions in the pore-water were analysed to better understand the depth ranges and reactions related to the early diagenesis. In addition, three different types of sulfur, acid volatile sulfur (AVS), pyrite sulfur (PS) and elemental sulfur (ES), and their transformations during early diagenesis were also studied.

<span"> Results showed that low concentrations of both sulfate and organic carbon have occurred between 0-30cm depth of the sediment core, suggesting a reaction between sulfate and organic carbon. The concentration of ES is lower than its detection limitation between 0-25cm, as well as the low concentration of AVS, which is consistent to high PS content in this depth interval, suggesting the production of pyrite will lead to the reduction of ES and AVS. With the reaction between sulfate ion and organic matter, hydrogen ion content in the pore-water also increased accordingly, resulting in a decrease of pH value in the pore-water, and suggesting an influence of early diagenesis. A low concentration of dissolved cadimum ion occurred in the pore-water at a depth interval from 0 to 30cm, while total cadimum concentration in the sediment reached its maximum in this depth interval, indicating that cadimum in the pore-water has been absorbed on the surface of mineral particle and/or combined with the Fe/Mn oxides in the sediment. High percentage of exchangeable cadimum speciation reinforced this presumption. Exchangeable cadimum was the dominant phase in the sediment (57.6%), followed by Fe/Mn oxides phase (25.9%), residual phase (12.5%) and organic/sulfide phase (4.0%).

<span"> Correlation, cluster and factor analysis showed that cadimum is mainly originated from weathering of rock on land. The absorption of clay mineral, Fe/Mn oxides in the sediment and pH values variaton in the pore-water are main influencing factors for the mobilization,migration and transformation of cadimum in sediment. Total diffuse flux of cadimum in the sediment is 0.042 mgm-2a-1. Almost 50% of cadimum in the sediment is redissolved into pore-water and another 50% cadimum is deposited or adsorbed on the surface of solid sediment.

Title: Does Science Improve The General Public Information? The Example of Preparedness Actions For The Seismic Risk in Martinique (FWI).

Presenter/First Author: Jean-Christophe Audru, ACFAS, Montreal, QC

Presenter/First Author Email: jc.audru@brgm.fr

Published Material: Audru J.C, Vernier J.L., Capdeville, B., Salindre, J.J. and Mouly É. (2013)–Preparedness actions towards seismic risk mitigation for the general public in Martinique, French Lesser Antilles: a mid-term appraisal. Natural Hazards and Earth System Sciences 13, 2031-2039

Abstract Body: Martinique is a French Overseas island of the Lesser Antilles archipelago; it straddles the subduction of the North American plate beneath the Caribbean plate. This geodynamic position implies a high seismic hazard, and several strong intensity events have hit the island in the past until the recent 2007 earthquake (Mw = 7.4 and EMS98 int.VI–VII). Since 2006, Martinican stakeholders involved in seismic safety formed the "Réplik" ("Aftershock" in French) working group; it includes state and regional councils representatives, mayors, architects, geoscientists, civil defense and consultants specialized in media, communication and social psychology. This poster presents a mid-term appraisal of the seismic awareness campaigns organized by the Réplik group from 2006 to 2011, and how it has modified, or not, the public education and preparedness to a high magnitude earthquake.
Despite efforts from the Réplik team to improve its efficiency through surveys, a growing gap is noted between the reported awareness and the actual preparedness of the public. As observed elsewhere, gender, age, educational level, then boredom and saturation contribute to this discrepancy; strong cultural items probably also influence the perception of actions. To remain efficient, to respond to security standards and to public's expectations, Réplik actions must evolve: consideration of religion and local beliefs, comprehensive messages on TV and radio featuring families, use of Creole language, participatory experiences and drills, with only a little bit of science. So that, the Réplik campaign can hope to increase the Martinique public's efficiency and involvement into the preparedness process.

Title: Interactive Mapping of Mars (iMARS): A New Interactive Online Educational Resource

Presenter/First Author: Gordon Richard Osinski, University of Western Ontario, London, ON

Presenter/First Author Email: gosinski@uwo.ca

Co-authors: Melissa Battler, , , ; Tanya N Harrison, Malin Space Science Systems, San Diego, CA; Eric Pilles, University of Western Ontario, London, Canada; Haley M Sapers, University of Western Ontario, London, ON, Canada; Livio L Tornabene, University of Western Ontario, Washington, ON, Canada

Published Material: iMARS has been presented at two conferences in the past year.

Abstract Body: One of the major goals of The Centre for Planetary Science and Exploration (CPSX; http://cpsx.uwo.ca) at The University of Western Ontario is to strengthen and grow the Canadian and international space community through inspiring and training the next generation of scientists and engineers. With funding from the Natural Sciences and Engineering Research Council (NSERC) of Canada's PromoScience program and support from the Department of Earth Sciences at Western, the CPSX has developed a new web-based initiative called Interactive Mapping of Mars (iMARS). The centrepiece of the iMARS program is an interactive online activity in which users conduct and eventually plan missions to the Mars. To do so requires an understanding of the various landforms or features that shape the surface of Mars. iMARS integrates learning about the surface of Mars with the mission planning so that knowledge is gained in a fun and immersive way. Upon creating a simple login, users plan a series of series of increasingly complex mission scenarios, be-ginning with "Search for Ancient Riverbeds". Users collect badges along the way for successful completion of individual missions (Fig. 3). Ultimately, users are able to select and plan their own mission. Some key aspects are iMARS are: 1) users will learn the educational material as they go along, and earn rewards along the way; each mission will be designed to be only a few minutes long, to keep them interested and the missions as a whole will be designed to teach all of the surface features; they will get reward badges displayed in their user profile for accomplishments; after successfully accomplishing a number of missions, participants can design their own, with options including rover platform, etc. Training in image analysis and the recognition of landforms is provided through the Tutorial and Feature Example Pages. Once a mission is "launched," a mission control blog provides updates on the status of a mission and a "choose your rover" option provides the opportunity to unlock more advanced rovers by collaborating with other scientists and rating their missions.

Title: Twitter for Science Outreach: A Beginner's Experience of Communicating Fieldwork from a Remote Antarctic Glacier

Presenter/First Author: Trevor Williams, Lamont Doherty Earth Obs, Palisades, NY

Presenter/First Author Email: trevor@ldeo.columbia.edu

Co-authors: Rebecca Fowler, Lamont Doherty Earth Observatory, Palisades, NY

Abstract Body: Here we discuss the benefits of using Twitter to communicate the experience of doing geoscience fieldwork. Most of us will never visit Antarctica, but free social media tools, such as the micro-blogging platform Twitter, can increase understanding of the continent and research taking place there. In December 2014, a team of four from Lamont-Doherty Earth Observatory and Indiana University-Purdue University Indianapolis (IUPUI) spent three weeks based in Antarctica's remote Thomas Hills on a NSF-funded project to collect samples of rock debris from three of the region's major ice streams. We set up a Twitter account prior to the expedition with the aim of providing a window into the world of Antarctic science and fieldwork. Daily tweets, often with photos, shared the team's science activities, some of their initial findings, and a taste of life in Antarctica. An expedition hashtag, #AntarcticaG297, enabled Twitter users to follow along with the expedition narrative and ask questions. Photos and text were sent over a moderately reliable satellite phone data link and posted on Twitter by a communications officer at Lamont. This outreach initiative resulted in three outcomes: increasing awareness of the science goals and fieldwork with a broad audience of students, researchers, and the general public; facilitating dialogue between this audience and the scientists while they were at work in the field; and forging unexpected connections and collaborations with new colleagues in polar research.

Title: Creating Context for Learning About Minerals

Presenter/First Author: Erica Toni Williams, Retired, Maple Ridge,

Presenter/First Author Email: ericawil@telus.net

Abstract Body: Provincial science curricula tend to be disconnected theoretical and abstract little boxes, the complete antithesis of how we learn. An isolated Grade 7 Minerals unit will not lead to any significant learning of the connections with the multitudes of metal containing products that we use daily. We miss out the complex physics, chemistry and environmental issues of not just mining but of processing, extraction and refining of the metal, creation of alloys, of fabrication, pollution, recycling and community impact. At the end of the day we scratch our heads and continue with the same old practices of memorizing mineral properties, not realizing or understanding that by repeating traditional practices we are contributing to common disconnections with the bigger world.

Just attending a 3 h workshop on minerals for example will rarely lead to significant behavioral change in the classroom, as there will have typically been little contextual layering during the workshop process. Frequently the teacher goes away with an armful of goodies but on returning back to school my experience is that they just end up in a cupboard, and if they occasionally come out it is usually only to follow an isolated exercise in the textbook. The average teacher has not had a background of industrial processes through which they can embed context into their teaching. We have made little progress in trying to develop curricula that embed contextual multi-layered learning in our future populations. This in a time when some scientists are already deeply concerned about such issues as resource extraction, climate change and food supply in a world in which the population has increased 300% since I was born.

This session will describe a Grade 11 Science Unit focused on the processes by which common objects are made by developing a foundational approach to student understanding of the role of mineral resources in their daily lives. For evaluation each student had to choose a metallic object and present a report deconstructing how that object was made. Because of the lack of general print resources much of this research had to be done on line. For many students, it turned out to be a very powerful learning experience.

Title: Developing and Implementing Instruments for Measuring Scientific Reasoning Abilities using Online Intelligent Tutoring Systems

Presenter/First Author: Lev Horodyskyj, Arizona State Univ, Mesa, AZ

Presenter/First Author Email: LevH@asu.edu

Co-authors: Sanlyn Buxner, Planetary Science Institute Tucson, Tucson, AZ; Steven C Semken, Arizona State University, Tempe, AZ; Ariel D Anbar, Arizona State University, Tempe, AZ

Abstract Body: Evaluation of educational activities tends to focus on content knowledge, which is often relatively easy to evaluate. However, this is only one component of scientific reasoning and literacy. A student's inability to reason scientifically can be a result of high-level failures (linking concepts and building mental models), but can also be a result of low-level failures (basic literacy and numeracy). Different student difficulties require different interventions to help students succeed and ultimately improve scientific literacy in general education science courses, whether they are online, in-person, or hybrid.

Habitable Worlds is an introductory level online-only astrobiology lab course that has been offered at Arizona State University since Fall 2011. The course is built and offered through an intelligent tutoring system, Smart Sparrow's Adaptive eLearning Platform, which provides in-depth analytics that allow the instructor to investigate detailed student behavior, from time spent on question to number of attempts to patterns of answers.

Analysis of multiple semesters of course data has revealed deficiencies in lesson design, which have informed subsequent redesign efforts. Yet despite significant gains in content knowledge, we have failed to make gains in students' high-level concept comprehension. There are many points of failure between basic information and true concept comprehension, which we are currently not tracking. We are aiming to develop and will discuss our formal definition of scientific reasoning and literacy, its components, and metrics we can use to measure component competencies. This will allow us to develop a suite of generalized tools and activities that can be deployed in any context that can score a student's abilities in various core competencies before, during, and after a course to determine course effectiveness as well as provide instructors with deep insight into problematic skills for individual students.

Title: Science at Phoenix ComiCon: Connecting with a Science-Attuned Audience

Presenter/First Author: Lev Horodyskyj, Arizona State Univ, Mesa, AZ

Presenter/First Author Email: LevH@asu.edu

Co-authors: Sara I Walker, Arizona State University, Tempe, AZ; Jennifer H Forrester, University of Wyoming, Laramie, WY

Published Material: Concept of participating in a ComiCon and initial data were presented at AGU's fall meeting. 2015 programming details and more robust data interpretations will be presented here.

Abstract Body: The Phoenix ComiCon (PCC) is a rapidly growing annual four-day pop culture event, featuring guests, costuming, exhibits, and discussion panels for popular sci-fi, fantasy, horror, and anime franchises. The 2014 show, which drew 77,818 attendees, featured 30 hours of science programming, which were coordinated and organized by Horodyskyj. Programming consisted of discussion panels, mixers, and signature events on topics ranging from planetary sciences to biotechnology to artificial intelligence. Activities were staffed by industry specialists, early career and established scientists, and STEM outreach enthusiasts.

Some panels were surveyed to determine audience reception of the scientific topic and panel scientists. Preliminary results indicate that the audience who attended the science programming were enthusiastic about science and walked away with an extremely positive impression of the presenting scientists. Attendance at science panels was statistically indistinguishable from non-science panels, indicating that "science" was as big a draw for the attending audience as *Star Trek*, *Doctor Who*, or *Game of Thrones*. Anecdotally, a number of attendees, panelists, and PCC management tracked down Horodyskyj and other scientists to praise the science programming, some even months after the convention ended. For some attendees, the science programming was their exclusive reason for attending the PCC.

PCC and other events like it provide a unique opportunity for scientists to connect with a science-attuned audience through pop culture. Public outreach at these events may not convey deep content knowledge, but may be useful in connecting enthusiasts more deeply with the scientific endeavor and scientists themselves.

Title: Geoheritage Recognition in Canada and its Role in Defining Global Geoparks

Presenter/First Author: John Calder, Organization Not Listed, Halifax,

Presenter/First Author Email: jhcalder@gov.ns.ca

Co-authors: Godfrey Nowlan, , ,

Abstract Body: As biotic creatures, humans do not intuitively connect with the abiotic world of geology. Here lies the eloquent power of the concept of geoheritage, the best vehicle for bridging this fundamental divide. At the core of a successful and impactful geoheritage strategy is a methodically developed list of geoheritage sites, one that can be universally applied across the provinces and territories of Canada. The purpose of a geoheritage list is to build public awareness of their geologic heritage and its influence on a region's cultural history. Geoheritage provides the best vehicle for geoscientists to engage the public, to help people better value geology and the role of geoscience in our lives, including two great issues facing humanity: i) access and limits of mineral and energy resources, by increasing public awareness of the connections between our cultural heritage and geology; and ii) better understanding of current and future global change by consulting the geologic record. The concept of geoheritage was given form in Digne, France, in 1991, in the eloquent Déclaration Internationale des Droits de la Mémoire de la Terre. Early on, the concept was embraced primarily in Europe, where it fueled the explosion of European Geoparks. The Global Geoparks Network has now become truly international, and here in Canada is receiving growing interest from communities seeking truly sustainable, community-based economic development. Geoparks and geoheritage are linked, but are not synonomous. Geoheritage establishes the intrinsic value of a region of sites, and requires the deep knowledge of geoscientists. Global Geoparks draw their identity from those established values to draw people to the region. A well-founded list of geoheritage sites is therefore key to identifying prospective Global Geoparks and in defining a strong, identifiable theme that embues a specific Geopark with unique character that will also serve interpretation and marketing. As interest in candidate Global Geoparks grows across Canada, the need for systematic inventory of geoheritage sites is pressing.

Title: The Climate Voices Science Speakers Network: Connecting to Communities Through Non-partisan Conversations about Climate

Presenter/First Author: Kristin Wegner, University Corporation for Atmospheric Research, Boulder, CO

Presenter/First Author Email: kwegner@ucar.edu

Co-authors: Cynthia Schmidt, University Corporation for Atmospheric Research, Boulder, CO

Abstract Body: Scientific reports such as the National Climate Assessment (NCA) and the Intergovernmental Panel on Climate Change (IPCC) influence politics and inform the public about current scientific findings. But how can the general public connect with scientists to decipher this climate science research? And how can climate science research be used as a catalyst to meaningful community dialogues about climate change? Over the past two years, our Climate Voices Science Speakers Network (climatevoices.org) has grown to a robust network of nearly 400 speakers across the United States. In this presentation, we will discuss the various ways we have approached community groups, ranging from working with grassroots groups to establishing and fostering regional partnerships. We will present our processes of engaging in conversations with faith-based, service organizations, and general interest education groups to better understand how to meet the diverse needs of audiences. We will also share samples of techniques employed by our speakers, as well as some of the resources and "climate science coaching sessions" we provide to our network.

Title: Digital Tools for Teaching and Learning about Non-renewable Resources in the K-12 School System

Presenter/First Author: Eileen Van der Flier-Keller, University of Victoria, Victoria, BC

Presenter/First Author Email: fkeller@uvic.ca

Co-authors: Tim Pelton, , , ; Leslee Francis-Pelton, , ,

Abstract Body: Earth science topics are identified in school curricula in most jurisdictions in Canada. In addition, many informal education environments such as museums and youth groups include Earth science in their exhibits and activities. Formal and informal educational settings can both provide accessible environments for Earth scientists to engage with communities to share their passion for Earth science. Societally relevant earth science topics are diverse and include natural hazards, global change, non-renewable resources, energy, surface processes, and water. In many Canadian communities non-renewable resources are particularly relevant, providing important common ground for communicating about Earth science.

Building on hands-on activities and resources for engaging the public with non-renewable resources, we have developed a suite of digital tools which can be used in the classroom or in informal education settings to teach young people about non-renewable resources. The resources "Mining in BC: Interactive Map", "Canada Resources Map App", "Household Minerals App", and "Materials in a Bicycle App" have been presented and tested with teachers and informal educators, and modified based on their input. Comparisons will be made between the responses of teachers, and their students, to more traditional hands-on activities as compared with the digital resources. Benefits and drawbacks of these different delivery modes as mechanisms for engaging local communities with Earth science include variable access to good rock and mineral specimens in different educational environments, level of technology support and resourcing in schools, teacher comfort levels with Earth science topics, background materials available, and support from experts.

Title: EARLY WARNING SYSTEMS FOR CLIMATE CHANGE RELATED HAZARDS

Presenter/First Author: Asha Mutenyo Sitati, United Nations Environment Program, Nairobi,

Presenter/First Author Email: asha.sitati@unep.org

Published Material: The work was presented during the AGU Conference in San Francisco in December, 2014

Abstract Body: Early warning systems are a tool with which to minimize risks posed by climate related hazards. Although great strides have been made in developing early warning systems most deal with one hazard, only provide short-term warnings and do not reach the most vulnerable. This presentation will review research results of the United Nations Environment Programme's CLIM-WARN project. The project seeks to identify how governments can better communicate risks by designing multi-hazard early warning systems that deliver actionable warnings across timescales. Household surveys and focus group discussions were conducted in 36 communities in Kenya, Ghana and Burkina Faso in order to identify relevant climate related hazards, current response strategies and early warning needs. Preliminary results show significant variability in both risks and needs within and between countries. For instance, floods are more frequent in rural western parts of Kenya. Droughts are frequent in the north while populations in urban areas face a range of hazards - floods, droughts, disease outbreaks - that sometimes occur simultaneously. The majority of the rural population, especially women, the disabled and the elderly, do not have access to modern media such as radio, television, or internet. While 55% of rural populace never watches television, 64% of urban respondents watch television on a daily basis. Communities have different concepts of how to design warning systems. It will be a challenge for national governments to create systems that accommodate such diversity yet provide standard quality of service to all. There is a need for flexible and forward-looking early warning systems that deliver broader information about risks. Information disseminated through the system could not only include details of hazards, but also long-term adaptation options, general education, and health information, thus increasingly both capabilities and response options.

Title: What We Think About - When We Try Not To Think About - Global Warming: The New Psychology of Climate Science Communication

Presenter/First Author: Per Espen Stoknes, Norwegian Business School, Oslo,

Presenter/First Author Email: per.espen@stoknes.com

Published Material: Energy Research and Social Sciences (2014)
DOI: 10.1016/j.erss.2014.03.007

Abstract Body: Climate science has provided ever more reliable data and models over the last 20–30 years, thereby indicating increasingly severe impacts in the coming decades and centuries. Nonetheless, public concern for climate change and the issue's perceived importance has been declining over the past few decades, thus giving less public support for ambitious climate policies. Conventional climate communication strategies have failed to resolve this "climate paradox." This presentations reviews research on the psychology of the climate paradox, and rethinks and presents new original strategies for how to resolve it in the coming decades.

Understanding human responses to climate change is now at least as urgent as understanding climate change itself. The time has come for a climate science communication that works with, rather than against, human nature. The new strategies are social, positive, and simple—making climate- friendly behaviors easy and convenient. This presentation gives an evidenced based overview of the social psychological barriers and connected solutions to overcome them.

Title: The Ivory Tower of Song: Science and Live Arts Performance

Presenter/First Author: Sarah MB Beatty, McMaster University, Hamilton, ON

Presenter/First Author Email: beattysm@mcmaster.ca

Abstract Body: Science literacy is an important part of a well-functioning science culture. Community outreach helps to connect science and scientists with a wider public audience and nurtures science culture. Connecting, however, can be uniquely challenging for both scientists and the public; even when science literacy is high. Popular science publications, primetime television, and internet sources work directly or indirectly to communicate science concepts, discoveries and news to a broad public audience with equally broad interests. While useful in generating consumable science content, these mediums may sanitize the experience, limit the ability to engage, and fail to surmount underlying science literacy development needs – particularly in adults. Performing artists have a long history of presentation to audiences with diverse backgrounds. While the sciences and humanities are often considered disparate or culturally segregated subjects, many scientists are also performing artists (storytellers, comedians, musicians, dancers, thespians), presenting either professionally or in an amateur capacity. Such art practices already serve to communicate human experiences for artists and arts consumers, however, there is an opportunity to utilize these forms to 1) humanize and communicate contemporary science topics and concerns, and 2) increase interaction among science practitioners and the wider public.

Over the course of 100+ live performances, as a songwriter and a scientist, I have used music as a medium to communicate science and engage communities. By combining performance principles, artistic practice, and science language in an informal (non-institutional) setting, my work has facilitated discussions around complex scientific topics and personal science histories, while fostering meaningful interactions between scientists and the wider community. In doing so, science, particularly geoscience-based concepts have become more accessible, engaging, participatory, and transferrable in adult audiences that I interact with. In this presentation I will share personal anecdotes, examples, and relay practical insights on effective strategies that help to entertain, passively educate, and fully engage broad audiences through science songwriting and live arts performance.

Title: Mineral Project Disclosure on Web Sites and Corporate Presentations: The CSA's Perspective

Presenter/First Author: Luc Arsenault, Organization Not Listed, Montreal, QC

Presenter/First Author Email: luc.arsenault@lautorite.qc.ca

Abstract Body: L'Autorité des marchés financiers, the body mandated by the Quebec government to regulate the province's financial markets, will presents in this talk the requirements of *National Instrument 43-101 Standards of Disclosure for Mineral Projects ("NI 43-101")* as they apply to mining company websites and corporate presentations.

The knowledge and command of NI 43-101 is indispensable for any person working with mining issuers be it as a director, officer or as a geologist or engineer acting as qualified persons which mandate may include the review of an issuers' technical information.

The objective of this talk is to improve your knowledge of the NI-43-101 requirements in order to avoid situations where regulators are require to ask for the restating of previously filed documents.

Title: Quality control: An indispensable mindset in professional geosciences

Presenter/First Author: Réjean Réjean, Geoscientists IOS Services Inc, Saguenay, QC

Presenter/First Author Email: rejeang@iosgeo.com

Abstract Body: Implementation of a quality control program (QAQC) in exploration and mining project is a compulsory requirement in regard of NI 43-101 regulation. The necessity of this requirement is easy to understand considering the capital requirement of any of these projects, the inacceptable failure rate and the general lack of understanding of the consequences of errors by geoscientists. Brief review of NI-43-101 technical reports indicates that for most geoscientists, QAQC is merely synonymous of assays control. However, the rigorousness of data acquisition and verification is a process which needs to encompass any data acquisition, from drill core description to structural measurement. As example, calculating a resource, the ultimate geologist professional act, requires the multiplication of a volume, a density and a grade. While any NI 43-101 report describe extensively the controls on assays, description of the controls on density measurements are near inexistent. Error propagation needs to be understand, as well as the consequences of total error build-up on the decision making process. Thus, quality control shall be a mindset to any geoscientist, and shall be implemented to all level of data acquisition. Geoscientist must be educated regarding how errors are generated, both by human and machine, and how to test for and quantify these. Examples of catastrophic failures caused by minute errors will be presented.

Title: Investigating Geoscience Competencies for a Better-Prepared Future Workforce

Presenter/First Author: Heather R Houlton, American Geological Institute, Alexandria, VA

Presenter/First Author Email: hrh@agiweb.org

Co-authors: Michael Solem, , , ; Christopher M Keane, American Geosciences Institute (AGI), Alexandria, VA; Jamie Ricci, American Geosciences Institute, Alexandria, VA

Published Material: Some of these findings have been previously presented at AGU Fall Meeting 2014, GSA Annual Meeting 2014

Abstract Body: Competency-based education has been moving slowly beyond its roots in business and medicine and into STEM (Science, Technology, Engineering and Mathematics) disciplines. With the retirements of the Baby Boomers, and current and projected job growth, according to the Bureau of Labor Statistics (BLS), the American Geosciences Institute (AGI) estimates that there will be a deficiency of nearly 135,000 geoscientists by 2022, in the United States. Employers and recent graduates are consistently reporting critical gaps between degree outcomes and initial workforce readiness, which further complicates addressing the emerging talent gap. Starting to investigate and adopt competency-based education to aptly prepare our graduates with the practical skills needed to meet workforce demand is becoming an imperative for the geosciences. The National Science Foundation (NSF) awarded funding to AGI and the Association of American Geographers (AAG) to investigate what competencies are being taught by faculty, learned by students in non-PhD preparatory Master's programs, and in turn compare those to what employers currently in the geoscience workforce indicate as important to their careers. The project is titled Geoscience Career Master's Preparation Survey (Geo Career MaPS). This presentation will describe the results from this study and how AGI and AAG are using these data to help departments and administrators prepare students.

Title: Keeping Our Members Engaged and Informed – AIPG's Successes and Challenges

Presenter/First Author: Robert A Stewart, American Institute of Professional Geologists, Thornton, CO

Presenter/First Author Email: ras@aipg.org

Abstract Body: AIPG is an international organization, with nearly 8,000 members, of which about 3,000 are students and young professionals. This demographic split is very significant in terms of how AIPG can best serve all its members, and to do so, AIPG must stay in touch with them. Traditionally, AIPG relied on its journal, ***The Professional Geologist (TPG)***, to inform the membership of news and events. With the advent of the Internet and online publishing, plus financial pressures, the publication frequency of TPG (issues per year) dropped from 10 in 2003 to four in 2014. AIPG established its eNews in 2013, which has been popular in its own right, without duplicating the contents of TPG. AIPG contemplated discontinuing the print version of TPG altogether; however, print media are recovering in popularity, due partly to the blizzard of online information leading to an overwhelmed audience. The print version of TPG has also been an excellent marketing "take-away" at conferences and trade shows.

Over the past decade, AIPG has developed a variety of programs to attract and engage our student members and also young professionals in their early careers, based on our student chapters. AIPG's programs for students have been highly successful due to the efforts of our established members, who volunteer their time to organize field demonstrations of geologic tools for field sampling and analytical testing, and trips to observe the practice of geology at mines, quarries, environmental restoration sites, and other venues. Also popular are conferences and colloquia dealing with professional practice and geoethics, allowing younger members a chance to discuss such matters with practitioners an informal basis. Of specific interest to students and practitioners are the disciplinary procedures and sanctions that may affect geologists through government licensure or private certification, such as the Certified Professional Geologist (CPG) granted by AIPG. Although the subject matter varies, all events have proved thoroughly rewarding to our younger participants and older volunteer members.

The key to these successes is the generosity of our volunteers, which is also one of our greatest challenges – finding the volunteers. With age comes a wealth of experience, an invaluable asset to be shared with future geoscientists.

Title: Are Professional Geoscientists Equipped to Assume their Social Responsibilities?

Presenter/First Author: Jan A. Boon, Carleton University, OTTAWA, ON

Presenter/First Author Email: jboon@nrcan.gc.ca

Abstract Body: The social responsibility of organizations is to take responsibility for their social impacts on society, which requires that their employees are capable of acting in a socially responsible manner. This should apply especially to professional employees. Most of the problems on which professional geoscientists work have a social dimension, for example social conflicts may develop in relation to mineral exploration, groundwater, civil engineering, baseline geochemical studies and other projects. In all cases, there is significant potential for conflicting expectations and conflicting understandings, and often the actors involved adhere to widely different value systems. As earth underpins all human activity and has an important influence on cultural and social beliefs and practices it is not surprising that geoscientists' work frequently exposes them to social issues and associated struggles.

Are geoscience professionals ready to take responsibility for their social impacts on society? Much anecdotal evidence from my field of study (mineral exploration) suggests that while there are examples of stellar performance, there seem to be many more examples of lack of awareness and understanding that led to serious but avoidable problems. The Geoscientists Canada document "The Geoscience Knowledge and Experience Requirements for Professional Registration in Canada" makes no reference to social responsibility and scant reference to "geoscience and society". In view of this it is lamentably improbable that geoscientists' studies have prepared them to face social situations. Many risk making social mistakes that cause anxiety and grief to members of society and that can be very costly to their employers.

An impressive body of knowledge in Corporate Social Responsibility (CSR) has been developed and it is time to incorporate this treasure of knowledge into the education and capacity building of geoscience professionals, and into their professional profile. The Canadian Institute of Mining and Metallurgy (CIM) has established a Working Group to promote this concept for both engineers and geologists. It has been more difficult to "get this show on the road" than initially anticipated and any advice is appreciated.

Title: SHOULD PROFESSORS TEACHING GEO STUDENTS TO BECOME P.GEO.'S, BE P.GEO.'S THEMSELVES?

Presenter/First Author: Gord White, Association of Professional Associations of Ontario, Toronto, ON

Presenter/First Author Email: gwhite@apgo.net

Abstract Body: Across Canada, Professional Geoscientists are regulated in ten jurisdictions. Through Geoscientists Canada, a set standard of general knowledge and experience requirements are set. This standard is accepted through all jurisdictions – to be accepted in one is to be accepted in all. This is a common approach with many professional designations in Canada.

It is also common in Canada and elsewhere that students are taught by accredited professionals for many of these professional designations. Lawyers to be are taught by lawyers. The same goes for engineers and doctors. These professions would see it as contraindicated to not have a licensed professional teach the next generation.

This is not the case for geoscientists. At least not in Ontario. Few Professional Geoscientists instructing tomorrow's P.Geo.'s are actually P.Geo.'s.

Issues to be discussed:

- Is it important that professors teaching geo students to become P.Geo.'s be P.Geo's?
- If it is important, how do can this issue be resolved going forward?
- Is there common ground between those that regulate Professional Geoscientists and those that train them?

The purpose of this session is to open this discussion, seek out different points of view, and purposely set a directional course. Opinions welcomed.

Title: Geoscience Knowledge Requirements for Professional Registration: A 2015 Primer for Undergraduate and Graduate students as to the Use of the GKE Document

Presenter/First Author: Kevin Michael Ansdell, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: kevin.ansdell@usask.ca

Co-authors: Cliff Stanley, , ,

Abstract Body: A goal for many geoscience (geology, geophysics, environmental geoscience) students in Canada is to become a Professional Geoscientist (PGeo) in order to practice as a licensed professional.

Requirements for professional registration are tabulated in the "Geoscience Knowledge and Experience Requirements for Professional Registration in Canada" (GKE). This document, developed by the Canadian Geoscience Standards Board, a committee of Geoscientists Canada (GC), provides a comprehensive summary of the foundation and elective science and geoscience curricula and work experience considered to be appropriate background for licensure as a PGeo. This presentation outlines how regulators across Canada use this document, which will be of interest to students. In addition, information will be provided on a recent project undertaken by GC designed to outline the skills or competencies that a PGeo should have by the time of registration. This may include the completion of a particular course or set of courses during a B.Sc. program; others may be demonstrated via specific work experience.

The fundamental assumption in the GKE is that geoscience knowledge is gained through the equivalent of a 4-year BSc. degree in Canada, which includes 9 courses in "foundational" science (e.g. chemistry, physics, mathematics), and 18 courses in specific "foundational geoscience" subjects. In Quebec, the provincial regulators have accredited the programs at Laval, McGill, UQAC, and UQAM. Elsewhere, there is no formal accreditation process and so local regulators develop a list of courses that are available in their province that cover the required areas. This set of courses is used as a check list for each individual applicant. Students who might not have majored in geoscience, but who have taken the necessary courses can satisfy the requirements for registration. Also, part of the time in a graduate program may count towards the geosciences experience requirement for registration.

Title: Course Promotion for Ethics, Culture and Community-based Research for Graduate Student Training.

Presenter/First Author: Dianne P Quigley, Brown University, Wrentham, MA

Presenter/First Author Email: Dianne_Quigley_1@brown.edu

Published Material: Quigley, D. (2013) Promoting Human Subjects Training for Place-based Communities and Cultural Groups in Environmental Research – Curriculum Approaches for Graduate Student/Faculty Training. , *Science and Engineering Ethics*, Springer Science+ Business Media Dordrecht 2014 Under Review at Journal of Environmental Studies and Sciences: " Research Ethics and Cultural Competence Training for Environmental Research with Place-based Communities and Cultural Groups: Reflections from a Collaborative University Partnership Dianne Quigley, PhD, Adjunct Assistant Professor, Center for Environmental Studies, Brown University, Providence, RI* David A. Sonnenfeld, PhD, Professor of Environmental Studies, State University of New York College of Environmental Science and Forestry, Syracuse,NY Phil Brown, PhD, Distinguished Professor of Sociology, Northeastern University, Boston, MA Linda Silka, PhD, Professor of Community Psychology, University of Maine, Orono, ME Linlang He. Graduate Assistant, Brown University Qing Tian, Graduate Assistant, Brown University Under Review at Society for Natural Resources. Cultural Competence/Humility Applied to Environmental Sciences, Diann Quigley

Abstract Body: Abstract for Course Promotion for Ethics, Culture and Community-based Research for Graduate Student Training.

The Northeast Ethics Education Partnership (NEEP), at Brown University has developed course syllabi and curriculum materials for two new graduate courses in Ethics, Culture and Community-based Research for Environmental Studies/Sciences and Marine Science Ethics. NEEP is funded through the National Science Foundation (NSF) Ethics Education in Science and Engineering (EESE) Program. NEEP has developed short and long graduate courses and Certificate Training for research ethics, cultural competence, community-based research for environmental studies/sciences at Brown University, SUNY-ESF, Northeastern University and UMASS-Dartmouth. Additionally, NEEP has developed ethics courses for engineers at the above universities.

We would like to share our new course syllabi and PowerPoint training materials with other research scientists/teaching faculty to gain feedback on critical ethical challenges facing environmental sciences/studies and marine sciences for field research in place-based communities and with cultural groups. It is part of our NSF grant objectives to disseminate our work on training graduate students. We can provide an overview of our training emphases and a selection of these slide shows: individual/group human subjects protections, cultural competence for working with communities, informed consent with cultural groups, community-based research, environmental justice, ethics of sustainability, environmental ethics and research integrity in these various geosciences. This presentation can include critical reasons for conducting ethics training for graduate students who will conduct field studies in place-based communities so that researchers will maximize beneficence, reduce research risks/harms, allow commuinity consulation and partnership approaches and mimimize exploitation and unfair burdens/benefits.

Title: A Pilot Study: Integrating Ethical Issues to a Physical Geology Course

Presenter/First Author: Catherine Pappas Maenz, Dawson College, Montréal, QC

Presenter/First Author Email: cpappas@dawsoncollege.qc.ca

Abstract Body: There is a strong consensus amongst science educators that inclusion of ethics in sciences is necessary for the development of students into science professionals and well-rounded citizens. We need also to realise that science is changing rapidly, not only in its research techniques and organisational structures but also in its relationships with society at large. Overall ethical issues are either lacking or not sufficiently introduced in most geoscience courses. Undergraduate students should be adequately trained in ethics either within their earth science courses or in a specialized course elsewhere in the curriculum. The author is part of a working group involved with developing geo-ethical resources for geosciences. A pilot study was conducted at Dawson College using a new approach for teaching physical geology by integrating an ethical dimension to an existing physical geology course. This initiative incorporated case studies and class discussions to stimulate students to think creatively and critically about ethical issues emerging from a variety of geological topics. The primary objective being to increase students' awareness of ethical issues and dilemmas in many areas concerned with geology. The discussions and case studies were introduced during a two-hour "laboratory" period. The longer class period allowed students to watch a short video followed by a short discussion, or read through a short case study followed by small group discussions. The focus was on understanding the differing viewpoints of individuals within a case and identifying multiple courses of action for resolving the issue. The results of the ethics component to the existing course curriculum were assessed via a student survey. All students agreed that their awareness of ethical issues in earth science was enhanced by the inclusion of ethics and that there is a great need to include ethics in geology.

Title: Connecting pedagogy to geology and ethics

Presenter/First Author: Anne Marie Ryan, Dalhousie University, Halifax,

Presenter/First Author Email: amryan@dal.ca

Co-authors: Carl-Georg Bank, University of Toronto, Toronto, ON, Canada

Abstract Body: The interface of ethics and geoscience, **geoethics**, links the science of geology directly with its societal responsibilities and connections. In a recent study the authors asked anonymous participants to suggest ways to teach geoethics in an undergraduate program. Responses varied from some suggesting that geoethics is not the perview of academic studies in geology, to those regarding it as an important aspect to include in the undergraduate curriculum. This latter group offered a variety of approaches for how best to achieve this. Among the suggestions raised were: use of case studies (either within a dedicated course or integrated into other courses), role-play, a course co-taught by experts from different disciplines, a series of seminars or workshops, use of professional ethics criteria as a starting point, and integration of ethics into specific courses such as mineral deposits or environmental geoscience courses. However, to be effective, it is not sufficient to simply link the geologic with the societal: it is important to also consider the pedagogical aspects of geoethics. The way in which we teach geoethics is crucial to effectively incorporating and encouraging geoethical behavior into disciplinary practice in its various forms. We review guiding principles to consider, both in terms of learning stages as well as content to include. These considerations involve: the development of decision-making skills, the fostering of critical thinking approaches to problem-solving, the importance of developing courage, open-mindedness, and tolerance for ambiguity, the significance of being cognizant of the societal implications of our science, and the concept of our own responsibility in working for the greater good.

Title: Seeking Community Input to a Modular Course on GeoEthics

Presenter/First Author: Vincent S Cronin, Baylor University, Waco, TX

Presenter/First Author Email: Vince_Cronin@baylor.edu

Co-authors: Anne-Marie Ryan, , , ; Giuseppe Di Capua, INGV-National Institute of Geophysics and Volcanology, Rome, Italy; Nancy McHugh, Wittenberg University, Springfield, OH; Cindy M Palinkas, University of Maryland Center for Environmental Science, Cambridge, MD; Catherine Pappas Maenz, Dawson College, Montréal, QC, Canada; Silvia Peppoloni, National Institute of Geophysics and Volcanology, Rome, Italy

Published Material: This author group presented a poster at the AGU Fall Meeting 2014 describing the idea of developing a modular course on geoethics. This presentation focuses more on our efforts to solicit input from the geoscience community related to that course. The overlap is primarily in the initial description of the course we are developing.

Abstract Body: Communities are defined in many ways: kinship, culture, common interests, shared sense of purpose, a common understanding of behavioral norms. The geoscience community is no different. Given the dynamic nature of the geosciences, ours is a vibrant community whose intellectual progress benefits all humankind.

It is the persistent responsibility of members of this community to articulate and share our ethical norms with students who are developing as geoscientists. It is also essential to help them develop an ability to assess and critically evaluate those values. There are enough examples of unethical choices made by geoscientists to warrant a more deliberate effort to promote the ethical development of geoscientists while they are still students.

We are engaged in a project to develop, test and make available educational resources to help geoscience students develop into ethical members of our community. We intend to develop these resources across the spectrum ranging from very compact activities (texts, discussion prompts, videos, writing projects) that might take just a few minutes of class time, all the way up to an entire course on geoethics. We recognize that shorter activities are easier to assimilate into existing courses throughout the geoscience curriculum, but we also recognize the utility of developing activities that might take an entire class period, or multiple classes, or a week or more. We plan to develop modules of 1-3 week duration on a variety of topics in applied geoethics that can be combined to form an entire course.

Our most important task at present is to gather input from members of the geoscience community about their ethical concerns. What ethical lapses seem to be common? What ethical issues are most important because of the significance of their effects? We learn from our mistakes, so we seek case studies that involve ethical choices by geoscientists. We recognize that there are ethical issues that are specific to particular segments of our community (participants in higher education and academic research, various types of applied geologists, regulators). These are no less important because they might not be universal. Accounts of ethical problems and concerns, provided to us by the broader geoscience community, are essential if we are to develop resources that are relevant to current practice.

Title: Aldo Leopold, Deep Time, and the Ethics of Geoscience

Presenter/First Author: Gary David Rosenberg, , ,

Presenter/First Author Email: Grosenbe@iupui.edu

Published Material: Another aspect of this presentation was delivered orally at GSA Vancouver. That presentation focused on the evidence for Aldo Leopold's interest in deep time, but it did not focus on deep time as the basis of the ethics of geoscience and the consequence for the ethics of the science as a result of the diminishment of historical geology in the geology curriculum. None of this has yet been submitted for publication in a scientific journal.

Abstract Body: The concept of deep time is central to geoscience and its ethical concerns. The geologic record indicates that natural resources formed long ago over time spans vastly exceeding the lifespan of civilizations, under conditions that may no longer be extant, and in limited abundance that is never uniform among or within nations. Further, extracted resources are often out of equilibrium with, hence labile in and hazardous to, the existing environment that differs from the primordial environment in which the resources formed.

In other words, geologic history explains why natural resources are limited, non renewable, subject to depletion, and their use is not sustainable. The question is how to reconcile our need for them with the lessons of geological history?

Aldo Leopold raised this question in his book (1949), "A Sand County Almanac." His complaint was the excessive commodification of natural resources. He found the rationale for environmental stewardship in the evolution of the Earth and life. He could not have been more explicit about the ethics of deep time when he wrote that in our appreciation of geologic history "lies objective evidence of our superiority over the beasts."

Appreciation for deep time needs to be instilled in students from the start of their geology curriculum and reinforced throughout because it takes years to internalize and then apply to a career reconciling needs with geological realities.

Unfortunately, historical geology has become marginalized in the curriculum. Historical classes are disappearing and the enrollments have plunged. Consequently publishers are reluctant to produce historical texts even for the majors curriculum. As though immersion in fundamentals and active participation in the process of historical thinking are no longer material to the science.

If geoscience forsakes historical geology it will forsake its unique contribution to ethics, beginning with environmentalism.

Title: Global Geoscience Professionalism - The Importance of Building a More Connected Professional Community and The Role of Professional Geoscience Organizations in Supporting How Geoscientists Can Better Serve Society.

Presenter/First Author: Oliver Bonham, Geoscientists Canada, Burnaby, BC

Presenter/First Author Email: obonham@geoscientistscanada.ca

Co-authors: Ruth Allington, , ,

Published Material: This presentation has not been given, or published, before, but it will cover matters that are either public policy or matters that may already be in the public domain. It parallels, in-part, a related contribution submitted for presentation at the European Geosciences Union, General Assembly meeting in Vienna, in April 2015 (Allington and Fernandez).

Abstract Body: In 2012, the International Union of Geological Sciences (IUGS) formed the Task Group on Global Geoscience Professionalism ("TG-GGP") to bring together the expanding network of organizations around the world whose primary purpose is self-regulation of geoscience practice. TG-GGP was also formed to foster a new "connecting up" of geoscience globally, around the concerns common to academia, industry, and government service: competence, ethics and professional accountability.

This talk will briefly introduce TG-GGP and will summarize the status of self-regulation of geoscience around the World. It will describe established approaches to setting minimum professional standards and assessing practice competence, codes of ethics and conduct, and obligations of the professional in a number of settings. It will touch on mechanisms to handle complaints and impose professional discipline. It will also explore how the emerging academic study of geoethics might best inform, and be informed by, the promotion and support of competent, professionally accountable and ethical geoscience practice.

Codes of Ethics, to which all registered professionals are bound, incorporate such foundational tenets as: safeguarding the health and safety of the public, scientific integrity, and fairness. Codes also increasingly include obligations concerning welfare of the environment and sustainability.

While legal regimes for the oversight of professions differ around the world, principles of peer-based self-regulation universally apply. This makes professional organizations ideal settings for geoscientists to openly consider what Society should expect of us in the range of roles we fulfill. They also provide the structures needed to best determine what expectations, in the public interest, are appropriate for us to collectively impose on each other as fellow professionals.

Title: Social Responsibility in Mineral Exploration - Lessons from Nine Case Studies

Presenter/First Author: Jan A. Boon, Carleton University, OTTAWA, ON

Presenter/First Author Email: jboon@nrcan.gc.ca

Published Material: The AGU presentation is based on my Ph. D. thesis that I will defend soon. I have used bits of my thesis research in presentations at Argentina Mining and to general audiences in Buenos Aires at events organized by the Canada-Argentina Chamber of Commerce in cooperation with the embassies of Canada and Australia

Abstract Body: Nine case studies of mineral exploration projects in Canada, Mexico, Ecuador, Peru and Argentina were conducted, involving over 220 interviews of members of the various actor groups. The results were analyzed and interpreted using a sociological theoretical framework. It was found that relationships exerted a significant influence on the course of social events and on the perceived present and future benefits and harms of mineral exploration projects. Key concepts used included: meeting transactional needs; trust building; meanings; reference communities; identities and relationships. Relationships were successfully operationalized using the indicators trust; respect; communication; mutual understanding; conflict resolution; goal compatibility; balance of power; focus; frequency; stability; and productivity. These indicators clearly differentiated the cases. The "scores" on the relationship indicators resulted from the underlying processes: meeting transactional needs and implementing the trust building dimensions: visibility; sincerity and personalization; showing face; and establishing routines. A seven-stage generalized model was developed that describes the sociological processes leading to the development of relationship patterns and new social structures surrounding mineral exploration projects, and determining the course of social events and the perceptions of present and future benefits and harms. The processes at the core of the proposed model are: creating dialogue space that enables meeting transactional needs; developing relationships; and continual adjustment of meanings through interactions. It is argued that knowledge and application of these social aspects is essential to the overall success of an exploration project if not more so, than is detailed knowledge of the geology of an area and of hydrothermal alteration processes. While the present study focused on mineral exploration, similar observations would apply to many other areas in which the geosciences find application. Unfortunately the present accreditation criteria for geoscientists do not touch on social responsibilities.

Title: Hydropower Influences on River Ice Dynamics and Channel Morphology: A Matter of Thermal and Flow Scales

Presenter/First Author: Robert Ettema, University of Wyoming, Laramie, WY

Presenter/First Author Email: rettema@uwyo.edu

Abstract Body: Hydropower development of a river raises questions regarding the influences of the development on ice dynamics and channel morphology in the river downstream: Will the development change ice dynamics in the river; if so, how? If the changes are substantial, how will the modify channel morphology of the river; if so, how? My paper addresses these questions and shows how these questions revolve around the relative scales of thermal and flow processes at the development site. In simple terms, the scales define the volume of ice formed in the river relative to the volume of water flow passing through the channel during winter. Hydropower may alter the relative magnitude of the two scales, typically doing so by changing the quantities of water and water-borne heat entering the channel during winter. At the extremes of a hypothetical gauge formed by the relative magnitudes of the two scales, hydropower exerts little influence on river ice processes and channel morphology, because the volume of water flow dwarfs the volume of ice formed (large river, lower latitude), or conversely the volume of ice dwarfs the volume of water flow (small river, higher latitude). However, hydropower shifts the relative scales of ice and water, moving river conditions to a more dynamic, middle region of the gauge. When such a shift occurs ice potentially becomes a more active agent in shaping channel morphology, as it affects the distribution of an erosive flow, and the flow in turn has sufficient force to drive ice against channel boundaries. The nature of the material forming channel boundaries plays a substantial role limiting the extent to which the river ice and water flow influence channel morphology. More resistant boundary material will withstand higher levels of abrasion by water flow and ice, while boundaries formed in alluvium and weak soils are less able to do so. My paper discusses the hypothetical gauge concept and suggests topics for research.

Title: Defining the state-of-the-art cold regions river engineering practice with fluvial morphology concepts

Presenter/First Author: Benoit Turcotte, Organization Not Listed, Québec,

Presenter/First Author Email: benoit.turcotte@gci.ulaval.ca

Abstract Body: Cold region river engineers work in an environment that is rarely accurately defined in textbooks. In cold countries, the formation of ice at the drainage system scale can depress the downstream discharge by over 50%, hydro-production peaking can generate a river ice breakup event, frazil ice can block water intakes, about 30% of all flooding events are caused by ice, the development of an ice jam may cause the water level to rise faster than 1 m/min, and ice jam release events can generate flow velocities up to 10 m/s. From freezeup to breakup, multiple river ice processes directly affect sediment transport rates, sediment supply and the overall stability of cold region channels. Because hydraulic conditions can explain the occurrence of specific ice processes, it is logical that a retroactive link exists between such winter processes and the morphology of a channel. This link has been documented in recent years and it is now possible to predict how an ice cover will form along a given channel knowing its morphology and simple climate parameters.

The impact of this research advance on cold regions river engineering is significant. Indeed, understanding the retroactive link between ice processes and the channel morphology fills up a gap in the engineering practice because identifying potential ice cover formation and breakup patterns is the first important step towards (1) the efficient monitoring of river ice processes using field instrumentation, (2) the accurate simulation of river ice processes using numerical ice-hydrodynamic models (in which multiple parameters need to be imposed) and (3) the appropriate design of hydraulic structures (for flood protection, transportation, hydro production, water consumption, ice control, etc.) and floodplain infrastructures (flood resilient constructions, transport systems, etc.). In past decades, the overdesign, failure, low efficiency, or unexpected undesirable effect of hydraulic and floodplain infrastructures due to river ice processes could be excused by a lack of scientific knowledge. In a nearby future, with the advances now documented in this field, cold region river engineers will become liable for their designs and decisions. Fluvial morphology concepts undoubtedly represent an important piece of the state-of-the-art cold regions river engineering puzzle.

Title: A Numerical Model for Ice Influenced Sediment Transport and Bed Change

Presenter/First Author: Ian Michael Wood Knack, Clarkson University, Potsdam, NY

Presenter/First Author Email: iknack@clarkson.edu

Co-authors: Hung T Shen, Clarkson Univ, Potsdam, NY

Abstract Body: The presence of surface ice has significant effects on sediment transport and channel morphology. Studies on the interaction of sediment transport and surface ice are limited although it can be a significant period of bed change for rivers in cold regions. An improved understanding of the interaction of surface ice and sediment transport processes is essential for river engineering and morphological studies. This paper presents a two-dimensional coupled hydro-thermal-ice-sediment river dynamics numerical model. The ice model component considers the dynamics of ice transport and ice cover evolution, as well as thermal processes. The thermal component includes water temperature, frazil ice, anchor ice, and the thermal growth and decay of ice cover. The sediment transport and bed change model considers the effect of surface ice and water temperature on sediment transport capacity. The sediment transport equations were developed from an analysis of data from existing flume experiments, each with a limited range of flow, ice, and sediment transport conditions. The analysis showed that by expressing the flow strength in terms of the bed shear stress, bed load transport can be described by conventional relationships for the equivalent free-surface flow. It was also found that suspended sediment transport rates can be calculated using a modified Rouse formulation which considers the effect of surface ice on flow velocity and diffusion coefficient. Examples of simulations using the numerical model illustrating the ice effects on sediment transport and bed changes in ice influenced alluvial channels are presented.

Title: MODELING RIVER ICE DYNAMICS USING MIKE11-ICE

Presenter: Tristan Aubel, Lasalle | NHC, Montreal, QC

Presenter Email: taubel@lasallenhc.com

First Author: Wael Taha, Northwest Hydraulic Consultants, Montreal,

First Author Email: wtaha@lasallenhc.com

First Author Student?: No

Co-authors: Isabelle Theriault, , ,

Abstract Body: Over the past decade, the close collaboration between LaSalle | NHC, Hydro-Québec and DHI Water&Environment has led to the joint development of river ice modules for the MIKE11 hydrodynamic modeling package, which represents today a state-of-the-art hydraulic modelling tool of Nordic rivers. Two separate modules were developed, the first is for ice generation, transport and accumulation, while the second for formation of ice jams. The ice generation, transport and accumulation module couples the unsteady, one-dimensional St. Venant flow equations with river ice processes. It simulates ice formation in a stretch of river throughout an entire winter season. At every time step and at every point along the river, the model makes a full balance of thermal exchanges between the water, the atmosphere, and stationary or moving ice. The net balance between the gain and loss of heat brings about changes in both water temperature and frazil production that is used to compute the ice discharge – all within the context of the growth of border ice. Typical studies performed with this module are concerned with problems related to flooding due to the formation of hanging dams, water level increase due to the presence of ice in a river reach, ice accumulations on surfaces due to supercooling and the extents and thicknesses of the ice cover for snowmobiling. The second module is for modeling the formation of ice jams following the breakup of an ice cover. The module formulation is based on a stationary mechanical stability of the jam transverse sections, enabling to calculate the ice jam geometry at a specific location along with the resulting water surface elevation profile and velocities. The studies performed with this module cover essentially winter and spring flooding problems caused by ice jams. Typical applications are presented for both modules.

Title: Tree rings as indicators of ice jam regimes, triggering conditions and geomorphological impacts : the case of the Mistassini River (Eastern Canada)

Presenter/First Author: Etienne Boucher, GEOTOP-UQAM, Montreal,

Presenter/First Author Email: boucher.etienne@uqam.ca

Co-authors: Stephanie Morin, , , ; Annie Lagadec, , , ; Thomas K Buffin-Belanger, University of Quebec at Rimouski UQAR, Rimouski, QC, Canada; Daniel Germain, , ,

Abstract Body: Tree ring records provide invaluable sources of information concerning river ice jam dynamics. They can help researchers rely on a robust spatio-temporal framework that facilitates the analysis of triggering conditions, frequency-magnitude relationships, and geomorphological impacts associated with such extreme events. Here, we provide field evidences that dendrochronological markers have contributed to shed light on river ice jam dynamics in the Mistassini River watershed (Eastern Canada). First, an exhaustive sampling of ice scars along the banks of this highly problematic river revealed that hydro-climatic conditions prevailing during both freeze-up and break-up periods have a tremendous influence on the triggering of river ice jams in the watershed. Based on such relationships with climate, a predictive classification model was constructed and accurately predicted 88% of the events that occurred in the Mistassini River since AD 1960. Second, dendrochronological surveys were coupled to an extensive geomorphological description of river banks. This allowed linking the occurrence and distribution of ice-induced landforms to the properties of the ice jam regime (mostly downstream changes in frequency – magnitude). Among other things, our analysis revealed that extensive ice-related erosion did not necessarily occur where ice jams were the most frequent, but is maintained where events had the greatest magnitude. Our works revealed that tree ring markers may provide a strong basis that can orient risk management strategies, particularly in context where observations of past ice jams are scattered, if not inexistent.

Title: Under ice cover roughness and flow structure.

Presenter/First Author: Thomas K Buffin-Belanger, University of Quebec at Rimouski UQAR, Rimouski, QC

Presenter/First Author Email: thomas_buffin-belanger@uqar.ca

Co-authors: Sylvio Demers, University of Quebec at Rimouski UQAR, Rimouski, QC, Canada; Taylor Olsen, University of Quebec at Rimouski UQAR, Rimouski, QC, Canada

Published Material: Data were presented at the ACFAS meeting in Montréal in 2012. The presentation was in french.

Abstract Body: Quantifications of under ice roughness and flow structure under an ice cover are scarce but relevant to analyse the effects of ice cover on flow dynamics and to validate flow modelling. This paper documents the turbulent flow structure and the under ice cover roughness on two gravel-bed rivers. An ADV was used to measure twelve velocity profiles under various types of ice covers. A clear double turbulent boundary layer appears in most velocity profiles with an increase in turbulent intensity near the ice cover. Upstream from each velocity profile, the ice cover was subsequently exposed and scanned using a terrestrial laser to quantify the ice cover roughness. The under ice covers reveal great variability of forms that promote various scales of roughness. Forms are described and roughness is quantified by semivariance analysis. The under ice cover roughness affects the flow properties. The location where the highest velocity is found is further away from the ice cover when roughness is high, but the ice cover shear stress is not related with the under ice cover roughness. Scenarios describing the turbulence dynamics and structure of the boundary layer are proposed and discussed in the light of roughness conditions encountered in this study.

Title: Sediment Tracking Throughout the Winter and Spring Breakup in a Gravel-bed River

Presenter/First Author: Daniel Alexandre Bleau, University of Sherbrooke, Longueuil,

Presenter/First Author Email: daniel.bleau@usherbrooke.ca

Co-authors: Jay Lacey, , , ; Robert Leconte, University of Sherbrooke, Sherbrooke, QC, Canada; Normand Bergeron, INRS, Quebec, QC, Canada

Abstract Body: A field study was conducted on two different reaches of a gravel-bed river (Stoke River) located in the Eastern Townships, Québec, Canada. The study was performed to quantitatively assess the mobility of the bed sediments due to ice. At both sites, PIT tags were placed in the river bed and were tracked via a dual antenna system. Fixed antennas were placed in the river bed and were connected to a data logger in order to follow the tagged particles over the winter and spring breakup. To complement this system surveys were made with a mobile antenna in order to measure the exact movement of the particles. The redundancy of our methodology was useful to overcome the difficulties of surveying tagged particles during winter time. This was especially effective during the spring thaw, at a time where most rivers are too active to be surveyed. The fixed antenna recorded, though not as precisely as the mobile antenna, the time of arrival and departure of each moving marker. After the water level decline, surveys with the mobile antenna were performed to record the precise location and 3D displacement of the marker. The only downfall of the fixed antenna system is in order to gain more precision (denser grid), a denser fixed antenna system is required, along with a higher number of equipment (batteries, loggers, antennas, etc.) which are difficult to maintain at a sufficient power level during winter time.

Title: Influence of Dynamic Ice Cover on Sediment Transport in an Alluvial Channel

Presenter/First Author: Soheil Ghareh Aghaji Zare, University of Ottawa, Ottawa, ON

Presenter/First Author Email: soheil.zare@uottawa.ca

Co-authors: Stephanie Astrid Moore, University of Ottawa, Ottawa, ON, Canada; Colin D Rennie, University of Ottawa, Ottawa, ON, Canada; Ousmane Seidou, University of Ottawa, Ottawa, ON, Canada; Jarrod Malenchak, , , ; Habib Ahmari, , , ; Saber Ansari, , ,

Published Material: 1. 21 st Canadian Hydrotechnical Conference- 2013- Published2. IAHR congress - 2013- Published3. River Flow conference- 2014- Published4. IAHR Ice symposium- 2014- Published5. ASCE journal of Hydraulic Engineering- under review6. Journal of water resources researches - under review

Abstract Body: Dynamic ice cover alters flow in ice covered rivers by adding a new boundary to the top of the stream. River hydraulics vary as a function of ice cover presence and condition. Amongst the important hydraulic characteristics influenced by ice cover, velocity magnitude and distribution, water stage and boundary shear stress are particularly consequential. Variation of these parameters has potential to affect the channel morphodynamics and morphology due to changes in sediment initiation and transport. On the other hand, dynamic ice cover conditions throughout the winter restrict field studies and thereby limit most research to laboratories. Hence, despite the importance of ice cover processes on river morphodynamics, it is poorly studied in rivers. This research studies ice cover effects on river hydraulics and morphodynamics by *in-situ* field investigations using acoustic techniques. Utilization of acoustic instruments provides the possibility of continuous measurement of water velocity and stage throughout the winter period. A 1200 kHz Teledyne RD Instruments Acoustic Doppler Current Profiler (ADCP) and 546 kHz ASL Shallow Water Ice Profiling Sonar (SWIPS) were deployed simultaneously on a bottom mount at Lower Nelson River, Northern Manitoba for four months (March-June, 2012). Different stages of the ice cover, its thickness and associated variation in water velocity and stage are demonstrated based on acoustic data. Variation in sediment transport is also estimated based on backscatter intensity of the emitted sound which can be interpreted as the concentration of suspended sediment particles. Considerable effect of ice cover on river hydraulics and sediment transport, especially during the break-up period, is concluded from the results. Data illustrate that average velocity and sediment flux respectively vary by factors of 2 and 10 compared to the open water condition.

Title: Characterization of Arsenic Species in Lake Sediments Surrounding Giant Mine, NWT.

Presenter/First Author: Martin Didier Van Den Berghe, Queen's University, Kingston, ON

Presenter/First Author Email: martin.vandenberghe@gmail.com

Co-authors: Heather E. Jamieson, Queen's University, Kingston, ON, Canada; Mike Palmer, , ,

Published Material: This presentation was first shown at the Yellowknife Geoscience Forum (Yellowknite, NT) in November 2014.It will also be presented at the Gananoque Environmental Engineering and Science Conference (Gananoque, ON) in February 2015.

Abstract Body: Giant Mine is was gold mine a few kilometers north of Yellowknife, NT that operated between 1948 to 1999. Roasting of arsenopyrite at Giant Mine released approximately 20,000 tonnes of arsenic aerosols to the environment from roaster stack emissions, 86% of which was released in the first 14 years of operations. Recent studies have shown elevated levels of arsenic in lake sediments beyond the boundary of the property, raising questions about their origin and associated risks to local ecosystems and public health.

The purpose of this study is to determine whether the arsenic present in regional lake sediments is of natural or anthropogenic origin, and whether these lakes act as a sink (capture) or a source (release) of arsenic in the overlying lake waters. This may be done by assessing the speciation of arsenic in both lake sediments and associated porewaters using dialysis arrays, major and trace elements analysis, synchrotron-based analysis, and advanced scanning electron microscopy. From there we can evaluate the relative stability of arsenic species in these different chemical media, and thus establish the long term trends of arsenic in the aquatic environment.

A field program was completed in July 2014 during which three local lakes were sampled downwind of the roaster stacks. These lakes offer a range of physical and chemical characteristics such as lake depth, organic contents and nature of substrate and immediate catchment. Focusing on these lakes will allow us to better constrain various physical and chemical parameters of lakes geochemistry in relation to arsenic mobility.

Preliminary results of this program indicate arsenic concentrations in sediment porewaters range from 80 to 1,600 parts per billion, consistently peaking 2-6 centimeters below the sediment-water interface. This might indicate a trend for arsenic to remobilize and migrate upwards through the sediment column after deposition. Whether this remobilized arsenic gets released into the lake water or gets trapped into a more stable mineral phase has yet to be determined.

Understanding the sources and behaviour of arsenic in such lakes is very important in understanding contaminated site attenuation and remediation efforts, helping constrain chemical behaviour of contaminants, and associated health risks to ecosystems and Human populations.

Title: The Role of Mineralogical Research in Mine Site Characterization

Presenter/First Author: Jeanne B. Percival, Geological Survey of Canada, Ottawa, ON

Presenter/First Author Email: jperciva@nrcan.gc.ca

Co-authors: Alexandre J. Desbarats, , , ; Katherine E. Venance, , , ; Michael B. Parsons, Geological Survey of Canada, Dartmouth, NS, Canada

Abstract Body: Over the last decade, the GSC, under the Environment and Health Programs, has conducted research into selected ore deposits as a means to: characterize mineralogical and geochemical signatures; provide public geoscience knowledge for decision makers; and promote deeper understanding of mine sites to aid technical reviews of Environmental Impact Assessments for new mine sites. To date, studies have been completed on lode Au deposits in two different geological and geographic environments (Nova Scotia and British Columbia). Currently, studies are near completion on U-REE granitic pegmatites in central (Bancroft) Ontario. U, Th and REEs have been mined in the Bancroft region since the early fifties. Demand for these commodities is increasing and there is renewed interest in re-appraising the region for exploration and development. Several old mine sites were sampled (rock core, tailings, soils, stream/lake sediments, groundwater, radon) for detailed characterization. This presentation will focus on mineralogy and hydrogeology of the Croft Mine that was explored in the early fifties and again in the early seventies. Representative core samples include pegmatite and gneisses (amphibolite, metapelite, quartzofeldspathic). Samples consist of abundant plagioclase and K-feldspar with subordinate quartz, amphibole and biotite. The metapelite contains sillimanite, garnet and allanite. Minor to trace fluor-apatite was detected in one sample and several of them contain minor to trace calcite or dolomite. A variety of oxides (magnetite, hematite, ilmenite) and sulphides (pyrite, pyrrhotite, chalcopyrite) occur in minor to trace amounts. Sediment collected from the outlet of the adit reflects the overall mineralogy of the sampled pegmatite and gneisses. Characterization of the mineralogical signature (ore, gangue, alteration) at this site helps to constrain the mass transfer of U and other species to mine drainage using geochemical inverse modelling.

Although these studies are on abandoned mines, they have provided sites and samples to develop new methods for analytical, geostatistical, hydrogeological, mineralogical and geochemical characterization. Identifying the factors that control geological processes will contribute to the development of models for environmental risk assessment.

Title: A Case Study using Stable and Radiocarbon Isotope Analysis as a Tool to Assess Biodegradation of Hydrocarbon Contaminants in Permafrost, Old Crow, Yukon

Presenter/First Author: Fiona D'Arcy, University of Ottawa, Ottawa, ON

Presenter/First Author Email: fdarc102@uottawa.ca

Co-authors: Bronwyn E Benkert, Yukon College, Whitehorse, YT, Canada; Liz Van Warmerdam, , , ; Ian Douglas Clark, University of Ottawa, Ottawa, ON, Canada

Published Material: Preliminary data presented in poster format at Arctic Change 2014 conference held in Ottawa, Ontario in December 2014.

Abstract Body: Old Crow is an arctic fly-in community located in northern Yukon along the banks of the Porcupine River. The village relies heavily on the use of fuel storage tanks to supply the motorized vehicles used in town, the daily airplane, and oil used for heating. All of the storage tanks are kept on a raised gravel pad located several metres from the banks of the river. Over the years, the land surrounding this tank farm has become contaminated with hydrocarbons which have leaked into the subsurface during daily fuel transfers. The clean-up of the site poses a significant challenge considering that the contamination extends into the permafrost, and natural bioremediation must be considered as an option. Natural attenuation of hydrocarbons through biodegradation can be recognized by carbon isotopes measured in the soil CO_2 which should incorporate the ^{13}C and ^{14}C signatures of any hydrocarbon being oxidized. Similarly, substrate consumption can be accompanied by a Rayleigh-type enrichment of ^{13}C in the residual hydrocarbons. Furthermore, the CO_2 created during biodegradation would contain no ^{14}C, which should be reflected in isotopic composition of the soil CO_2. In this experiment, soil gas samples as well as both active layer and permafrost cores containing the hydrocarbons have been collected from the site in order to sample CO_2. The $\delta^{13}C$ isotopic ratios and ^{14}C concentration in the carbon dioxide have been determined and show biodegradation occurring at the site. Microbial characterization of the active communities through microcosm and PCR techniques is recommended as a next step which will support these isotope studies. This method of assessing in-situ attenuation of hydrocarbons demonstrates natural bioremediation to be a viable treatment option in permafrost regions.

Published Material: These findings were published as: M. Sut, T. Fischer, F. Repmann, T. Raab and T. Dimi- trova, "Feasibility of Field Portable Near Infrared (NIR) Spectroscopy to Determine Cyanide Concentrations in Soil," Water, Air & Soil Pollution, Vol. 223, No. 8, 2012, pp. 5495-5504. doi:10.1007/s11270-012-1298-y.

Abstract Body: Importance of the industry in the world economic development has always been based on enhancing the economic welfare of citizens and supplying the material goods they consume. However, in this industrially careless race we often forget that intensive anthropogenic activity generates large amounts of waste material or by-products, causing a potential environmental threat. In recent times, when soil remediation has become of major importance, developing rapid and non-destructive methods for detection and screening of contaminants in-situ saves time and money. We would like to present our results concerning the novel application of a Polychromix Handheld Field Portable Near-Infrared (NIR) Analyzer to assess the cyanide concentrations in soil.

Iron-cyanide complexes have been observed at many industrial sites, either as an outcome of industrial processes or as an incident product. In this study, a calibration model was developed, using multivariate calibration algorithms, in order to determine NIR spectral response to the cyanide concentration in soil samples collected at the former Manufactured Gas Plant site. As a control, the contaminant concentration was determined using conventional Flow Injection Analysis (FIA). The experiments revealed that portable near-infrared spectrometers could be a reliable device for identification of contamination 'hot spots', where cyanide concentration are higher than 2400 mg kg^{-1} in the field and >1750 mg kg^{-1} after sample preparation in the laboratory, but cannot replace traditional laboratory analyses due to high limits of detection.

Title: The Use of High Resolution Characterization to Develop and Implement Site Remediation

Presenter/First Author: Rick McGregor, InSitu Remediation Services Limited, St George Brant, ON

Presenter/First Author Email: rickm@irsl.ca

Abstract Body: Remediation of impacted sites can be challenging due to numerous factors including geologic heterogeneity which can result in complicated distribution of the compounds of concern. Remedial efforts to remediate these compounds of concern are often frustrated due to a lack of understanding of the geology, hydrogeology and geochemistry. Site specific factors such as geology, hydrogeology, geochemistry, contaminant distribution, etc. play important roles in controlling the design of any successful remedial program especially in situ based programs. Very few studies have been completed in the field to look at why in situ remedial programs have had mixed success.

A comprehensive field study was carried out at a site in Southern Ontario to evaluate the effect of various injection and delivery methods for three common oxidants; persulphate, percarbonate and hydrogen peroxide. The effect of the oxidant type and delivery method on the distribution and persistence of the oxidant within the subsurface was also examined. Delivery methods examined for each oxidant included direct push using drop points and side tools along with vertical wells. The results of the study indicated that the method of injection had a significant impact on the distribution at the site tested. The persistence of the oxidants were also evaluated and a large variability in persistence was noted between the three oxidants with percarbonate existing the longest within the subsurface followed by activated persulphate and hydrogen peroxide. These results suggest that the choice of oxidant and delivery method are key design parameters for any in situ remedial program.

Title: The Magha Caldera, its Local Inhabitants, and Related Landslides in Wabane, Cameroon

Presenter/First Author: Nkeze Atemnkeng, University of Buea, Kumba,

Presenter/First Author Email: nkezeabeakic@hotmail.com

Abstract Body: Magha is in a caldera of volcanic origin with hot springs, and is located near the Bamboutus Mountains in West Cameroon. It is in a humid tropical area, with steep slopes, visible earth fractures and continuous human activity where tilling the soils for agriculture and housing is common. These and other events such as earthquakes, soil texture, high and long lasting rainfall contribute in triggering the repeated landslides that have characterized this area and its surroundings in the past half century. In 2003 one of the deadliest landslide disasters in the area killed 21 inhabitants, and people smelled gas characteristic of gunpowder immediately following the incident. This suggests that renewed volcanic activity may be associated with the frequent landslide activities experienced in this part of the country. If this is true, then the people of Magha and Cameroon need to brace up for a greater disaster in the making. The loss of human life and farm land due to landslides is already so high that the area has been categorized as a major social and environmental problem region for its inhabitants.

Despite the topography of the Magha area, its very fertile soils have attracted many farmers in recent years. Farming is practiced throughout the year in valleys and even on very steep slopes.

Title: Turbulence characteristics in the approach flow of Piano Key Weir (PKW)

Presenter/First Author: Harinarayan Tiwari, Indian Institute of Technology Roorkee, Haridwar,

Presenter/First Author Email: haribit31@gmail.com

Co-authors: Nayan Sharma, , ,

Abstract Body: Dams whose fail could cause loss of life or enormous assets injure are painstaking to survive a probable maximum flood (PMF), but the PMF in various locations has been amplified at regular intervals, resulting in spillways that no longer convene the proposed norms. Spillway rehabilitation is required for lots of dams in India; in order to get better hydraulic competence. Catastrophe in Uttarakhand & Jammu-Kashmir (June 2013 & August 2014) necessitates the research aspect of spillway rehabilitation. In recent years, a novel idea of Labyrinth weirs has been developed by means of a new shape, called Piano Key Weir. Piano Key Weir (PKW) is an innovative alternative of non-linear (labyrinth type) weirs that has a higher discharge capacity with a relatively smaller footprint. This alternative of Labyrinth weir provides an increase in the steadiness of the structure which can be positioned on the top of most existing or new diversion or storage dam structures. The PKW has a rectangular nonlinear weir crest layout (in planform), unlike traditional labyrinth weirs, the sloped floor in the inlet and outletcycles, referred to as keys, overhangs the apexes providing a longer crest length than a rectangular labyrinth weir, and several times to the transverse weir width. The Piano Key Weir doesn't have any gates. So it will involve very little operation & maintenance and would be very much cheaper than conventional dam spillways or barrage structure. Since in mountainous river of India, use of PKW may be promoted by answering the question of sedimentation behind it. As sediment from upstream normally moves downstream by flowing water, geographical features are changed and hydro-ecological habitats are subsequently affected. To support recovery of sediment continuity in rivers, the Piano Key Weir might be used as an alternative transverse structure. It needs the elemental sediment transport study in the approach flow PKW to point out the physical hydraulic characteristics. Since the sediment transport is linked with turbulence present in flow. This paper presents the experimental observations of the first and second order velocity profiles in piano key weir approach flow. Different turbulence characteristics including turbulent kinetic energy & turbulence intensity is also discussed in the paper.

Title: Neotectonic influence on geomorphology in the Gandak megafan of the Indo-Gangetic foreland basin, India

Presenter/First Author: Rudra Mohan Pradhan, Indian Institute of Technology Roorkee, Roorkee,

Presenter/First Author Email: rudra90.iitkgp@gmail.com

Co-authors: Pitambar Pati, Indian Institute of Technology Roorkee, Roorkee, India

Abstract Body: Geomorphic evolution of any foreland basin is mainly controlled by spatial and temporal occurrence of tectonism and sediment inflow into it. The Indo-Gangetic foreland basin, bordered by the Himalayas witnesses rapid changes in geomorphology and sedimentation processes due to frequent subsidence and upliftment of the fault bounded tectonic blocks. The fluvial geomorphology of the basin is greatly controlled by this neotectonic process.

The Gandak megafan, a witness to the neotectonism in the Indo-Gangetic foreland basin records three distinct phases of shifting of course of the Gandak River due to eastward tilting of the megafan block. Post tilting surface faulting developed four terminal fans in different times. Temporal and spatial distribution of these depositional units contributed significant geomorphological changes on the megafan surface, particularly in the Gandak depression of the Indo-Gangetic foreland basin. The Oldest exposed part of the Gandak megafan shows gentle slope with numerous SW flowing small channels. However, the overlying subsequent terminal fans show south flowing channels with greater slopes. Localized sediment accumulation as terminal fans significantly modified the geomorphology of the megafan system. Surface faulting too modified the fluvial system in the region as down-thrown blocks show high drainage density and surface ponding which are generally not observed on the up-thrown blocks. Differential upliftment and subsidence divided the whole block into two distinct geomorphic entities i.e. uplands in the north and low-lying swampy area in the south. As the terminal fans are the indicator of surface faulting in the Indo-Gangetic foreland basin, these have been dated by OSL technique to work out the temporal faulting activities and the geomorphological evolution of the region. Satellite imageries since 1985-2005 show continuous growth of the younger terminal fans and gradual cover up the older units. This study highlights the role of neotectonism in geomorphological modification in the Indo-Gangetic plain.

Published Material: Raab, A., Takla, M., Raab, T., Nicolay, A., Schneider, A., Rösler, H., Heußner, K.U., Bönisch, E., 2014. Pre-industrial charcoal production in Lower Lusatia (Brandenburg, Germany): Detection and evaluation of a large charcoal-burning field by combining archaeological studies, GIS-based analyses of shaded-relief maps and dendrochronological age determination. Quaternary International, doi: 10.1016/j.quaint.2014.09.041.

Abstract Body: The North European lowland has been formed by glacial and periglacial processes in the Late Pleistocene. Multiple reshaping since the Late Glacial considerably changed the landscape up to and including especially historic times. Sediment sequences and (fossilized) soils can improve our understanding of Late Quaternary landscape development, but mapping of buried soils and surfaces is often limited to single outcrops. Ongoing archaeological rescue excavations in the pre-field of the open-cast mine Cottbus-Nord (northeastern Germany) with dense excavation trenches in an about 10 ha dune and drift sand area reveal multilayered sediment sequences with fossilized soils and sediments from the Late Pleistocene to the Late Holocene. Archaeological findings ranging from Paleolithic and Mesolithic flint stones to an about 200 year old ceramics in eolian sediments covering plow horizons and wheel tracks suggest that eolian relocation of sandy material was intensive about 200 years ago. Still unpublished OSL dating underline the intense eolian activity. Recent studies showed that between the 15Th to the 19Th century an iron smelter 5 km to the west of our study site was supplied with charcoal, which was produced in a forest 5 km east to our study site. Our current findings about Late Holocene eolian activity raise the question if this eolian reshaping of the landscape is connected with the operation of the iron smelter either directly by transport or bog iron ore winning or indirectly by population pressure caused by the prospering iron smelter. Our ongoing research indicates, that already for historic land-use off-site effects causing further landscape changes have to be considered.

Title: Optical Dating and Sedimentary Characteristics of Holocene Dunes on the South Shore of the Central St. Lawrence lowlands, Quebec, Canada

Presenter/First Author: Guillaume Thiery, GEOTOP-UQAM, Montréal,

Presenter/First Author Email: thiery.guillaume@courrier.uqam.ca

Co-authors: Martin Roy, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Michel Lamothe, GEOTOP-UQAM, Montreal, QC, Canada; Robert-André Daigneault, UQAM-Université du Quebec à Montreal, Montreal, Canada; François Hardy, UQAM-LUX-GEOTOP-Université du Quebec à Montreal, Montreal, Canada

Abstract Body: Systematic mapping of surficial sediments of the central St. Lawrence lowlands allowed the delineation of the distribution of the main Quaternary morpho-sedimentary systems. The surficial geology maps reveal the occurrence of large (multi-km) eolian sediment systems characterized by many convex parabolic dunes towards the SW. Although these sedimentary landforms cover substantial areas, uncertainties remain regarding their origin and age, as well as their stratigraphical significance within the global framework of the last deglaciation. Here we report sedimentological and chronological data from dunes located near the locality of Villeroy, Qc (NTS map sheets 21L05 and 21L12), in order to gain insights on their depositional setting and age. The distribution of these eolian features was mapped through the analysis of aerial photographs and high-resolution (LiDAR) digital elevation models, combined with field observations. Four sites were chosen for detailed investigations. Geophysical soundings (GPR) were carried out on the dunes to gain information on their internal sedimentary structures. The dunes were sampled for grain-size analysis and mineralogical identification. Sediment facies displaying clear evidence for eolian transport were sampled for optically stimulated luminescence (OSL) dating of the K-feldspar fraction. Our results indicate that this large eolian system likely derives from the reworking of beach and deltaic sands that were deposited in postglacial Champlain Sea. The main orientation of the parabolic dune fields suggests deposition by strong NE (N35°) anticyclone winds, which probably played an important role in the formation of these dunes and the remobilization of sand-sized sediments in the lowland. GPR results tend to suggest a single period of deflation. OSL investigations show that the sand particles were well exposed to sunlight prior to burial and preliminary results yielded ages of ca. 8 ka. Utlimately, results from this study will provide constraints on the period of eolian activity that followed the retreat of the Laurentide ice sheet and Champlain Sea, in addition to refine the chronostratigraphic framework for the deglaciation of the Central St. Lawrence Lowlands.

Title: Thermo-hydro-mechanical Behavior of Granite under Cyclic Temperature Changes

Presenter/First Author: Meysam Najari, McGill University, Montreal, QC

Presenter/First Author Email: meysam.najari@mail.mcgill.ca

Co-authors: Antony P Selvadurai, McGill University, Montreal, QC, Canada

Published Material: Part of the work was presented in the Environmental Earth Sciences journal by Meysam Najari and APS Selvadurai:http://link.springer.com/article/10.1007%2Fs12665-013-2945-3

Abstract Body: This research deals with the computational and experimental investigation of thermo-hydro-mechanical processes that are induced by the boundary heating of a granite cylinder containing a cylindrical cavity. The study is of interest to geomechanics problems associated with the deep geologic disposal of heat-emitting nuclear fuel wastes, the extraction of geothermal energy, oil and gas recovery, and the geologic sequestration of carbon dioxide in supercritical form. Temperature changes can influence a saturated porous geomaterials in several ways: it can cause skeletal deformation due to thermal expansion of the rock; induce fluid flow due to the fluid pressures generated by the differential thermal expansion between the porous skeleton and pore fluid; and alter the physical characteristics of the migrating pore fluid.

A cylindrical granite sample measured 15.24 cm in diameter and 30.48 cm in height containing a sealed fluid-filled cavity with a diameter of 2.54 cm and a depth of 15.24 cm was prepared. Prior to performing the THM experiment the permeability of the sample was estimated using constant flow rate steady state technique. The sample was then subjected to a cycle of temperature changes on its outer surface and the temperature and fluid pressure changes in the fluid-filled cavity were measured. It was observed that regardless of how precisely the cavity was filled with de-aired water, air bubbles can still exist in the cavity and influence the fluid pressure changes. A novel technique was suggested for taking into account the influence of the volume of trapped air and eliminating its effect in the estimation of the fluid pressure changes in the fluid-filled cavity. The experiment was computationally modeled using the finite element code COMSOL Multiphysics™ and the experimental results were compared with the computational estimates. The computational model took into account the compressibility of the water, the porous skeleton and the solid grains.

Title: Frequency Response of a New Closed-Path Trace Gas Analyzer for Eddy-Covariance Flux Measurements

Presenter/First Author: James Somers, Campbell Scientific, Logan,

Presenter/First Author Email: jsomers@campbellsci.com

Co-authors: Steve Sargent, , ,

Abstract Body: The TGA200A (Campbell Scientific, Inc.) is a new trace gas analyzer designed to measure nitrous oxide or methane mixing ratios, or carbon dioxide isotope ratios. It is similar to the earlier TGA200, but it uses a thermoelectrically cooled laser to avoid the need for cryogenic cooling. The TGA200A also uses a smaller sample cell to provide good frequency response for eddy covariance applications, even with a lower-power sample pump.

The frequency response of the TGA200A was measured by injecting an impulse of N2O at the inlet. This measured impulse response was then Fourier transformed and normalized to give the frequency response. This test was repeated at various flow rates that represent a range of pump capacities to demonstrate the tradeoff of frequency response vs. power required for the sample pump.

Title: Spatial-Temporal effects of Landuse changes on Land surface Temperature in Nairobi.

Presenter/First Author: JAMES MUMINA Muthoka, Regional Centre for Mapping of Resources for Development, Nyeri,

Presenter/First Author Email: muminajames@gmail.com

Co-authors: Charles Ndegwa Mundia, Dedan Kimathi University of Technology, Nyeri, Kenya

Published Material: The findings were published in a Proceedings of the 2014 International Annual Conference on Sustainable Research and Innovation at Jomo Kenyatta University of Agriculture and Technology.

Abstract Body: Land Surface Temperature (LST) forms an important climate variable which is related to climate change and forms a good indicator of the energy balance at the surface because it is one of the key parameters in the physics of land-surface processes. The main objectives of this study is to examine the spatial temporal effects of land use land cover changes on surface temperature, through the analysis of the temperature differences between the land covers and Normalized Differential vegetation Index using Landsat TM and ETM+ data for a period of 24 years. The effectiveness of remote sensing technology methodson surface temperature at local and regional levels is examined too.

The multispectral bands of Landsat TM and ETM+ of the dry season were used in generating the land surface temperature, NDVI and LULC. The data was checked against ground data information and measurements and statistically normalized for correlation with vegetation vigour and land cover types such as vegetated areas, barren land, water, shrubs/grasslands and built up areas.

The finding indicate a strong relationship between the land surface temperature and the land use/ covers with a negative correlation with the vegetation The relationship between land surface temperature and the land use validates the suitability of the techniques used in analysing land surface temperature for micro-climates assessment. Remote sensing data provides an efficient and relatively cheaper method for carrying out micro-climate studies thus effective in local and regional analysis. The research recommendsmitigation techniques that facilitate the reintegration of natural elements into the built environment hence reversing the climate change effect.

Title: Voxelization approach to model soil reinforcement by root systems: application for landslides risk assessment of forested hillslopes

Presenter/First Author: Nomessi Kokutse, University of Lome, Lome,

Presenter/First Author Email: mkokutse@gmail.com

Co-authors: André Guy Tranquille Temgoua, University of Douala, Douala, Cameroon

Abstract Body: Root reinforcement is considered as an increase of soil shear strength and this help in reducing slope failures. To investigate effects of tree root systems on slope stability, field experiments can be conducted. Such tests are difficult to perform. Numerical model appears as an alternative approach to investigate root reinforcement and risk assessment of forested slopes without taking explicitly into account roots elements in soil.

This paper presents a new and an integrated model of soil reinforcement. The model is based on voxelization technique which consists in converting 3D geometric objects from continuous geometric representation into a set of voxels that best approximates each element of a root system. Based on this technique, a root system located in a block of soil can be divided into a set of voxels or volume elements. In each voxel, roots parameters such as root area ratio, tensile resistance and roots mean orientation can be extracted for the purpose of local soil additional cohesion computation. Root cohesion in different voxels can therefore be assigned to a similar domain meshed into 3D finite elements for the field of strain computation. The process enables to search finite elements at the same spatial position as the considered voxel prior to root cohesion assignment. With this model, simulations of forested slope failure and direct shear tests of rooted-soil were performed in a finite elements environment. Results of the simulations are found to be in good accordance with similar experimental tests found in the literature. This help to investigate slope reinforcement with different types of root systems and plantation patterns. The investigations showed that, among the three main families of roots architectures (tap, heart and plate root systems), the tap root system is found to be the best in terms of soil reinforcement. Staggered in rows forest pattern was found to increase slope stability much better than all other patterns investigated.

Title: Physically Accurate Soil Freeze-Thaw Processes in a Global Land Surface Scheme

Presenter/First Author: Vanessa Elizabeth Haverd, CSIRO Canberra, Canberra, ACT

Presenter/First Author Email: vanessa.haverd@csiro.au

Co-authors: Matthias Cuntz, Helmholtz Centre for Environmental Research UFZ Leipzig, Leipzig, Germany

Published Material: Preliminary Results were Presented at AGU Fall Meeting 2013

Abstract Body: Transfer of energy and moisture in frozen soil, and hence the active layer depth, are strongly influenced by the soil freezing curve which specifies liquid moisture content as a function of temperature. However, the curve is typically not represented in global land surface models, with less physically-based approximations being used instead. In this work, we develop a physically accurate model of soil freeze-thaw processes, suitable for use in a global land surface scheme.

We incorporated soil freeze-thaw processes into an existing detailed model for the transfer of heat, liquid water and water vapor in soils, including isotope diagnostics – Soil-Litter-Iso (SLI, Haverd & Cuntz 2010), successfully used for water and carbon balances of the Australian continent (Haverd et al. 2013). A unique feature of SLI is that fluxes of energy and moisture are coupled using a single system of linear equations, a feature preserved in the extension to include freeze-thaw processes. The extended model is evaluated extensively in stand-alone mode (against theoretical predictions, lab experiments and field data) and as part of the CABLE global land surface scheme.

SLI accurately solves the classical Stefan problem of a homogeneous medium undergoing a phase change, and accurately reproduces observations of the freezing front from laboratory experiments (Hansson *et al.* 2004). Tests against observations at a permafrost site in Tibet (Weismüller et al. 2011) reproduce seasonal thawing and freezing of the active layer to within 3 K of the observed soil temperature (fig 1) and to within 10% of the observed volumetric liquid soil moisture. Tests in the presence of snow show good agreement with observed snow-water equivalents and soil temperatures, although refreezing of melted snow water is highly sensitive to the number of model snow layers, which influence density and temperature gradients in the snow-pack.

SLI was run globally on 1ºx1º grid as the soil part of the land surface scheme CABLE. We could therefore demonstrate that this detailed and physically-realistic formulation is fast enough to be a feasible alternative to the much simpler default soil-scheme in CABLE. Modeled northern hemisphere permafrost extent and depth are shown to be sensitive to incorporation of the soil freezing curve in the model.

Title: Mass Movement by solifluction and Syngenetic Dynamic of Permafrost in the High Arctic, Ward Hunt Island, Canadian High Arctic

Presenter/First Author: Manuel Verpaelst, Université de Montréal, Montréal, QC

Presenter/First Author Email: manuel.verpaelst@umontreal.ca

Co-authors: Daniel Fortier, University of Montreal, Montreal, QC, Canada; Michel Paquette, University of Montreal, Montreal, QC, Canada

Published Material: These findings were partly presented as a poster in ArcticChange 2014. These findings are not under review or accepted by a scientific journal.

Abstract Body: According to recent climatic scenarios, climates changes will affect the Arctic more than any other region of the planet. The high Arctic, which is essentially bare of vegetation, will have a strong response to climates changes and will be characterized by an acceleration of periglacial processes associated with permafrost thawing. Mass movements on slopes will be favored by the deepening of the active layer increasing the creep and continuous sliding of the material over the ice-rich permafrost table.

Our project focused on the influence of solifluction lobes movements on permafrost dynamics at Ward Hunt Island, Nunavut (Canada). On the island, many solifluction lobes deform and entrain sediments downslope. Considering the recent deepening of the active layer, the increase of material downslope may modify permafrost dynamics, a question that is not currently considered by permafrost model scenarios.

We used 3D laser scanning techniques and total station surveys to reconstruct the microtopography and volume of solifluction lobes. Permafrost coring and ground penetrating radar surveys were used to characterize solifluction lobes cryostratigraphy. Permafrost cores were then analyzed using micro-computed tomography to quantify the different components of permafrost (sediments, ice, organic matter and gas) which were also measured in laboratory.

Our study demonstrated that the movement of solifluction lobes leads to the accumulation of coarse material (gravel) with high hydraulic conductivity on the peripheral ridges of the lobe which strongly modifies slope hydrology. In the center of the lobes, the recurrent and substantial accumulation of finer-grained material downslope modifies permafrost dynamics and promotes the aggradation of ground ice. These findings suggest that the occurrence of these ice-rich zones may contribute to slow down the degradation of permafrost, due to the important effect of latent heat represented by this new volume of ground ice.

Title: Black Spruce (*Picea mariana*) Water Use Response to Moisture Deficits on a Permafrost Peat Plateau

Presenter/First Author: Rebecca Kathleen Warren, University of Guelph, Guelph, ON

Presenter/First Author Email: warrenr@uoguelph.ca

Co-authors: Aaron A Berg, University of Guelph, Guelph, ON, Canada; William L Quinton, Wilfrid Laurier University, Waterloo, ON, Canada; Jennifer Lynn Baltzer, Wilfrid Laurier University, Waterloo, ON, Canada

Published Material: Preliminary data and trends were presented on a poster at the ArcticNet conference in December 2014. Since then further data analysis has occured.

Abstract Body: Large-scale permafrost degradation is occurring rapidly over the discontinuous permafrost regions of the Canadian subarctic. Within this region, peatlands are particularly vulnerable as permafrost controls the hydrology, carbon cycling, and the health and distribution of vegetation. This study examines the degree to which *P. Mariana* responds to water stress in relation to changing frost and water table depth, soil tension, and soil moisture. These findings will aid in advancing our understanding of the processes governing forest browning and the hydrological modeling of cold regions. Three *P. Mariana* were instrumented with 5 Heat Ratio Method sap flow sensors (SFS) on a peat plateau at Scotty Creek, NWT in the summer of 2014. Tensiometers were placed at a depth of 15 cm and at distances of 20 and 100 cm from the focal tree along SFS monitored roots. Volumetric soil moisture over the top 5 and 20 cm was measured every 10 cm along four transects that intersected the instrumented roots. Frost table depth was also measured along these transects. Two water table wells were installed near the bog and in the plateau interior. Diurnal patterns of soil tension, sap flow, and water table depth were observed within an overall drying trend throughout the summer. A correlation existed between soil water tension and sap flow velocity. Complex feedback processes were observed between tension, frost table depth and sap flow. Increasing frost table depth resulted in decreased water table height, as well as decreased surface soil moisture, causing drought stress in *P. Mariana* and reducing transpiration. Large precipitation events and proximity to bogs or fens may also temporally induce waterlogging. A conceptual model of *P. Mariana* response to water deficits was developed and compared to the predicted response.

Title: Spatial and Temporal Patterns of Net Carbon Exchange in the Polar Semi-Desert Vegetation Community on Melville Island, NU

Presenter/First Author: Emma Buckley, Queen's University, Kingston,

Presenter/First Author Email: emma.buckley@queensu.ca

Co-authors: Neal A Scott, Queen's University, Kingston, ON, Canada; Paul Treitz, Queen's University, Kingston, ON, Canada

Published Material: Preliminary results presented as a poster at the 2014 Arctic Change conference.

Abstract Body: While studies across latitudinal gradients in mesic tundra have shown decreasing levels of net ecosystem exchange (NEE) of carbon dioxide at more northern sites, little work has explored the factors regulating NEE in the polar semi desert, a vegetation community which is widely distributed across the High Arctic.

In 2013, we deployed eight ADC Automated Carbon Exchange (ACE) systems to quantify the contribution of the polar semi-desert plant community to the landscape-scale NEE. As polar semi-desert plant cover varies at relatively small spatial scales, the chambers were distributed between vegetated areas (18-51% cover) and bare soil. Measurements were made every 30 minutes from late May to late July. Air temperature, soil temperature, and soil moisture measurements were collected in conjunction with NEE readings. In July 2013, Normalized Difference Vegetation Index (NDVI) data were collected to quantify variability in vegetation cover within the polar semi-desert. NDVI varied from -0.12 to 0.31, with the highest values occurring at vegetated sites and low values occurring on bare soil. Percent vegetation cover and NDVI correlated well at peak biomass ($R^2 = 0.96$).

NEE is driven by variability in several biophysical factors, and the factor that best predicts NEE varies throughout the season. In the early season, respiration drives NEE, and air temperature is the strongest predictor (R^2 = 0.23 to 0.55). During the warmer part of the season, photosynthesis is the dominant component of NEE, and photosynthetically active radiation (PAR) becomes the best predictor. Our results suggest a threshold temperature above which photosynthesis dominates NEE in polar semi-desert plant communities. Longer growing seasons, if associated with higher temperatures, would enhance NEE. NEE correlated positively with vegetation cover ($R^2 = 0.96$) later in the season. These relationships may be useful for quantifying NEE in polar semi-deserts using remotely-sensed data.

Title: Dissolved Organic Matter Quality from a Discontinuous Permafrost Area and its Susceptibility to Photolytic and Microbial Degradation

Presenter/First Author: Pieter Aukes, University of Waterloo, Waterloo, ON

Presenter/First Author Email: paukes@uwaterloo.ca

Co-authors: Sherry L Schiff, University of Waterloo, Waterloo, ON, Canada; Michael English, Wilfrid Laurier University, Waterloo, ON, Canada

Published Material: Some of this data was presented at ArcticNet 2014 (Ottawa), but I'll be focusing on a different component (not the same presentation!)

Abstract Body: Northern environments are some of the most susceptible to a warming climate, experiencing increased active-layer thickness and permafrost degradation. Such changes can influence subsurface carbon cycling. Particularly, previously-frozen carbon can become mobilized into the hydrosphere as dissolved organic matter (DOM) and make its way into surrounding surface waters. Dissolved organic matter plays a number of important environmental roles including absorbing harmful ultra-violet radiation in surface waters, affecting the pH, and acting as an important nutrient source for microbes. Furthermore, DOM can influence water quality by binding and transporting heavy metals, as well as potentially forming carcinogenic disinfection by-products during the chlorination of drinking water. Reactivity of DOM is dependent upon its quality, which can vary depending on source, amount of degradation, and season. In northern environments, it is uncertain how degrading permafrost will influence DOM quantity and quality and the subsequent effect upon drinking water and aquatic health, especially in ice-poor permafrost areas. Our research used a variety of DOM characterization methods and geochemical techniques to quantify DOM quality from four different sources (subsurface peat porewater, ponds, streams, and rivers) in an area with degrading permafrost near Yellowknife, NWT. In addition, we conducted microbial and photolytic degradation experiments to determine whether the lability of DOM differs with source, how DOM quality changes with environmental processing, and how this ultimately influences parameters linked with drinking water quality and aquatic health.

Title: Impact of temperature increase on methane emission from arctic soils

Presenter/First Author: Juyoung Seo, Yonsei University, Seoul,

Presenter/First Author Email: jay_seo@yonsei.ac.kr

Co-authors: Yoo Kyung Lee, Korea Polar Research Insitute, Incheon, South Korea; JI Young Jung, KOPRI Korea Polar Research Institute, Incheon, South Korea; Namyi Chae, Korea Polar Research Institute, Incheon, South Korea; Hojeong Kang, Yonsei University, Seoul, South Korea

Abstract Body: Arctic tundra is one of the largest carbon stocks, of which amount is estimated up to 1,600 Pg. Global climate change models predict the greatest surface temperature rise in Arctic regions, which may result in faster decomposition of organic carbon and consequent releases of greenhouse gases such as CO_2 and CH_4. In particular, CH_4 is a significant GHG and can contribute to positive feedback on climate change; however, dynamics of CH_4 emission from arctic tundra under warming is yet to be fully understood. In this study, we conducted temperature manipulation experiments for arctic soils at field and laboratory scales and monitored CH_4 fluxes along with related microbial abundances (methanogen and methanotroph). Open-top chambers were installed in Cambridge Bay, Canada and intact soil cores collected along a melting gradient in Nome, Alaska were incubated under increasing temperature (from -20 to 20 ℃) for 60 days. At a field scale, *ca.* 1 ℃ increase in soil temperature for one growing season induced a slight increase in CH_4 emission while abundances of methanogen and methanotroph did not show any shift. . At a laboratory scale, CH_4 emission from a wetland soil was higher than that from dry soils and appeared to increase at thawing temperature (0.5 ± 1 ℃). However, a little oxidation of CH_4 was observed in dry soils at thawing temperature.

Overall results of this study suggest that CH_4 flux from arctic soils under warmer conditions is constrained not only by temperature but also by water availability.

Title: Measurement of Permafrost Greenhouse Gas Emissions through a New Closed Chamber Automated System

Presenter/First Author: Samuel Gagnon, Centre d'études nordiques, Québec, QC

Presenter/First Author Email: samuel.gagnon.1@gmail.com

Co-authors: Michel Allard, Laval University, Quebec City, QC, Canada; Esther Lévesque, Université du Québec à Trois-Rivières, Trois-Rivières, QC, Canada

Published Material: The methodology was first presented orally at the ArcticNet Annual Scientific Meeting in Halifax, December 2013. In December 2014, a poster was presented at the Arctic Change convention in Ottawa.

Abstract Body: Over the past 30 years, the Arctic has experienced a rapid increase in surface temperatures, which has led to important consequences such as the beginning of permafrost thaw. Permafrost thaw is expected to contribute to increased emissions of greenhouse gases (GHG). Such emissions have been quantified indirectly through mathematical models and from sporadic field measurements using portable gas chambers. However, modeling still holds a lot of uncertainty and direct measurements with chambers are both labour-intensive and time-consuming.

The main objective of this project was to measure permafrost CO_2 and CH_4 emissions in a polygonal peatland located in Salluit, Nunavik. In order to assess the future impact of warming on arctic carbon fluxes, GHG emissions were measured under the current climatic conditions and inside an open-top chamber (OTC), which can reproduce the climatic conditions expected in about 50 years. In addition, the spatial variations of GHG emissions in the polygonal peatland, from dry tundra polygon centers to wet troughs where permafrost is decaying, were studied in order to determine the effects of soil water saturation on GHG emissions and composition.

This project also aimed to test a new instrumentation: a closed chamber automated system. The new system was designed and built to take precise measurements over long periods of time with low-cost gas sensors instead of using conventional ways to measure carbon concentrations, which are often expensive. In addition, the system was designed to operate autonomously and maintain the integrity of the studied sites.

Four automated closed chambers were used for the project: one chamber in natural conditions (C_n), on chamber in an OTC (C_{OTC}), one chamber measuring emissions on a site without vegetation (C_{soil}) and one chamber between two polygons where the soil is permanently water-saturated (C_{sat}). Two chambers were operated every day, alternating chambers each day. The chambers were closing for 30 minutes three times a day (7h30, 13h30, 19h30).

Preliminary results show that the new automated system underestimates CO_2 fluxes, but that the trends of carbon emissions are similar to a commercial system. The greatest CO_2 emissions came from C_{sat}, followed by C_{OTC}, C_n and C_{soil}. Emissions were most influenced by air temperature and water table depth.

Title: Detached Eddy Simulation (DES) of Turbulent Flow in Isolated Pool-Riffle Bedforms

Presenter/First Author: Hamed Dashtpeyma, University of Waterloo, Waterloo,

Presenter/First Author Email: hdashtpe@uwaterloo.ca

Co-authors: Bruce MacVicar, University of Waterloo, Waterloo, ON, Canada

Abstract Body: One of the most common topographical elements of rivers is pools and riffles. The deeper parts of undulations in the bed are called pools, whereas the shallower parts are riffles. Pool-riffle sequences can be shaped naturally, but are also made artificially to control the stream energy, improve fish habitats, or control the sediment transport rate. Many researchers have focused on the hydraulic characteristics of pool-riffle sequences by numerical analyses, experimental investigations, and field work processes. However, in contrast with other types of investigations, a transient numerical analysis is particularly suited to illustrate the complex mechanisms of flow such as vortex creation and dissipation, turbulence structures, and instantaneous bed shear stress. In this research, detached eddy simulation (DES) of turbulent flow in isolated pool-riffle with different width is presented. The numerical results are verified with experimental data. The simulations show a series of vortex generation near the wall at the downstream end of riffles. Based on the width of the channel, it is illustrated that these vortices can attach to each other and form a tube of vortices or they can break into smaller scale vortices and be dissipated at the downstream by energy cascading. It is illustrated that the narrower channels generate stronger vortices; therefore, these vortices need larger pool length for dissipation. The wall and bed shear stress show more critical conditions for narrower channels. The results of this research can help designers to choose a proper geometry and location for pool-riffle sequences, and give them an insight about the mechanism of natural undulation shaping, and the sediment sorting by size of natural bedforms. In addition, a rational design of pool length can let the flow to be restored and decreases the unwanted erosion at the downstream.

Title: Pattern Observation during Bed-Form Development Due to Turbulence around Obstacles in river

Presenter/First Author: Haradhan Maity, Indian Statistical Institute, Kolkata,

Presenter/First Author Email: maitym_r@isical.ac.in

Abstract Body: The objective of this study is to better understanding the mechanism of formation of different kinds of bedform structures due to obstacles immersed on the plane sediment beds in unidirectional fluid flow. Experiments have shown how local scour develops around obstacles of different shapes in non-cohesive sediments. The study shows that obstacle is the dominant cause of the initiations of scour pattern. Obstacle and the stagnation eddy together onset the scour hole at the bottom of the sediment bed, when the critical pressure gradient associated with the initiation of scour is reached. The pressure drop between the stagnation pressure upstream and wake pressure downstream of the obstacle induces this hydraulic gradient. This study explores the temporal development of scour around obstacles resting on flat bed composed of uniform, cohesionless sediment.

This study will show the statistical modeling of various turbulent parameters like velocities and Reynolds stresses; and predict the natural phenomena, like trends of coherent structure over equilibrium scour holes induced by obstacles of different shapes on the river bottom. The turbulent flow field within the equilibrium scour mark was measured in a laboratory flume using 3-D Micro acoustic Doppler velocimeter (ADV). The scours marks may be named as current-crescent preserved in geological record are traditionally used as indicators of palaeo-current direction. Using quadrant threshold technique for coherent motion, it has been shown that over the smooth surface ejections and sweeps are the largest contribution near bed region and outward and inward interactions are the largest contribution near the water surface, but within the scouring region that is not true. Also note that the qualitative and quantitative behaviors of bursting events fit well with experimental data on the smooth surface. But within the scour-hole qualitative behavior of bursting events fits well with experimental data. It is interesting to note that the *yz* and *xy*- planes are much more important in the scouring regions, but reverse are true for the smooth surface.

Moreover, this is important for interpretation of turbulence and flow structures across the scour marks available at the ancient sedimentary structures in the light of modern analog- *present is the key to the past*.

Title: Stream instability risk assessment in an urban area as a management tool

Presenter/First Author: Genevieve A Marquis, Organization Not Listed, Washington, DC

Presenter/First Author Email: gmarquis@jfsa.com

Co-authors: Hugues Lachance, J.F. Sabourin and Associates inc., Gatineau, QC, Canada

Abstract Body: Stream stability in urbanized watersheds is an increasingly critical issue for planners and managers. Unfortunately, due to lenient legislation and a lack of awareness of the impact of changes in land use, urban development in the province of Quebec has heavily impacted streams and rivers. It has also resulted in the construction of roads and houses within the migration channel of these water courses.

The St-Regis creek drains a 93 km^2 watershed located in the Saint-Lawrence lowlands, an area known for its fertile soils. Only 3 km^2 of forest cover remains in the watershed which is now predominantly occupied (82 %) by the culture of major crops. The remaining area (15 %) is relatively dense and continuous suburban development located in the downstream area of the St-Regis watershed. Many of the watercourse's meanders have been straightened during the urban development and subsequent and extensive bank stabilization was added to protect roads and houses. Yet, the channel continues to migrate. A problematic section of approximately 3.5 km is the focus of this study. A risk assessment approach has been proposed to the city managers to advise the planning of stream interventions. The risk assessment approach is seen as a compromise between the need for stable banks and allowing for the natural stream functions of flooding and migration.

Future channel trajectories can be predicted by considering stream history and hydraulics, in combination with RVR meander software output, to classify the fluvial plain according to the risk of channel migration on a

short, mid and long term basis. Based on these data and long term land use plans, stream interventions are devised focusing on minimal impact to the stream and cost-efficient methods. The integration of geomorphological concepts and the consideration of stream history and trajectory, is a new approach in Quebec and a potential sustainable replacement to the usual interventionist approach.

Title: Habitat Suitability and Hydraulic Signatures of Geomorphological Units in a Restored Channel

Presenter/First Author: Paul Villard, GEO Morphix Ltd., Milton, ON

Presenter/First Author Email: paulv@geomorphix.com

Co-authors: Jaclyn Cockburn, University of Guelph, Guelph, ON, Canada; Cara Hutton, , ,

Abstract Body: Channel reaches consist of a series of geomorphological units. In many 'restored' channels these geomorphological units are a sequence of riffles and pools designed to mitigate flow velocity and provide suitable aquatic habitat. Geomorphological units such as pools and riffles should display morphological, sedimentological and hydraulic signatures. If we can use a hydraulic signature to differentiate between these units we can evaluate the proportion of a given geomorphological unit within a reach. Similarly, a given fish species will require specific hydraulic conditions for different activities. We can use the hydraulic signatures to evaluate suitability of reaches and geomorphological units for target fish species. Therefore, we should be able to assess 'restored' and natural channels in relation to the proportion of different geomorphological units and in the area within the channel that is suitable for a given target fish species. 650 m of creek and valley was realigned in Brampton, Ontario to facilitate development and was an opportunity to restore a degraded system. The channel studied consisted of riffle-pool sequence within a larger channel realignment and floodplain design. Velocity, water depth and substrate were measured at numerous cross-sections through a variety of flow conditions between May and September 2013. This study uses these measurements to evaluate the hydraulic signature of each geomorphological unit and the habitat suitability based on velocity and depth for a range of target species. The assessment illustrated that the approach provides quantitative methodology to examine geomorphological units within natural channels. The approach also provides a quantitative method to examine habitat suitability of target species through variable flow conditions.

Title: Determining residence time of a pocket wetland and evaluating urban runoff quality through a pocket wetland in Brampton, Ontario.

Presenter/First Author: Jason Krompart, University of Guelph, Dundas,

Presenter/First Author Email: jkrompar@uoguelph.ca

Co-authors: Jaclyn Cockburn, University of Guelph, Guelph, ON, Canada; Paul Villard, GEO Morphix Ltd., Milton, ON, Canada

Abstract Body: Stormwater treatment trains improve urban runoff quantity and quality by remediating water quality and mitigating peak flow. A pocket wetland (PW) at the outlet of a stormwater pond is designed to increase runoff detention, while increased residence time within the PW provides, a 'polishing' step with respect to water quality. A PW in Brampton, ON was monitored to assess effluent discharge and water quality. Discharge, temperature and electrical conductivity (EC) were monitored upstream, downstream and at the inlet of the PW from May – Oct 2014, while Suspended sediment concentrations (SSC) were determined through discrete and automated pump samples. The changes between up and downstream monitoring points were used to monitor PW effluent discharge and quality. The PW attenuated event flows on average for 2 ± 0.8 h during rainfall events. The maximum change in discharge between up and downstream was 0.55 mm due to 31 mm rainfall suggests a slow release of stormwater from the PW. A change in storage capacity after an intense rainfall (17.5 mm/hr) event in early August resulted in poor correlation between influent and effluent PW discharge ($R^2 = 0.2$). A difference of means t-test suggested there was no change in water quality due to the PW, but in-depth event analyses suggest a minor change in EC and SSC at 'first flush'. The PW remediated water quality well through rainfall events, but incised channels downstream of the monitoring area would continuously flow from the PW. Small volumes of warm surface water with an increase in EC and SSC resulted in increased temperatures (0.1 - 0.5°C), EC and SSC. Water quality parameters remained within the provincial water quality levels. The PW provided flow attenuation while increased residence time ensured good water quality. Further improvements in residence time may improve water quality and further justify the use of stormwater treatment trains for best management practice in urban stormwater management systems.

Title: Human Modifications and Watershed Hydrologic Processes in a Postglacial Landscape

Presenter/First Author: Brett Gerard, University of Maine, Bangor, ME

Presenter/First Author Email: brett.gerard@maine.edu

Co-authors: Sean MC Smith, University of Maine, Orono, ME; Alexander Sivitskis, , , ; Andrew S Reeve, Sen. George J. Mitchell Center, Orono, ME; Brian Mathys Van Dam, University of Maine, Orono, ME

Published Material: Some of this work (the hydrologic modeling component) was part of a poster presentation for the 2013 AGU conference in San Fransisco. However, that work was in an earlier stage and additional work (the geomorphic assessment) has been added to this abstract.

Abstract Body: The rates and magnitudes of watershed hydrologic processes in northern New England are influenced by the post-glacial terrain and landscape modifications made by humans following European colonization of the area in the early 1600s. The extent to which glaciation and human activities control the surface hydrologic conditions and geomorphology of the region is the focus of this research. We examine: 1) How channel geomorphic conditions vary relative to watershed characteristics; and 2) How human modifications influence stream flow regimes in the region. This research is conducted in the Sebago Lake watershed of southern Maine. Despite extensive human interventions in the watershed over the past three centuries, the region remains predominantly rural and forested. However, projections indicate a change to more extensive development in future decades, which could have hydrologic, geomorphic, and water quality implications for Sebago Lake and its tributary network.

The geomorphic assessment component of our investigation examines fluvial conditions in our study area relative to sub-basin attributes and calculated hydrologic estimates using statistical techniques. Changes to surface flows influencing stream conditions are evaluated based on simulations with a distributed watershed hydrology model using predicted scenarios for land cover, hydraulic controls, and drainage network

expansion in a sub-basin of the Sebago Lake watershed. These scenarios represent a range of watershed and drainage network modifications commonly associated with human development in the region. All scenarios result in alterations to flow conditions and the sub-basin water budget. Future work seeks to link surface flow regimes derived from varied climate and land cover scenarios with stream bed dynamics and the hydraulic conditions of the hyporheic zone.

Title: Coastal Response to Physical Setting and Variable Forcing Across the Canadian Arctic

Presenter/First Author: Donald L Forbes, Natural Resources Canada Dartmouth, Dartmouth, NS

Presenter/First Author Email: dforbes@nrcan.gc.ca

Co-authors: Nicole J Couture, Geological Survey of Canada -, Halifax, NS, Canada; Trevor Bell, Memorial University of Newfoundland, St. John's, NL, Canada; Thomas S James, Geological Survey Canada, Sidney, BC, Canada; Dustin Whalen, , , ; Gavin K Manson, , , ; Benjamin A Bagnall, Memorial University of Newfoundland, St. John's, NL, Canada

Published Material: This is an invited overview paper that draws on many years of experience across the Canadian Arctic and inevitably some of the ideas have been previously reported in contributions such as Forbes, D.L. and Hansom, J.D. 2012. Polar coasts. In: Treatise on Estuarine and Coastal Science, vol. 3, 245-283, Academic Press, Waltham. In addition, the results related to RSL change in northern Canada are drawn from a recently published Geological Survey of Canada Open File, cited in the abstract. The presentation in this form as a synthesis of coastal sensitivity to climate change and other forcing across the Canadian Arctic, incorporating the latest RSL projections and unpublished field results, is original and not under review or accepted elsewhere.

Abstract Body: Canada's northern coasts comprise over 180 000 km of shoreline extending across 80° of longitude (Beaufort Sea to Labrador Sea) and >30° of latitude (James Bay to Lincoln Sea). Large environmental gradients in temperature, ground ice, sea ice, sea-level trend, storm climate and other factors across this vast area interact with a complex mosaic of geology and geography to produce a wide range of coastal features and sensitivity to environmental change, an understanding of which is needed to minimize negative impacts and challenges to sustainability. Relative sea-level (RSL) trends and projections, available for 22 sites across northern Canada (1), range from rapidly falling to rapidly rising RSL. Trends and projections are affected by global mean sea-level rise, glacial isostatic adjustment (GIA), gravitational fingerprinting, and dynamic oceanography. GIA dominates regional variability of RSL in northern Canada. Some areas such as the transgressive breached-lake and ice-rich permafrost shores of the Beaufort Sea already exhibit rapid change. Rising temperatures, promoting thermal abrasion, and expanding open-water, enabling more energetic waves, promote rapid and locally accelerated coastal retreat in this region. Where sediment supply is high, shoreline progradation can counteract the effects of rising sea level. Elsewhere, stable or falling sea levels against resistant rock shorelines limit rates of coastal change, except where rapid emergence (forced regression) is ongoing. Even in such areas, expanding open water and increased wave activity can promote unexpectedly rapid coastal realignment, as at Arviat and Hall Beach, Nunavut. Ice-locked, low-relief, coasts on unlithified formations in the Sverdrup Basin are primed for rapid wave reworking should open water become more extensive, but this area may be among the last to see a reduction in sea ice.

Title: Consequences of climate change on soft cliff erosion on the North Shore of St.Lawrence, Québec

Presenter/First Author: Geneviève Boucher-Brossard, University of Quebec at Rimouski UQAR, Rimouski,

Presenter/First Author Email: genevieve.brossard@gmail.com

Co-authors: Pascal Bernatchez, Université du Québec à Rimouski (UQAR), Rimouski, QC, Canada; Maude Corriveau, , , ; Yvon Jolivet, , ,

Abstract Body: Cliffs composed of fine sediments along the North Shore of the St.Lawrence are eroding rapidly due to cryogenic, hydrogeologic and hydrodynamic processes. Six monitoring cameras were installed along the cliff of Rivière-St-Jean between 2008 and 2012 to identify mechanisms responsible for cliff retreat. Data analysis reveals a strong seasonal behavior with activity peaks during winter and spring, which account for two-thirds of total erosional events. Small magnitude processes but frequently occurring, such as thermo-erosion, micro-gelifraction, solifluction and mudflows, induced rapid cliff retreat. Historical and seasonal monitoring using field markers, coupled with photo-interpretation and historical archive analysis, indicates an average annual erosion rate of 2 meters per year since 1948. An acceleration in retreat occured during the last 70 years, leading to a maximum between 1997 and 2005 (3,60m/yr). Lithostratigraphy exerts an important control on erosion rates which are described by three modes of retreat (hydrogeological, cryogenical or hydrodynamical). We are able to describe individual erosional events in an environmental and climatic context due to the use of high resolution data collection. Critical conditions promoting high erosion rates include the absence of an icefoot in winter, the absence of snow cover on cliff face allowing unrestricted solar radiation and the repetition of winter warm spells events.

Title: A Comparison of Sable Island Dune Morphology using 1988 and 2009 Profile and Digital Data

Presenter/First Author: Mary-Louise Byrne, Wilfrid Laurier University, Waterloo,

Presenter/First Author Email: mlbyrne@wlu.ca

Published Material: These results were published in a report to Parks Canada as part of an environmental Impact statement for Sable Island Natioanal Park Reserve. The results were also published in a popular science style collection.

Abstract Body: The dunes of Sable Island can be categorized into four physiographic regions: the west spit, the main body, the wide flat beaches on the south part of the island including the plain of former Wallace Lake, and the east spit. Five profiles were measured using a theodolite and stadia rod in 1987 and 1988 across the island to define its basic morphology and dimensions. Using 2009 digital images and data similar profiles were digitized to determine changes that have occurred in the dune geomorphology over the twenty-year period. A summary of the results is outlined in this paper. In addition the dune morphology and a classification of the dunes, based on physiographic processes, vegetation cover, and morphology is presented.

The morphology of the dunes is variable, with elevation increasing toward the east, and width of the dune belt changing along the length of the island according to variations of width of the beaches and the Sandy Plain. In some areas the twenty plus years have resulted in remarkably little change in the profile of the dunes across the island. In other areas, there has been significant erosion and redistribution of sediment resulting in an overall decrease of the dune elevations. The unvegetated dunes can be classified as primary (dunes that develop as a result of wind action and the movement of sand over a uniform surface) or secondary (dunes that involve the deposition of sand on or behind pre-existing obstacles that slow wind speed in its lee). Vegetated dunes may be primary, secondary, or tertiary, depending upon the type of vegetation, the rate of change, and stability of the formation.

Title: Assessment of the Approach Used to Design a Salt Marsh Restoration on the Bay of Fundy, NB, Canada and of Overall Project Success from a Geomorphic Perspective

Presenter/First Author: Jeff Ollerhead, Mount Allison University, Sackville,

Presenter/First Author Email: jollerhead@mta.ca

Published Material: Early results from this work were presented at the 2013 Binghamton Geomorphology meeting and the 2014 ACCESS meeting.

Abstract Body: With rising relative sea level and climate change, restoring a salt marsh as part of a dyke abandonment plan may be desirable in Atlantic Canada in coming years. As a pilot project, a salt marsh restoration on the Bay of Fundy was designed in 2009-2010 and implemented in 2010. Three openings (breaches) were cut in an old dyke to allow the adjacent areas to flood with salt water at high tide. Restoration has been monitored since 2010 and key environmental variables measured. One aspect of the monitoring was to take collected data for sediment deposition, site topography, and water flows through the breaches and in the restoration area, and use them to both improve the implementation of the hydrodynamic model used to design the breaches and to assess the relative success of the design used. Using measured water levels, breach geometry, and site topography, the type of model used to design the breaches was rerun for tide cycles for which flow data were recorded using an acoustic Doppler velocimeter (ADV) and/or an acoustic Doppler current profiler (ADCP). Overall, the results obtained are very promising. The model predicts flows in the restored area reasonably well, especially when a high drag coefficient is used. Correlation coefficients between modeled and measured flow values are generally high. For sediment deposition, the modeled results generally agree with measured results. The model is effective for showing where sediment is likely to accumulate to the greatest degree (i.e., relative deposition). The study confirms that the design approaches taken were sound, effective, and could certainly be used to design a future salt marsh restoration project on the Bay of Fundy.

Title: The impact of climate change on Arctic coastal erosion

Presenter/First Author: Nicole J Couture, Geological Survey of Canada -, Halifax, NS

Presenter/First Author Email: ncouture@nrcan.gc.ca

Abstract Body: The Arctic Coastal Dynamics (ACD) project is an effort sponsored by the International Arctic Science Committee (IASC) to better understand coastal processes in the circum-Arctic by focussing on the physical properties of the coast and some of the major environmental forcings that affect it. The presence of ice along Arctic coasts -- both in the form of sea ice and of ground ice within permafrost -- results in conditions and processes that differ greatly from what is found in more temperate regions. ACD's primary goal was to assess the sensitivity and erosion potential of over 100,000 km of Arctic coastline. Two other initiatives sponsored by the Geological Survey of Canada (GSC) both fed into and were inspired by the ACD project. These focus on characterization and mapping of northern coasts at a Canada-wide scale (CanCoast) and a regional level (GSC Coastal Information System). All three provide a basis for classification and mapping of shore-zone topography, geomorphology, composition and exposure in relation to relative sea-level trends, atmospheric and oceanographic forcing, sea-ice conditions, and other aspects of the physical setting. Here, we present the methodology used for classification at the various scales and some of the insights emerging from these efforts. These include the regional variability of erosion rates and carbon input to the Arctic Ocean on a circumpolar basis (Lantuit et al. 2012) and the geographic variability in coastal sensitivity to climate change across the Canadian Arctic.

Title: Ice Wall Growth and Decay: Meteorological Analysis and Modelling

Presenter/First Author: Francis Gauthier, University of Quebec at Rimouski UQAR, Rimouski,

Presenter/First Author Email: francis_gauthier@uqar.ca

Co-authors: Michel Allard, Laval University, Quebec City, QC, Canada; Bernard Hétu, , ,

Published Material: Recently accepted by a scientific journal (Permafrost and Periglacial Processes)

Abstract Body: The growth and decay of three ice walls was surveyed and analyzed during the winter of 2010-2011. Ice walls form on a cliff face due to the freezing of seeping ground water: two of the studied ice walls are on north-facing rock faces and one over a south-facing cliff. Ice walls growth and decay models were developed using meteorological data collected in their immediate surroundings and checked against growth and decay rates measured by volume changes from terrestrial LiDAR images. A complete energy balance model is first proposed and compared with two other simplified models. The first one is a temperature index or freezing degree-hours model (FDHm), and the second one is a model that combines the FDHm and the radiation heat budget (Q_{rad}). Both models reveal that heat loss from air convection from the seeping water to the atmosphere is the dominant heat transfer flux responsible for the north-facing ice walls growth and decay. Solar radiation also plays a major role for the melting of these ice walls. The overall evolution of the south-facing ice wall is more dependent of the daily variation of Q_{rad}. When the air temperature is cold, the ice forms mostly during the night while solar radiation favours its melting during the day.

Title: Quantifying Heat Advection by Groundwater Flow in the Active Layer: Laboratory Simulations

Presenter/First Author: Sabine Veuille, University of Montreal, Montréal,

Presenter/First Author Email: sabineveuille@gmail.com

Co-authors: Manuel Verpaelst, Université de Montréal, Montréal, QC, Canada; Simon Charbonneau, , , ; Katerine Grandmont, University of Montreal, Montreal, Canada; Daniel Fortier, University of Montreal, Montreal, QC, Canada

Abstract Body: Rising temperatures due to climate change affect permafrost thermal regime through convective heat transfer at the air-soil interface. Surface run-off and groundwater flow also impact the ground thermal regime by convective heat transfer processes and must be taken into account to obtain an accurate global thermal balance. The magnitude of surface run-off and subsurface water flow is strongly related to topography, and both processes contribute to the thawing in the active layer. This phenomenon is even more pronounced where the active layer is ice-rich. Although the influence of heat advection has already been demonstrated, the efficiency of thawing by convection compared to thawing by conduction has been poorly quantified so far. This knowledge gap has been in part created by the impossibility to control all parameters in natural settings. The Peclet number is an indicator that can be used to determine which of the two phenomena is predominant. However latent heat is not included in the equation which limits the analysis, especially with very low flow.

To overcome field variability, experiments were carried out in a controlled environment to link field conditions with laboratory tests. To replicate physical permafrost models and compare the efficiency of thawing by convection versus thawing by conduction, eight cells were designed and filled with different saturated soils. The cells were submitted to two different air thawing conditions: 15 and 5°C. Four cells were thawed by conductive heat transfer whereas four others were submitted to sub-surface flow. Slope and water temperatures, 15 and 5°C, varied with the experimentations. Results show that the efficiency rate of thawing by convection in comparison to thawing by conduction is proportionally correlated with temperatures, water flow and slope. Convection is 2 orders of magnitude more efficient when temperatures are different (warmer water temperature) than when they are equal.

Title: Dynamics of sporadic mountain permafrost – case study of Mont Jacques-Cartier (1977-2014), Chic-Chocs Range, South-eastern Canada

Presenter/First Author: Gautier Davesne, University of Montreal, Montréal,

Presenter/First Author Email: davesne.g@gmail.com

Co-authors: Daniel Fortier, University of Montreal, Montreal, QC, Canada

Abstract Body: In southern Quebec, mountain permafrost is restricted to the highest bare ground flat summits of the Chic-Chocs Mountains (Northern Appalachians, Gaspé Peninsula). The existence of a contemporary permafrost body was reported on Mt Jacques-Cartier – the highest point in southern Quebec (1273 m a.s.l.) – in 1977 by way of a thermistors cable installed in a 29 m deep borehole. With a 36-year long record of ground temperature, this summit is one of the longest permafrost-monitoring sites in North America and is therefore of great interest to study the impact of climate change on sporadic mountain permafrost.

The rounded summit of Mt Jacques-Cartier is mantled by a 3m-thick regolith cover reworked into periglacial landforms. The soils on the plateau support an alpine tundra vegetation and isolated krummholz patches. To determine the factors controlling ground surface temperature (GST) on the summit, 20 sensors have been installed in the near-surface (-5 cm) in sites with different terrain parameters (e.g. bare ground surface, krummholz, snow bed).

The results showed that the spatio-temporal variability of the GST over the summit is mainly correlated with the snowpack distribution which is controlled by the interaction between the prevailing NW wind and the summit topography and the surface roughness resulting from periglacial landforms and krummholz patches. On the wind-exposed plateau, the snow is systematically blown away as surface roughness is low. The mean snowpack depth is about 35 cm which corresponds to the maximum snow-retaining capacity created by the microtopography of blockfields and sorted-polygons. The mean annual GST was on average about -1°C in 2013 over the summit area. In the krummholz patches and in the topographic depression on the leeward slope, drifted snow accumulation is significant (> 2 m thick) and the mean annual GST was thus warmer (3°C in 2013) than on the wind-exposed plateau.

From 1978 to present, the air temperature increased about 1°C at the summit. The resulting ground temperature warming was +0.4°C at 14 m through this period. From 2008 to 2013, the warming trend was more pronounced with rapid warm-side deviation of the temperature profile (e.g. +0.08°C/year at 14 m). The active layer depth increased by +0.5 m/year over the same period.

Title: Impact of Land Cover Disturbances on Permafrost Landscapes in Yukon, Case Studies

Presenter/First Author: Katerine Grandmont, University of Montreal, Montreal,

Presenter/First Author Email: katerine.grandmont@umontreal.ca

Co-authors: Louis-Philippe Roy, Yukon Research Centre, Yukon College, Whitehorse, YT, Canada; Bronwyn E Benkert, Yukon College, Whitehorse, YT, Canada; Antoni Lewkowicz, University of Ottawa, Ottawa, ON, Canada; Daniel Fortier, University of Montreal, Montreal, QC, Canada

Published Material: Some of the case studies were presented at the ArcticChange (ArcticNet) Conference in Ottawa last December.

Abstract Body: The impacts of rising temperatures in permafrost regions are already being observed in many communities. Environmental changes can be exacerbated by human intervention and most of the time these operations (e.g. road installation, logging) can impact on the environment at a faster pace than those induced by climatic changes. When combined, climatic and anthropogenic changes can result in important hazards for community planning. From a project managed by the Northern Climate ExChange, case studies from Yukon were selected to illustrate the impacts of land cover changes on permafrost landscapes.

Under a FireSmart zone where trees are still present, the stability of the permafrost has been maintained with an active layer depth of 0.65 m. Illustrating how surface disturbance can impact the ground thermal regime, an adjacent cleared area has developed a near-surface talik (unfrozen zone over the permafrost) that reaches 8 m in depth.

To access gold bearing material, placer mining operations strip the first meters of soil and vegetation. A land plot shows early signs of permafrost degradation in a stripped area. By removing the insulating organic cover, the active layer has thickened to a depth greater than 1.6 m in just under 10 years. In comparison, an adjacent forested zone is showing a 52 cm thick active layer, underlain by ice-rich permafrost.

Removing vegetation and stripping the ground can also lead to the accelerated degradation of ice wedges, such as occurred at a residential area where a forest was cleared in the 90's for agricultural purposes. In a little over 20 years, degradation of ice wedges created linear subsidence and water ponding where the terrain was previously flat and polygonal network of ice wedges progressively appeared and are now clearly visible.

Our results indicate that land-use changes, especially those affecting the vegetation cover, can impact permafrost geosystems much more rapidly than changes induced by atmospheric warming only.

Title: Implications of Galling Herbivory on Ground Thaw Through Shrub-Soil Heat Transfers in Canada's Northern Boreal Forest

Presenter/First Author: Allison McManus, Wilfrid Laurier University, Waterloo, ON

Presenter/First Author Email: mcma9840@mylaurier.ca

Co-authors: Jennifer Lynn Baltzer, Wilfrid Laurier University, Waterloo, ON, Canada; William L Quinton, Wilfrid Laurier University, Waterloo, ON, Canada

Abstract Body: The significant climate warming faced by Canada's northern boreal forest has the potential to affect forest dynamics by altering the dispersion and abundance of resident natural enemies. Warmer air temperatures can impact the distribution and overwinter survival rate of these arthropods. Thus, the impacts of arthropod pests on their host plants require better understanding. Gall-inducing mites are a resident natural enemy in high latitude forests and have been shown to drive dramatic reductions in photosynthetic carbon uptake and transpiration rates of infested plants with the potential to alter shrub-energy balance. In this study we examine the impacts the gall-inducing eriophyoid mite, *Vasates oldfieldi*, has on *Betula* shrub energy inputs to the underlying ground surface. Two hypotheses will be tested: 1) a positive feedback to permafrost thaw through a reduction in evaporative cooling on the leaf surface increasing the canopy temperature of the *Betula* shrubs. The increase in the incident longwave radiation to the ground surface leads to an increase in the active layer thickness. 2) a negative feedback on permafrost thaw through a compensatory response in the shrub leading to an increase in leaf area index (LAI) to offset the loss of photosynthetic function. This reduces the amount of incident solar radiation at the ground surface resulting in a shallower active layer. To test these hypotheses, we measured soil moisture and surface temperature, leaf temperature, active layer thickness, shortwave radiation, transpiration and LAI. Our initial findings have shown an increase in active layer thickness and soil temperature under ungalled shrubs compared to galled shrubs of similar size for both the 2013 and 2014 field seasons. The results from this experiment are of great significance as the potential for a positive feedback of warming at a very local scale can potentially influence ground thaw in the northern boreal forest.

Title: Seasonal Dynamics of Ecosystem Carbon Exchange for a Wet Sedge Vegetation Community, Melville Island, NU

Presenter/First Author: Amy Blaser, Queen's University, Kingston, ON

Presenter/First Author Email: amy.blaser@queensu.ca

Co-authors: Neal A Scott, Queen's University, Kingston, ON, Canada; Paul Treitz, Queen's University, Kingston, ON, Canada

Published Material: Preliminary results were presented at Arctic Change 2014 conference December 8-12 (poster presentation).

Abstract Body: Wet sedge meadows are the most productive communities in the High Arctic. Preliminary research suggests that this plant community is a net carbon sink, yet the controls – and the scale at which those controls act – are not well understood. If climate change enhances wet sedge growth, we may observe increases in the percentage of land area occupied by these meadows, altering the carbon balance of high arctic landscapes.

We examined seasonal carbon exchange processes in three wet sedge meadows at the Cape Bounty Arctic Watershed Observatory (CBAWO). Automated and static CO_2 exchange systems recorded CO_2 exchange from June to August, 2014. In conjunction with these measurements, time-series NDVI images were collected to quantify the phenological stage of the community through the growing season. Simultaneous measurements of soil temperature, air temperature, PAR, soil moisture, and active layer depth were also made.

Net ecosystem exchange (NEE) measurements indicate carbon uptake through photosynthesis, and NEE rates differed in spectrally separable 'wet' and 'dry' sedge areas (-0.33 and 0.01 μmol m^{-2} s^{-1} means respectively; $p<0.001$). NDVI measurements captured spring greening and peak summer biomass, and will likely be a critical variable for modelling CO_2 exchange. Abiotic factors such as soil and air temperature may also influence CO_2 exchange, though this system is driven strongly by soil moisture.

Predictive models of ecosystem carbon fluxes will be created using NDVI and environmental measurements as predictors of carbon flux. This will allow us to evaluate the drivers of CO_2 exchange in these communities – spatially and temporally – and facilitate predictions of NEE based on NDVI and/or biophysical variables. We will also evaluate the scale (largely temporal) dependency of these controls to improve predictions of annual carbon fluxes at the landscape scale.

Title: Iron Isotopes for Characterizing Iron Cycling in the Amazon River Basin

Presenter/First Author: Franck Poitrasson, Universidade de Brasilia-IRD, Brasilia, Df,

Presenter/First Author Email: Franck.Poitrasson@get.obs-mip.fr

Co-authors: Daniel S Mulholland, , , ; Thierry Allard, CNRS, Paris, France; Lucieth Vieira, , Brasilia, Brazil; Patrick T. Seyler, HydroSciences Montpellier, Montpellier Cedex 05, France; Francis Sondag, , ,

Published Material: These were published in EPSL, Chemical Geology and GCA in 2014 and 2015

Abstract Body: With the global climate change and increasing anthropic pressure on nature, it is important to find new indicators of the response of complex systems like the Amazon River Basin. In particular, new isotopic tracers like those of iron may tell us much on processes such as the chemical exchanges between rivers, soils and the biosphere.

Accordingly, early studies revealed that for some river waters, large $\delta^{57}Fe$ fractionations are observed between the suspended and dissolved load, and isotopic variations were also recognized on the suspended matter along the hydrological cycle. Besides, soil studies from various locations have shown that $\delta^{57}Fe$ signatures depend mostly on the weathering regime.

We therefore conducted Fe isotope surveys through multidisciplinary field missions on rivers from the Amazon Basin. It was confirmed that acidic, organic-rich black waters show strong Fe isotope fractionation between particulate and dissolved loads. Furthermore, this isotopic fractionation varies along the hydrological cycle, like previously uncovered in boreal waters suspended matter. In contrast, unfiltered waters show very little variation with time.

It was also found that Fe isotopes remain a conservative tracer even in the case of massive iron loss during the mixing of chemically contrasted waters such as the Negro and Solimões tributaries of the Amazon River. Given that >95% of the Fe from the Amazon River is carried as detrital materials, our results lead to the conclusion that the Fe isotope signature delivered to the Atlantic Ocean is undistinguishable from the continental crust value, in contrast to previous inferences.

The results indicate that Fe isotopes in rivers represent a promising indicator of the interaction between organic matter and iron in rivers, and ultimately the nature of their source in soils. As such, they may become a powerful tracer of changes occurring on the continents in response to both weathering context and human activities.

Title: Multiple Isotopes as Tracers of Human Impacts on Geochemistry of Elements in River Systems

Presenter/First Author: Jiubin Chen, Institute of Geochemistry, Guiyang,

Presenter/First Author Email: chenjiubin@vip.gyig.ac.cn

Published Material: GCA,2014, 128, 128-143

Abstract Body: Zinc, Iron and Copper are anthropophile elements and are essential for biogeochemical and physiological functioning of terrestrial and oceanic organisms. Changes in the supply of these metals in continental rivers may affect their global bio-geochemical cycles and even the related metamorphic activities of aquatic organisms. It is thus essential to precisely determine the sources of these metals in river systems and the variations of fluxes of these metals input by human activities and to the ocean in modern environment. The recently developed isotope methods may be used for tracing the sources of these metals and characterizing their geochemical behaviors and fluxes in rivers. Multi isotopes may provide more complete picture of anthropogenic impact on geochemistry and the fluxes of these elements in rivers.

We report multiple isotopic compositions in both dissolved and suspended loads of the anthropogenically-impacted Seine River (France). The Seine basin displays two important characteristics: a relatively simple carbonated-dominated lithology and an increasing anthropogenic impact from the headland towards the estuary. In this study, the concentrations and isotope compositions of these metals, together with major and trace element concentrations, were measured for a wide sample sets including a geographic transect from headwater to estuary, a temporal series of samples collected in Paris and an anthropogenic sample series. Our data show that the concentrations of these metals in SPM clearly increase downstream, while their isotope compositions show a decrease. Calculation of enrichment factor relative to natural background points to an important anthropogenic input of these metals. This input could be traced by combining multiple isotopic data with the geochemistry of other major and trace elements. Taken as a whole, though Zn, Fe and Cu concentrations correlate very well, Cu displays different isotopic trends compared to those of Zn and Fe. Our study demonstrated the importance of multi-isotopes in studying the anthropogenic contribution and characterizing the geochemical behaviors of heavy metals in river systems.

Title: Bioindicators as Atmospheric Pollution Tracers: a Multi-Isotope Approach

Presenter/First Author: Genevieve Vautour, , Longueuil, QC

Presenter/First Author Email: vautour.genevieve@courrier.uqam.ca

Co-authors: Florence Gagnon, , , ; Andre Poirier, University of Quebec at Montreal UQAM, Montreal, QC, Canada; David Widory, GEOTOP-UQAM, Montreal, QC, Canada

Abstract Body: Air quality has become in recent years a focus of attention worldwide because of its direct impact on human health. However, even if the monitoring of contaminant concentrations gives a first idea on air quality, it lacks the capacity to give indication about the source(s) and processes controlling the budget of the contaminants. Recent studies[1, 2] have suggested that an isotope approach can help alleviate this difficulty. Lately, bioindicators (including moss and lichens) have shown their added value as passive samplers for monitoring atmospheric contaminants due to their ombrotrophic nature and their lack of protective membrane that allow them to concentrate elements to levels exceeding their physiological needs.

Our study is set in the mining region of the Abitibi-Temiscamingue in eastern Ontario and seeks to differentiate the atmospheric metal contribution from two smelters (nickel and copper) in the area using the concentration and isotope ratios of lead (Pb), strontium (Sr) and osmium (Os). We collected lichen samples from a 500 km transect from the city of Sudbury, Ontario to Rouyn-Noranda, Québec. The Sudbury region is home to Vale's and Glencore's nickel smelters. Osmium is a trace metal commonly found as a –significant- impurity in nickel and platinum ores. In the city of Rouyn-Noranda, 300 km from Sudbury, Glencore operates a copper smelter.

We previously conducted a similar study in two different environments: Hawaii, USA and Rigaud, Québec. The first is a recent basaltic island sourced from a mantle plume while the second is an old granitic intrusion (564 Ma[3]) within the sedimentary basin of the St. Lawrence Lowlands. The strontium and lead isotope ratios of the bioindicators differentiate between two natural sources (local basaltic rocks and the oceanic input) in Hawaii, and between natural and anthropogenic sources in Rigaud. The osmium isotope analyses will be conducted by the time we meet in Montreal.

Title: Isotopic analyses of *Hypogymnia physodes* (C, N, S, Pb) as a tool for assessing anthropopressure in the Świętokrzyski National Park (Poland)

Presenter/First Author: Monika Maria Ciężka, Organization Not Listed, Wrocław,

Presenter/First Author Email: monika.ciezka@ing.uni.wroc.pl

Co-authors: Maciej Górka, Department of Applied Geology and Geochemisrty, University of Wroclaw, Cybulskiego St. 30, Wrocław, Poland; David Widory, GEOTOP-UQAM, Montreal, QC, Canada

Abstract Body: Bioindicators eg. lichens are one of the most popular and useful tools for assessing an anthropogenic impact on air quality. The main goals of the present study are: (i) to compare air quality under different levels of human impact: low (Świętokrzyski National Park - ŚPN) and high (cities and industry in the vicinity of the ŚPN) and thus (ii) to assess the anthropogenic pressure on the environment using quantitative (atmospheric pollutant concentration) and qualitative (isotope compositions of carbon, nitrogen, sulfur and lead isotope ratios).

Samples were collected during heating season between the 1st and 3rd February 2013. Samples of *Hypogymnia physodes* were collected in 20 locations within the ŚNP (n=18) and in its nearest vicinity (n=2). Lichens were taken from bark and branches of *Abies alba* trees.

Concentrations of SO_2 and NO_2 in the surrounding air were analyzed by the Amay-Krochmal method using passive samplers. CO_2 concentrations and corresponding $\delta^{13}C$ were measured using Gasbench II-CF-IRMS. Isotope compositions of C and N from bioindicators were determined by EA-CF-IRMS and S isotope compositions by DI-IRMS and Pb ratios by MC-ICP-MS.

Preliminary conclusions of this work are as follows: (i) S, C, N and Pb point at distinct origins and different bio-physico-chemical pathways; (ii) $\delta^{13}C$ results shows an altitude effect but no relationship with the corresponding C concentrations; (iii) $\delta^{15}N$ shows a slightly positive relationship with altitude as well as with N concentration that could reflect inputs from fossil fuels combustion; (iv) $\delta^{34}S$ are currently analyzed and results will be presented during conference; (v) Pb isotope results indentify an industrial origin; (vi) the highest NO_2 concentrations are located near main roads; (vii) the maximum SO_2 concentrations are observed at the highest altitude and open locations indicating long-distance deposition of regional pollutants; (viii) anthropogenic air pollutants are reflection of industry derived by local dominant (S and SW) wind direction.

Title: Morphology and Sediment Transport in Semi-alluvial Channels

Presenter/First Author: Peter Ashmore, University of Western Ontario, London, ON

Presenter/First Author Email: pashmore@uwo.ca

Abstract Body: Definitions of semi-alluvial channels differ in detail but the term has been applied to describe those channels in which alluvial deposits are either thin or discontinuous but the underlying non-alluvial (usually cohesive) material in the bed, and /or exposed in the banks, is readily eroded by prevailing flows. The consequence is that river morphology and channel adjustment, e.g. cross-section dimensions and in-channel bars, may be very similar to that of alluvial channels with similar flows. Neither the geographical occurrence nor the controlling conditions of these types of channels are well known, but they appear to be common in glaciated regions with extensive and thick deposits into which rivers are eroded. In the Great Lakes region examples range from small headwater streams, through main-stem rivers and include some of the Great Lakes connecting channels. In some cases the primary depositional cover over the non-alluvial material is gravel-cobble. While these channel types may have some morphological and process characteristics of partially-alluvial bedrock channels, the extent to which concepts of erosion, cover formation-loss, and bedload transport developed for bedrock channels are applicable to semi-alluvial channels is an open question. It is also likely that process analyses such as bedload-transport formulations for fully-alluvial rivers are not directly transferrable to semi-alluvial cases. A systematic program of research is needed to expand knowledge of semi-alluvial river morphology and processes.

Title: Longitudinal variations in channel morphology in postglacial watersheds of the northeastern United States

Presenter/First Author: Noah P Snyder, Boston College, Chestnut Hill, MA

Presenter/First Author Email: noah.snyder@bc.edu

Published Material: Some aspects of the work were included in Snyder et al. (GSA Bulletin, 2013).

Abstract Body: Landscapes formerly occupied by continental ice sheets are characterized by exposed bedrock, till and localized thicker glacial deposits. Rivers in Maine, USA have alternating gravel-bedded steep (gradient > 0.002) and finer gradual (gradient < 0.0005) reaches imposed by the glacial geomorphic and geodynamic history of the region. The low-gradient reaches often include mainstem lakes that are infilling with sediment. These stair-stepped longitudinal profiles lead to discontinuities in sediment flux through the channel network, creating a series of downstream-fining sedimentary links (Rice and Church, 1998). In this presentation, I will review the development and testing of a model to predict bed grain size from a high-resolution (lidar) digital elevation model, based on assumptions of threshold single-thread channels with supply-limited conditions. The field area is a set of three watersheds in Maine, USA, where field ground-truth data were collected. My purpose is to explore how the success or failure of the model is influenced by longitudinal controls on bed shear stress or stream power (via slope and drainage area) and sediment supply (via tributary inputs and eroding glacial deposits). The model is most successful sediment-starved steep reaches, such as those downstream of mainstem lakes. The model is least successful in low-gradient, relatively fine-grained (median grain size < 16 mm) reaches. These variations in model success, which are connected to the glacial geology of the region, have implications for fish habitat, stream restoration, and geomorphic response to climate and land-use changes in the region.

Title: Three Quarters Alluvial: Constraining the Semi-Alluvial River Condition in the Glacial Landscape of Southern Ontario

Presenter/First Author: Roger TJ Phillips, University of Toronto, Milton,

Presenter/First Author Email: roger.phillips@utoronto.ca

Co-authors: Joseph R Desloges, University of Toronto, Toronto, ON, Canada

Published Material: Abstract is based on new set of classifications applied to semi-alluvial rivers. Mapping of field sites and original classifications are based on data in two recently published papers below. Phillips, R.T.J. and Desloges, J.R. (2014). Glacially conditioned specific stream powers in low-relief river catchments of the southern Laurentian Great Lakes. *Geomorphology*, 206: 271-287.Phillips, R.T.J. and Desloges, J.R. (2014). Alluvial floodplain classification by multivariate clustering and discriminant analysis for low-relief glacially conditioned river catchments. *Earth Surface Processes and Landforms*. DOI: 10.1002/esp.3681

Abstract Body: Rivers and streams of southern Ontario are carved into a diverse landscape of glacial landforms and deposits of varying thickness. Semi-alluvial channels are incised into non-alluvial boundary materials of glacial clay or exposed bedrock, with varying amounts of alluvial cover. In this paper, we question the degree to which semi-alluvial conditions are a "natural" state for fluvial systems in the low-relief glacial landscape of southern Ontario, and the degree to which intermittent contact with glacial materials modifies alluvial channel processes. To examine these questions, we consider the frequency and extent of semi-alluvial channels in the region, and the potential effects of post-settlement deforestation and urban land use history on their distribution.

An exploration of hundreds of field sites across peninsular southern Ontario provides evidence that reaches with extensive non-alluvial boundaries occupy only a small proportion of drainage networks in the region. For this study, field observations of semi-alluvial and alluvial reaches are organized within a recently published classification framework for alluvial floodplain types. Many river reaches have thick alluvial cover, with very little evidence of exposed glacial materials (or bedrock). Where alluvial channels intermittently come into contact with glacial materials, these glacial beds and bluffs are important sources of sediment, but they only impose local controls on channel behaviour. The morphodynamics of channels in intermittent contact with glacial boundaries are likely to be very similar to that of alluvial channels. Channels with thin alluvial cover and extensive glacial materials exposed on the bed and banks are often located on oversteepened tributary reaches and/or in watersheds impacted by urban development. The implications for channel morphodynamics and floodplain accretion processes in these glacial boundary reaches are still poorly understood.

Title: Development of sand-bedded rivers in glaciated, Southern Ontario

Presenter/First Author: Anna Marie Megens, University of Toronto, Etobicoke,

Presenter/First Author Email: anna.megens@mail.utoronto.ca

Co-authors: Joseph R Desloges, University of Toronto, Toronto, ON, Canada

Abstract Body: Many studies of river and floodplain sedimentology demonstrate their complexity and the need to simplify observations in the form of standard models. A standardized description, classification, and interpretation of fluvial deposits or facies models were revised by Miall (2010) to represent the behavior of meandering rivers. A field investigation was undertaken to test the applicability of the accepted meandering sand-bedded river facies model to sand-bed rivers in Southern Ontario. A challenge in this environment is the influence of non-alluvial channel boundary materials such as glacial outwash sands, till, and glaciolacustirne clay. The presence of these materials in some channel beds and banks, and entrenchment as these rivers approach the Lake Erie base level, suggest that these rivers are not in equilibrium and that recognized "models" may not be appropriate at predicting channel behaviour. A multi-faceted approach (sedimentology, channel surveys, geophysics, etc.) is used to characterize the mechanisms and formation of fluvial sedimentary structures and the processes controlling the lateral and vertical mobility of these active channels. It appears these sand-bedded rivers are resistant to change, and that laterally accreting surfaces may represent middle-late Holocene migration patterns. This is demonstrated by limited bank migration rates, anonymously tall (5 m+) meander bends with low width to depth ratios, and sediment profiles characterized by basal hardpan clays occasionally overlain by coarse gravel lag deposits. A C14 age of 8670 ± 30 years BP at river bed level also suggests that these channels, and associated floodplains, may be less dynamic over the long term when compared to the standard model of meandering, sand-bedded rivers.

Title: The Dynamics of Glacial Till Erosion: Hydraulic Flume Tests on Samples from Medway Creek, London, ON

Presenter/First Author: Leila Anne Pike, McGill University, Portland,

Presenter/First Author Email: leila.pike@gmail.com

Co-authors: Peter Ashmore, University of Western Ontario, London, ON, Canada; Susan J Gaskin, McGill University, Montreal, QC, Canada

Abstract Body: The erosion of till material from the river bank of Medway Creek in London, Ontario was studied to determine the erosion mechanisms and critical shear stress of the till, and to understand how the alluvial cover, particularly the gravel particles, impacts the erosion process. Samples were collected from Medway Creek and were tested under a unidirectional current in a hydraulic flume at McGill University under a unidirectional current. Samples were tested under three separate sets of conditions: samples at their natural moisture content in clear flow conditions, air-dried samples in clear flow conditions, and samples at their natural moisture content with large gravel particles present in the flume. The two latter tests were performed to determine any effects that weathering and the presence of alluvial material may have in the erosion process. The results show that mass erosion was the dominant form of erosion, occurring around natural planes of weakness and irregularities, such as gravel particles, within the material. The critical shear stress was observed to be approximately 8 Pa. The effect of drying on the erosion process was extreme – the critical shear stress dropped to below 1 Pa and the structure of the cohesive material disintegrated. The presence of gravel particles led to increased surface erosion due to impacts and a more rapid progression of the erosion. In summary, the till erodes around planes of weakness and irregularities, till exposed to a wetting-drying is most at-risk of erosion, and the presence of gravel does not provide a protective layer over the till and instead lowers the critical shear stress.

Title: Urbanization, Channel Adjustment, and Restoration of a Suburban Semi-Alluvial Creek: the Case Study of Wilket Creek in Toronto

Presenter/First Author: Bruce MacVicar, University of Waterloo, Waterloo, ON

Presenter/First Author Email: bmacvicar@uwaterloo.ca

Co-authors: Margot Chapuis, , , ; Vernon Bevan, , , ; Emma Buckrell, , , ; Andre Roy, University of Waterloo, Waterloo, ON, Canada; John Parish, , , ; Ryan Ness, , , ; William Snodgrass, , ,

Abstract Body: Land use changes related to urbanization are known to have a profound impact on stream hydrology, sediment transport, ecology, and aesthetic value. Wilket Creek in Toronto is an excellent example of urban development in the 1960's and 70's because it is largely suburban, stormwater conveyance was massively increased, and a portion of the creek was preserved as a part of linear park. It is also semi-alluvial, which means that classic models of channel evolution may not be applicable. The objectives of the current study were to 1) assess the character and degree of channel change that has occurred since development, 2) determine whether channel enlargement is still ongoing, and 3) assess the likelihood of success for recent in-stream restoration efforts. Historic analysis was completed using aerial photographs, measurements from a relic channel, and a 15 year monitoring program of channel dimensions. Assessment of in-stream restoration efforts was completed using channel surveys, water-level gauges, and sediment tracking using RFID tracers. Results show that the stream network has been effectively 'pruned' as a result of development and channel enlargement is widespread. Flood hydrology is extremely flashy, with water level increases of over 1 m in less than an hour during floods. Nevertheless, a coarse layer of glacial till continues to exert an important influence on the channel gradient. Downstream of the incision of the channel through this layer, the channel is steeper and has enlarged approximately 3x from its historic dimensions, which is close to what is predicted from an analysis of the cumulative imperviousness. Continued instability has been found over the last 15 years as the channel adjusts its planform and develops a new wandering-type morphology. RFID tracking results show that the constructed pool-riffle morphology may succeed in reducing particle mobility despite the extreme hydrology.

Title: Influence of Surficial Alluvium on Habitat Utilization by Fish in a Semi-Alluvial Clay-Bed Creek

Presenter/First Author: Parna ParsapourMoghaddam, University of Tehran, Tehran,

Presenter/First Author Email: Parsapour.p@gmail.com

Co-authors: Colin D Rennie, University of Ottawa, Ottawa, ON, Canada

Abstract Body: Morphodynamic processes play an essential role for the ecological integrity of river habitats. Fluvial dynamic processes and morphological changes in rivers can directly impact aquatic organisms; at different stages of their life-cycle they can be sensitive to sediment characteristics. Change in channel morphology can also influence habitat availability. Over the past few decades, efforts have been made to predict the influence of morphological change on aquatic habitat. Nevertheless, there are still large uncertainties in the degree to which erosion/deposition processes can impact the available habitat. The primary aim of the present study is to investigate relations between channel erodibility and habitat availability in a meandering semi-alluvial creek. The main focus of this paper is to examine whether channel erosion can affect the fish community, as the most commonly used indicator species, in two different meandering clay-bed reaches of Watts Creek in the City of Ottawa, Canada. These reaches have similar discharge and bed substrate, which consists of consolidated clay overlain discontinuously with surficial alluvium. However, one of these reaches has been destabilized due to meander confinement. In order to associate fish abundances with particular habitat features in the reach, habitat utilization by resident fish populations was evaluated in each reach. Finally, using a 3D morphodynamic model developed for the reach, along with the observed fish abundances, the effect of the channel instability and surficial alluvial material on habitat utilization is discussed.

Title: A Noval Wave Estimator Based On The Central-upwind Scheme For Simulating Rapid Bed Erosion under Shallow Water Flows

Presenter/First Author: Xin Liu, University of Southern California, Los Angeles, CA

Presenter/First Author Email: xliu111@uottawa.ca

Co-authors: Julio Ángel Infante Sedano, , , ; Abdolmajid Mohammadian, Associate professor, Ottawa, ON, Canada

Published Material: The corresponding results are written in a paper submitted to the Journal of Hydraulic Research on 14 Jun 2014, and this paper is currently under review.

Abstract Body: A coupled numerical model with a novel wave estimator is developed to simulate the rapid bed-erosion under fast varying flows. To solve the hyperbolic governing bed-load sediment transport equation using a Godunov type Central-upwind scheme, a novel scheme estimating the numerical fluxes of bed-load terms using a different pair of bonding waves from hydrodynamic system is proposed. The two-dimensional shallow water equations are adopted to solve the hydrodynamic parameters. The morphology is updated by an Exner-based equation containing bed-load sediment transport as numerical flux terms. A general form of a bed-load transport formula with a complex definition of the bed-load coefficient is applied to calculate a universal solution of the eigenvalues of the Jacobian Matrix. The linear reconstruction of variables with a multi-dimensional slope limiter and the second-order Runge-Kutta scheme are employed to achieve higher accuracy in space and time. The proposed coupled model with novel wave estimator shows better stability and accuracy than the conventional decoupled models, which are verified by several numerical tests.

Title: The Geomorphology of Ice Stream Beds: Recent Progress and Future Challenges

Presenter/First Author: Chris Stokes, University of Durham, Durham,

Presenter/First Author Email: c.r.stokes@durham.ac.uk

Co-authors: Martin Margold, University of Durham, Durham, United Kingdom

Published Material: This is a review of the topic (previous work and future challenges). It obviously contains previously publihsed material, but also new unpublished material. The review itself is original and is being prepared for publication.

Abstract Body: Ice sheets primarily lose mass by melting and discharge via rapidly-flowing ice streams. Surface and basal melting (e.g. of ice shelves) are closely linked to atmospheric and oceanic conditions, but the mechanisms that drive changes in ice stream discharge are more complex, and influenced by conditions at their bed, which may act to sustain, enhance or inhibit their motion. Although explicit comparisons are rare, the ice-bed interface is similar to the 'boundary layer' in fluvial and aeolian environments, where shear stresses (both basal and lateral in the case of ice streams) oppose the flow of the overlying medium. The analogy extends further because processes within the boundary layer create a distinctive geomorphology that is often characterised by subglacial bedforms that resemble features in fluvial and aeolian environments. Their creation results from erosion, transport and deposition of sediment which, in turn, is intimately linked to the mechanisms of ice stream flow. The study of ice stream geomorphology is, therefore, critical to our understanding of their dynamics. Despite difficulty observing the subglacial environment, our understanding of ice stream geomorphology has grown rapidly in the last three decades, from almost complete ignorance to a reasonably detailed knowledge of their geomorphological imprint. This has been brought about by two main approaches: (i) geophysical investigation of modern (active) ice streams, and (ii) sedimentological and geomorphological investigation of well-preserved palaeo-ice stream beds. The aim of this paper is to review progress in these two main areas; highlight the key questions that remain; and discuss the key opportunities that are likely to arise that will enable them to be addressed. It becomes clear that whilst each of these two main approaches have led to important advances, they have often been viewed as separate sub-disciplines, with minimal cross-pollination of ideas and concepts, particularly with respect to how landforms can be securely linked to process. However, it is argued that future surveys of modern-ice stream beds are likely to offer unprecedented opportunities to study ice stream geomorphology that will require the convergence of ideas from each of these two main approaches, together with a third approach – numerical modelling.

Title: Streamlined Landforms in Sweden: Core Types, Log-Normal Distributions and the Geomorphological Continuum

Presenter/First Author: Thomas Dowling, Lund University, Lund,

Presenter/First Author Email: tom.dowling@geol.lu.se

Co-authors: Matteo Spagnolo, University of Aberdeen, Aberdeen, United Kingdom; Per Moller, Lund University, Lund, Sweden

Published Material: Inital findings where presented at AGU2014. The analysis of this is now complete and a paper stemming from this work is currently under-review for the journal 'Geomorphology'.

Abstract Body: The newly available Swedish National Height Model is a 2.0 m horizontal, and 0.01 m vertical, resolution digital elevation model (DEM) that is free at the point of use for researchers based at Swedish institutions. With coverage currently at ~90% of the country and due to be completed by 2015 this spatially extensive, high resolution, dataset has opened up new avenues of research for Quaternary geology in the country. The work presented here utilises the new DEM to map and evaluate more than 10,000 glacially streamlined landforms. The extracted morphological variables of length, width and height are then used to test recent conclusions drawn from the glacially streamlined landscape of Great Britain and North America/Canada, to assess the impact of different core types on the morphological expression of said features.

It is found that in common with drumlins found in the British Isles their characteristics can be described by a log-normal distribution, however the long tail of the features characteristic distributions a cause problems for statistical methods of evaluation. Furthermore a re-appraisal of some conclusions drawn by previous works as to the presence of a fundamental scaling law in streamlined feature elongation is necessary. Additionally; based on a limited sample size it has been found that it is not possible to differentiate a streamlined landform's core type based on their morphological characteristics taken as whole. However the length metric does show differences between core types, and therefore may bear further investigation.

Published Material: Preliminary results of the local ice flow history near Dalby, Sweden, were presented by myself at the 2014 Geological Society of America Annual Meeting (October 19-22) in Vancouver, Canada. Implications for the evolution of the subglacial system were not included at this meeting.

Abstract Body: Temporal variability of the subglacial system is of critical importance for the dynamics of ice sheets, particularly in the case of ice streams. Herein, we explore the dynamics of the Baltic Ice Stream (BIS) through the application of Anisotropy of Magnetic Susceptibility (AMS) till fabric analysis. AMS provides a precise, unbiased, and robust assessment of the preferred orientations of silt-sized and smaller magnetic grains within the till matrix. AMS faithfully records shear strength and direction in laboratory and field situations where shear direction or ice flow is known (i.e., drumlins and flutes). In this study systematic AMS fabric analysis within an 8-meter section exposed in a quarry near Dalby, Skåne County, Sweden, reveals the dynamic nature of the BIS. This section contains over 6 meters of a dark grey, silt-clay BIS till overlain by a 1.5 m of the regional surface till – a weakly compacted, sand-rich diamicton likely deposited by the Scandinavian Ice Sheet (SIS) immediately prior to deglaciation. AMS fabric orientations in the BIS till display an apparent rotation of ice flow from northeasterly to the southwesterly, beginning approximately 0.5 m below and terminating coincident with a boulder line and discontinuous sand lenses located 3 meters from the base of the section. Above the boulder line, ice flow is from the SW. Additionally, systematic, non-linear trends in fabric strength (S_1 eigenvalue) and magnitude of anisotropy (P') punctuated by excursions coincident with the boulder line illustrate the temporal variability of bed deformation beneath the BIS during the late-stage Weichselian Young Baltic Advance (19-17ka). Each of these parameters display marked changes across the boulder line, indicating a pronounced change in the dynamics of the subglacial system during and following its formation. The surface till displays relatively high P' and susceptibilities; however, the five sample sites possessed weak fabrics (mean S_1 = 0.612) consistent with observations (e.g., lack of striated clasts) at the exposure indicating small amounts of shear. Fabric orientations from this unit indicate ice flow from the NNE indicating a SIS origin. These results have implications for the nature and evolution of bed deformation during the advance and retreat of short-lived ice streams.

Abstract Body: The geochemical and geochronological fingerprint of rock debris eroded and carried by ice streams may be used to identify the provenance of iceberg-rafted debris (IRD) in the marine sediment record. During deglacial times it has been shown that there is an increase in IRD accumulation in marine sediments underlying the western limb of the Weddell Gyre. We seek to find the provenance of this IRD, identify the ice streams contributing to the IRD load, and interpret the sequence of ice sheet retreat in the Weddell Sea embayment for the last three deglaciations.

In December 2014 we conducted fieldwork to collect samples of rock and sediment debris carried by three of the major ice streams draining the Weddell Sea embayment: the Foundation Ice Stream, the Academy Glacier, and the Recovery Glacier. We sampled both modern moraines at the edges of the ice streams and older till on hillsides next to the ice streams. In addition to rocks representing the geology of local outcrops, we found that each of the three ice streams carries a characteristic set of erratic lithologies from further upstream. The erratics also give clues to the geology hidden under the ice sheet. Over the next year we will characterize the mineralogy, $^{40}Ar/^{39}Ar$ thermochronology, U-Pb geochronology, Nd isotopic signatures, and Fe-Ti oxide compositions of these tills and erratics. The same measurements will be made on subglacial till and proximal glaciomarine sediment from core sites located at the edge of the Filchner and Ronne Ice Shelves along ice flow lines extending from the ice streams, collected on past expeditions of the RV Polarstern.

We will present initial results from this study in the context of our previous work on IRD and sediment provenance offshore of Antarctica, and discuss the possibilities for using provenance to understand ice stream dynamics over the course of glacial cycles.

Title: Bedrock Streamlining in Palaeo-ice streams: a Review of Bedrock Properties, Formation Mechanisms and Glaciological Implications

Presenter/First Author: Maarten Krabbendam, British Geological Survey Edinburgh, Edinburgh,

Presenter/First Author Email: mkrab@bgs.ac.uk

Co-authors: Nicholas Eyles, University of Toronto, Claremont, ON, Canada; Niko Putkinen, Geological Survey of Finland, Kokkola, Finland; Tom Bradwell, British Geological Survey, Edinburgh, United Kingdom

Abstract Body: Highly elongate bedrock landforms, including bedrock megagrooves, are increasingly recognised at the beds of former ice sheets. In contrast to soft-bedded elongate bedforms they i) are entirely formed by subglacial erosion, ii) may be formed over several glaciations; iii) are strongly influenced by bedrock geology. However, both soft-bedded and hard-bedded elongate bedforms require sustained unidirectional ice flow at the beds of (palaeo-) ice streams. Bedrock megagrooves occur in palaeo-ice streams where topographic steering is strong (Nass River, BC); weak (Ullapool, Tyne Gap, UK) or near-absent (Ontario, Quebec).

Bedrock control and formation mechanisms can be grouped:

1) Megagrooves on dipslopes/bedding planes (Sudbury, South Baymouth, ON; Assynt, UK); or gneiss (Georgian Bay, ON); often small-amplitude and wavelength, with round cross-profile and probably formed by abrasion focussed by debris concentrations;

2) Megagrooves parallel to bedrock strike. Low-angle dips often result in strongly asymmetric, angular cross-sections (Tyne Gap, Ullapool, UK; Isle Royale, Lake Superior); steeper dips give more symmetric grooves (Knapdale/Jura, UK). Lateral plucking is important for their formation, but in heterogeneous strata differential abrasion may also be significant.

3) Megagrooves at high angles to bedrock strike. Where strata dip with ice flow, 'bullet-shaped' mega-rock drumlins may develop (Niagara Escarpment, ON; Anticosti island, QC), with focussed erosion possibly guided by fractures and pre-glacial stream valleys.

The glaciological significance of megagrooves is that most grooved terrain is smooth parallel to ice flow: there are few bedrock obstacles, and no need for Weertman/Schoof type sliding. Instead, basal drag is controlled by a simple friction law, with (low) friction coefficients dependent on debris content. It is this smoothing that, once established, means that grooved terrain will steer and enhance fast ice flow during successive glaciations.

Title: Erosional Origin for Drumlins by Subglacial Erodent Layers: A Tribological Model

Presenter/First Author: Nicholas Eyles, University of Toronto, Claremont, ON

Presenter/First Author Email: eyles@utsc.utoronto.ca

Co-authors: Shane Sookhan, University of Toronto, Pickering, Canada; Niko Putkinen, Geological Survey of Finland, Kokkola, Finland

Abstract Body: We explore the hypothesis that drumlins and megaflutes (regardless of their cores) are residual immobile landforms formed by erosion of pre-existing sediment (or rock) below a mobile abrasive carpet of deforming subglacial debris; we draw on the industrial science of tribology where comparable remnant ridges and grooves ('wear tracks') are formed by abrasion below an 'erodent layer' at the interface of surfaces in relative motion to each other. Lineated surfaces are not unique to glacial environments and are produced by erodent layers at the base of gravity-driven mass flow deposits such as rock avalanches, landslides and debris flows, and are also very common along fault traces. Correspondingly, mega-scale glacially lineated surfaces are identified as wear tracks cut by a thin erodent layer consisting of deforming subglacial diamictic debris with erodents in the form of clast-rich debris or stiffer (frozen?) rafts entrained from the underlying substrate. Swales and megagrooves are cut into older pre-existing till sheets, sediment or rock leaving remnant high-standing drumlins and megaflute ridges with autochthonous cores of till, other sediment or rock. The common erosional origin of rock drumlins and 'sediment' drumlins explains their close juxtaposition in many drumlin fields. Many drumlins have till cores: the model predicts widespread deposition of thick subglacial till earlier in the glacial cycle followed by erosion and drumlinization accompanying the onset of ice streaming late in the glacial cycle. This implies widespread transient storage of till below ice sheets.

Title: Integrative Application of Traditional and Cutting-edge Techniques to Reconstruct Holocene Earth Surface Processes and Landscape Dynamics – A Case Study from the North German Lowland

Presenter/First Author: Thomas A Raab, BTU Cottbus, Cottbus,

Presenter/First Author Email: raab@tu-cottbus.de

Co-authors: Alexandra Raab, Brandenburg University of Technology, Cottbus, Germany; Melanie Takla, Brandenburg University of Technology Cottbus–Senftenberg, Cottbus, Germany; Alexander Nicolay, Brandenburg Technical University Cottbus, Cottbus, Germany; Florian Hirsch, BTU Cottbus, Cottbus, Germany; Anna Schneider, Brandenburg Technical University Cottbus, Cottbus, Germany; Horst Rösler, Brandenburgisches Landesamt für Denkmalpflege und Archäologisches Landesmuseum, Zossen, Germany

Published Material: Some findings were recently accepted for publication inArchaeological and Anthropological SciencesRaab, T. et al.: Opencast mines in South Brandenburg (Germany) - Archives for Late Quaternary landscape development and human-induced land use changes We will highlight important results from this publication and use these highligths to show the integrative application of our techniques. Moreover the most recent findings will be presented (oral presentation is preferred)

Abstract Body: This study outlines the opportunities to reconstruct Holocene landscape dynamics in active opencast lignite mines in southern Brandenburg (Germany). Studies on extensive outcrops that address geomorphology, pedology and archaeology provide unique insights into human-induced environmental changes. Our approach uses a variety of traditional and cutting-edge techniques to characterize small-scale landforms (high-resolution DEMs by micro-drone and LiDAR), to analyze soils and substrate properties in the field (GPR, ERT, geomagnetics, Field Portable XRF and XRD) and to provide chronological information (OSL, 14C, tree-ring dating). This approach is combined with a GIS for data integration. We present the most recent results and review important findings from the last several years. Studies conducted in the opencast mines focus on soil development and Late Quaternary geomorphodynamics and as well as past land use and the legacy of agriculture and woodland use.

Our results regarding the human-induced geomorphodynamics are similar to those in other regions in Central Europe, but we also observe regional differences caused by the local setting, e.g., intensification of soil erosion coinciding with the expansion of farming of cultivated lands in the Slavic Middle Ages. By analyzing LiDAR data the largest area of historical charcoal production in the Northern European Lowland (NEL) has been revealed.

We are clearly only beginning to understand the massive dimensions of charcoal production in the region and the impact on late Holocene geomorphodynamics. The usage of new high-resolution imagery is essential to identify small-scale anthropogenic landforms hidden in the landscape. Future work will consist of developing and improving our integrative approach. However, comprehensive ground truth data provided by the archaeological prospections in the open-cast mines are an excellent basis for GIS-based analyses of high-resolution ALS data and geomorphological research.

Title: Tectono-geomorphology of the Timiskaming Graben, Western Quebec Seismic Zone

Presenter/First Author: Katherine E Wallace, University of Toronto, Toronto, ON

Presenter/First Author Email: kwallace@utsc.utoronto.ca

Co-authors: Nicholas Eyles, University of Toronto, Claremont, ON, Canada; Michael Doughty, University of Toronto, Toronto, ON, Canada

Abstract Body: The Western Quebec Seismic Zone (WQSZ) is one of the most seismically active areas of the 'stable' North American craton where intraplate earthquakes pose a risk to older infrastructure built on soft glacial marine clays in the heavily populated cities of Ottawa and Montreal. Evidence suggests that these earthquakes are not a function of a short-lived phase of postglacial rebound but reflect ongoing crustal stresses and intraplate deformation. Within the WQSZ the Timiskaming Graben (TG) is an extension of the Ottawa-Bonnechere Graben and forms a prominent 50 km-wide fault-bounded morphotectonic depression along the Ontario/Quebec border. Lakes Timiskaming and Kipewa lie along the graben and their bottom sediments are extensively deformed by ongoing neotectonic activity in the form of slumps, debris flows and faults. This paper describes the results of on land investigation of the floor of TG surrounding these lakes mapping neotectonic fault scarps, landslides and liquefaction structures ('sand blows') using satellite imagery, land-based seismic and ground penetrating radar.

Title: Spatial extent of intermediate-time scale vertical tectonic motions across the eastern Zagros, Iran

Presenter/First Author: Behnam - Oveisi, Geological Survey of Iran, Tehran,

Presenter/First Author Email: ben.oveisi@gmail.com

Co-authors: Peter Van Der Beek, University Joseph Fourier Grenoble, Grenboble, France; Julien Carcaillet, University Joseph Fourier Grenoble, Grenboble, France

Abstract Body: The Zagros fold belt of Iran marks the present southern front of the broad Arabia-Eurasia collision zone. GPS and seismicity show the Zagros absorbs an important part of the overall convergence. Our study area covers south-eastern Zagros, where the continental collision (the Zagros) switches to the oceanic subduction (the Makran wedge). We have mapped deformed fluvial terraces along the Kol River using kinematic GPS and high-resolution imagery in order to unravel the spatial extent of vertical displacements and to analyze active deformation and its implications for seismicity. The Kol River intersects a few active folds and faults, as well as Mountain Front Fault (MFF) and High Zagros Fault (HZF). The long profile of the river shows two different spatial extent of vertical incision, 1) short-wavelength incision (d_s), controlled by structural reactivation of pre-existing structures and lateral folds propagation (plunge panel growth), and 2) long-wavelength incision (d_n) toward the entire course of the river (toward the HZF). We attribute both distribution patterns of vertical incision to reflect differential rock uplift along the river. The d_s and d_n are respectively consistent and inconsistent with the GPS strain distribution and the seismicity pattern. We suggest a young scenario of geologic strain accommodation over the active ramp of the MFF. On the other side, we estimate limited slip for the HZF, consistence with the current hypothesis about uplift propagation across the Zagros belt and through time toward the foreland. Cosmogenic nuclide exposure ages of the Kol River strath terraces (in process) improve understanding of recent crustal deformation rates and its variations through time and space across and eastern Zagros. Such information helps to provides more reliable estimates of seismic hazard for the Zagros, amongst the world's most seismically active mountain ranges.

Title: Examining Interactions Between Large Woody Debris, Beach-dune Morphodynamics and Shoreline Positions Using Remotely Sensed Data

Presenter/First Author: Ian James Walker, Department of Geography University of Victoria, Victoria, BC

Presenter/First Author Email: ijwalker@uvic.ca

Co-authors: Michael J Grilliot, , , ; Jordan BR Eamer, , ,

Published Material: A portion of the talk reports on an analytical method using LiDAR and related results from a 2010 study i published in Geomorphology 118: 33-47.

Abstract Body: Large woody debris (LWD) is widespread on beaches in British Columbia and consists mostly of historic logging material. In some areas, LWD traps significant amounts of sediment and can modify coastal sediment budgets, alter beach-dune morphodynamics and affect shoreline positions and vegetation stabilization rates. This paper presents research that examines relations between LWD, sediment storage, and beach-dune geomorphology using remotely sensed data. One method uses aerial LiDAR and orthophography to quantify aeolian sand deposition in LWD on Haida Gwaii. Sand storage ranged from 9.19×10^4 to 1.39×10^5 kg m^{-1} beach width with a further storage capacity of 1.04 to 1.70×10^4 kg m^{-1}. The capacity for deposition in LWD modulates landward sand transfer and affects foredune sediment budgets and morphodynamics. The additional store of sediment in LWD can enhance incipient dune development and can increase the buffering capacity of beaches against wave erosion and storm surges. Another method uses the USGS Digital Shoreline Analysis System and a supervised classification to analyze changes in LWD coverage, shoreline position and vegetation colonization from historical aerial photography at Pacheedaht Beach near Port Renfrew, BC. LWD coverage declined between 1968 and 2013 by 38%, which is consistent with other findings in the region. Despite these declines, the shoreline prograded 71.6 m and vegetation colonized seaward 48.6 m atop former dune and LWD deposits. These trends are interspersed, however, with intervals of shoreline retreat and pronounced LWD decline. Trends in shoreline position and LWD coverage are generally synchronous suggesting a direct, positive relationship between LWD and shoreline change. This is hypothesized to result from increased sediment storage in LWD and enhanced beach-dune development. Provided that key sources of error are quantified and incorporated, these methods provide simple, systematic and statistically robust means to quantify the geomorphic and sediment budget impacts of LWD on beaches.

Title: Morphodynamics of the Liwa Megabarchans as a Titan Analog : Reworking of Giant Linear Dunes by Unidirectional Winds

Presenter/First Author: Ralph D Lorenz, Applied Physics Laboratory Johns Hopkins, Laurel, MD

Presenter/First Author Email: ralph.lorenz@jhuapl.edu

Co-authors: Jani Radebaugh, Brigham Young University, Provo, UT

Published Material: paper is under review at GeoResJ

Abstract Body: We document the sand dynamics at the unusual megabarchans that begin abruptly at the Liwa Oasis in the northeastern Rub' Al Khali desert in the United Arab Emirates (U.A.E.). Their close, regular arrangement is not consistent with a conventional barchan corridor, and we propose that the dunes must have grown to their great (>100m) height as linear dunes, which are presently still more evident to the south and east of Liwa, but are now exposed to a unidirectional wind regime that forms a consistent slip face orientation and is eroding the linears into discrete but ephemeral barchan forms. We estimate present-day sand fluxes of ~4 m^3/yr/m from the ~0.1 m/yr advance of megabarchan slip faces and from combined field and satellite observations of the migration of small barchans across the interdune areas. These suggest a ~20kyr timescale to evolve into the present disequilibrium configuration, consistent with estimates of paleowind changes in Arabia. We note recent flume experiments demonstrating hooked barchans and a linear-barchan transition in mixed winds, and that similar linear-megabarchan transitions are seen on Saturn's moon Titan.

Title: 'Traction ribs' on the palaeo-ice stream tracks of the Interior Plains, North America

Presenter/First Author: Chris Stokes, University of Durham, Durham,

Presenter/First Author Email: c.r.stokes@durham.ac.uk

Co-authors: Martin Margold, University of Durham, Durham, United Kingdom

Abstract Body: Spatially distinct pattern of basal shear stress beneath a number of Antarctic and Greenlandic ice streams has recently been discovered by inverse methods using high resolution data of ice velocity, elevation and thickness (Sergienko and Hindmarsh, 2013: *Science*). Surrounded by regions of near-zero basal shear stress, these areas of high basal shear stress have been termed 'traction ribs' and hold important implications for the force balance of ice streams. The cause of the traction ribs is unknown (i.e. whether they have a topographic expression), but their horizontal dimensions and pattern lie somewhere between typical ribbed (Rogen) moraines and recently described mega-scale ribbed moraines identified on palaeo-ice sheet beds. However, whilst both of these landform types form with their long axis transverse to the ice flow direction, the traction ribs are most commonly oriented oblique to the ice flow at angles of 30-60 degrees. Here, we report new findings from the beds of palaeo-ice streams on the Interior Plains in Alberta and Saskatchewan where landform assemblages, similar to traction ribs, occur at several sites. Individual landforms at the mapped sites have typical lengths (transverse to flow) of 5-10 km, widths of ~2 km, and their down-stream spacing is ~2-3 km. As such, they appear to represent an intermediate scale of ribbed landform that overlaps with the more extreme (larger) values of classic ribbed moraine and the smaller values of mega-ribs. Unlike mega-ribs and ribbed moraines, we also note that many of the ribbed features we mapped are aligned obliquely to ice flow direction at angles that mimic the arcuate patterns of traction ribs seen under modern ice streams. Profiles across the ridges indicate that they have amplitudes of 10-15 m, which is comparable, but slightly lower than the mean value for ribbed moraines. We therefore suggest that traction ribs have a topographic expression that sits on a continuum between ribbed moraine and mega-ribs. However, it is not clear what mechanisms lead to their formation or how widespread they are on other palaeo-ice stream beds. Future work might search for these landforms and their assemblages using higher resolution DEMs and fieldwork would allow sedimentological investigation of till properties and characteristics.

First Author Student?: No

Co-authors: Niko Putkinen, Geological Survey of Finland, Kokkola, Finland

Abstract Body: Mega-scale glacially lineated terrains (MSGL) are widely recognised as the geomorphic footprint of fast-flowing paleo ice streams within otherwise slowly moving ice sheets. MSGL is common in Minnesota, USA, reflecting the convergence of several ice streams within the southern sector of the Laurentide Ice Sheet. The Wadena drumlin field of west central Minnesota consists of an estimated 2000 streamlined subglacial bedforms over an area of about 7500 km2. The field lies within a complex upland interlobate area surrounded by prominent end moraines with the Alexandria Moraine on its southern and western margins possibly marking the outer extent of the southwesterly-flowing Wadena Ice Stream at the time of drumlin formation. Light Detection and Ranging (LiDAR) data are revealing much new detail of the morphology of drumlins. This presentation posits that they are primarily residual landforms formed by erosion of a pre-existing sediment bed by a thin mobile 'erodent layer' of deforming diamictic debris that delivered subglacial debris to build morainal landforms at the outer margin of the drumlin field. We evaluate the erosional hypothesis by using a newly developed quantitative methodology based on relief curvature analysis of LiDAR imagery to evaluate subglacial debris fluxes below the Wadena Lobe.

Title: Streamlined and Lobate Landforms, Relating to Successive Ice Flows in the Smallwood Reservoir, Northern Labrador

Presenter/First Author: Roger C. Paulen, Geological Survey of Canada, Ottawa, ON

Presenter/First Author Email: roger.paulen@nrcan-rncan.gc.ca

Co-authors: Jessey M. Rice, University of Waterloo, Waterloo, ON, Canada; Beth McClenaghan, Geological Survey of Canada, Ottawa, ON, Canada

Abstract Body: Reconstruction of past ice-flow trajectories, their associated landforms and glacial landsystems are fundamental for successful application of drift prospecting as it provides information on dispersal characteristics of former Pleistocene ice sheets. The sequence of striation trends provides a complete chronology of ice-flow events, which is inscribed on many outcrops of the Smallwood Reservoir in Labrador, including the oldest documented ice flow to the northeast which originated in the Quebec Highlands. Local glacial landforms, however, do not reflect this oldest ice flow event. Lobate or reoriented landforms, with two principal axes parallel to later phase ice movements, occur within the Smallwood Reservoir. These lobate landforms have a multi-phase origin. The first and major landform-forming ice-flow phase was southeastward from ice flowing radially from the Hudson Ice Centre in northern Quebec. Nucleation of drumlin and other streamlined landform formation may have been pre-existing glacial sediments or bedrock outcrops. A subsequent eastward ice-flow remobilized the previously deposited tills and created elongated landforms with high length to width ratios, possibly indicative of fast flowing ice that surged to the Labrador coast. Esker systems in the region are also trend with this late eastward flow. Studies are ongoing to correlate the glacial record with till provenance, as part of the Geological

Survey of Canada’s GEM2 Hudson-Ungava Project.

Title: Ice stream catchments and till production records in core regions of the Laurentide Ice Sheet

Presenter/First Author: Martin Ross, University of Waterloo, Waterloo, ON

Presenter/First Author Email: maross@uwaterloo.ca

Co-authors: Tyler J Hodder, , ,

Published Material: Some of the material that will be presented has been shown at the GSA meeting in Vancouver. The majority is new and not yet submitted to a journal.

Abstract Body: Evidence of crosscutting flowsets in core regions of the Laurentide Ice Sheet (LIS) has lead to the idea that ice divide migration is one important factor of landscape evolution and till production in these areas, with deglacial records being possibly over-represented. Here we report on evidence suggesting that ice stream catchments extending far inside ice sheets is another important mechanism to consider for certain flowsets and to explain thick till successions in core regions of the LIS. In ‘ice divide’ areas, such as central mainland Nunavut on the Canadian Shield, geophysics, drillcores, and river sections show that till successions 10s of meters thick occur in places and appear to extend laterally across the till plain. In most cases, the thickest till sheet has a lithological provenance and fabric signature consistent with the orientation of a prominent landform imprint that is partially overprinted by the deglacial record. These well-preserved, but overprinted flowsets fit the criteria for paleo-ice streams such as landform elongation, converging patterns, and overall dimension/geometry. When pieced together they appear to form large systems that can be associated to an ice flow phase also responsible for widespread till production. Hence, these preserved sediments and landforms are interpreted as the record of a large and thick LIS. The partially overprinting sediment-landsystems are confidently assigned to the deglaciation. In one study area in central Nunavut, the associated surficial retreat phase till is thin (0-5 m) relative to the underlying till, which reaches up to 12 m. Ice stream catchments extending far inside an ice sheet may thus contribute in a major way to the evolution of glacial landscapes and to the stratigraphy of core regions of ice sheets. Ice stream dynamics at times of ice sheet maxima is not yet well understood and represent one important knowledge gap towards understanding ice sheets.

Title: Projecting Landslide Susceptibility Maps for Generating Future Scenarios: A Case Study of Cox’s Bazar Municipality, Bangladesh.

Presenter/First Author: Bayes Ahmed, University College London, Dhaka,

Presenter/First Author Email: bayesahmed@gmail.com

Abstract Body: Rainfall induced landslides are a common problem in the highly urbanized hilly areas of Cox’s Bazar Municipality (CBM) in Bangladesh. During monsoon it causes human casualties, property damage and economic loss. Therefore, it is important to identify the future landslide susceptible areas in advance so that it can redeem the severity of possible landslide disasters. Generating the existing Landslide Susceptibility Maps (LSM), using relevant factor maps, is a common practice among the scientists. But this paper is going to propose an innovative technique to project the future LSM. The basic concept of this new technique is to project the future scenario of the dynamic variables. Then using the projected dynamic variables and the existing static variables, it is possible to generate the future LSM of CBM (see attached figure). In this case, the dynamic variables are – the land cover and precipitation maps; and the static variables are – the slope, distance to road, distance to drain, distance to lineaments, geology and other relevant soil maps. The existing LSM is validated using the relative operating characteristic curves with an inventory map of 122 landslides in CBM. The land cover map is projected using the artificial neural network technique in IDRISI Taiga, and the parameters for rainfall projection are generated using the ‘RClimdex’ statistical package in R. The projected LSM using the new concept gives high accuracy (>85%) and is applicable for any landslide-prone area. The decision makers can incorporate this new concept in the country’s disaster management plan and help reduce human casualties in significant numbers.

Title: GIS-aided Statistical Landslide Susceptibility Modeling And Mapping Of Antipolo Rizal (Philippines)

Presenter/First Author: Jaime Angelo Sanvictores Victor, University of the Philippines, Quezon City,

Presenter/First Author Email: jaimeangelovictor@yahoo.com

Abstract Body: Slope instability associated with heavy rainfall or earthquake is a familiar geotechnical problem in the Philippines. The main objective of this study is to perform a detailed landslide susceptibility assessment of Antipolo City. The statistical method of assessment used was logistic regression. Landslide inventory was done through interpretation of aerial photographs and satellite images with corresponding field verification. In this study, morphologic and non-morphologic factors contributing to landslide occurrence and their corresponding spatial relationships were considered. The analysis of landslide susceptibility was implemented in a Geographic Information System (GIS). The 17320 randomly selected datasets were divided into training and test data sets. K- cross fold validation is done with k= 5. The subsamples is then fitted five times with k-1 training data set and the remaining fold as the validation data set. The AUROC of each model is validated using each corresponding data set. The AUROC of the five models are; 0.978, 0.977, 0.977, 0.974, and 0.979 respectively, implying that the models are effective in correctly predicting the occurrence and non-occurrence of landslide activity. Field verification was also done.The landslide susceptibility map was then generated from the model. It is classified into four categories; low, moderate, high and very high susceptibility. The study also shows that almost 40% of Antipolo City have been assessed to be potentially dangerous areas in terms of landslide occurrence.

Title: Physical and Chemical Predictors of Human Perceptions of Water Quality in Southwestern Ozark Rivers

Presenter/First Author: Amie West, University of Arkansas, Fayetteville, AR

Presenter/First Author Email: aowest@uark.edu

Co-authors: Justin Nolan, , , ; J. Thad Scott, University of Arkansas, Fayetteville, AR

Abstract Body: The rivers of Arkansas' southwestern Ozarks are ecologically, culturally, and economically significant. They support rich biodiversity and high endemism, and are popular public recreation destinations. The capacity to communicate effectively between human groups with vested interest in these rivers hinges on understanding the nature of water resource perceptions and the extent to which they vary intra-culturally. Ozark rivers are revered in the region and hold special designations by the Arkansas Department of Environmental Quality for their ecologic and scenic value. To investigate perceptions of water quality we deployed surveys and conducted interviews with water quality experts and non-experts. A pile-sort task was administered using images of the five rivers, for which we also collected chemical and physical data. Preliminary results indicate (1) cultural consensus in perceptions of water quality exists among all respondents and (2) water quality perceptions can be predicted by total suspended solids concentrations, chlorophyll-a concentrations, color, and horizontal visibility. The consensus suggests that human evaluation of water quality is guided by culturally-constructed criteria, regardless of respondent expertise. These results also imply that measured physical and chemical parameters may be communicated meaningfully across groups in terms of how they relate to visible attributes. A defined range of measured parameters may also be linked to favorable or unfavorable user perception that can inform resource management.

Abstract Body: More than three million kilometers of rivers flow through the Canadian landscape and provide a wide spectrum of vital services and goods to the Canadian society. In the light of future environmental and climate changes and competing interests putting high pressure on river ecosystems, we need to develop sustainable management practices so that our communities are prepared and resilient to cope with potential alterations.

Environmental flow requirements (EFR) can be defined as the water regime provided within a river to maintain ecosystems and their benefits. Most approaches to assess EFR rely on hydrological indices at the daily time step to identify critical components of river regimes that maintain a specific ecological status. However, daily discharge data is not available for all Canadian rivers.

River classifications are used in EFR assessments to define groups of rivers that have similar hydrological characteristics. This study proposes a new river type classification for Canada facilitated by the HydroSHEDS database at 500m pixel resolution. HydroSHEDS (HYDROlogical SHuttle Elevation Derivatives at multiple Scales) encompasses a suite of hydrologically relevant datasets including a river network and monthly discharge data at the Canadian scale.

This project is based on the Global River Classification framework relying on the creation of multiple sub-classifications based on different disciplines; in this case, integrating hydrology, physiography, climate, and geomorphology. Records from HYDAT (National Water data archive from Environment Canada) will be used to investigate the correlation between monthly (HydroSHEDS) and daily (HYDAT) discharge indices within the derived river types. This information will then be used to develop an appropriate suite of monthly discharge indices to facilitate the definition of EFR at large scales.

Title: Applications in Fluvial Geomorphology : a Multi-Scale Perspective.

Presenter/First Author: Hervé Piegay, CNRS, Paris Cedex 16,

Presenter/First Author Email: herve.piegay@ens-lyon.fr

Abstract Body: Fluvial geomorphology is providing critical knowledge and tools for improving river management, restoration or conservation because river managers recently widened their scope in term of spatial and temporal scales, following in Europe for example the implementation of the Water Framework Directive and the wish to promote sustainable solutions. As a consequence, scientific feedbacks for improving or designing management strategies can be expected at different spatial scales according to stake-holder expectations. Top-down approaches usually promoted by regional or national decision-makers for planning and targeting actions can capitalize on conceptual development (reference, valuiing process versus form, assessing success of policies) as well as on efforts to highlight riverscape organisation and provide tools to target actions (so-called “geomorphic regionalisation”). Bottom-up approaches, promoted at a local scale on reaches of several 10th of km or smaller basins (e.g., 1000 to 2000 km2), usually performed to identify sustainable solutions in term of ecological benefits or natural hasard assessment can be nourished by geomorphic diagnosis and retrospective analysis, experiment, modelling and risk analysis allowing to set the river trajectory and identify objectives for river improvement or conservation. A few examples will be introduced to highlight the different approaches and open the debate on the implication of the discipline in practices. The geomorphologist as actor of social arenes has also to be considered, as such context influences the knowledge production and question the scientific independence and the way of doing research.

Title: Riparian Forest Development Following Channelization and Dams on Large Rivers: the Role of Management History in Setting Divergent Ecological Pathways

Presenter/First Author: John C Stella, SUNY College of Environmental Science and Forestry, Syracuse, NY

Presenter/First Author Email: stella@esf.edu

Co-authors: Hervé Piegay, CNRS, Paris Cedex 16, France

Published Material: Approximately 30% of this material was presented as a poster at the 2014 AGU meeting in San Francisco.

Abstract Body: River management profoundly alters riparian forests, which respond to changes in channel mobility and disturbance regimes imposed by channel engineering, flow regulation and floodplain development. However, the specific impacts to riparian corridors (e.g., forest extent and community dynamics) can differ greatly among rivers, even ones with similar climates and development pressures, because of differences in river management history. In this study, we compared contemporary riparian forest and floodplain development along two of the most heavily modified rivers in the mediterranean-climate biome, the middle Sacramento (California, USA) and the lower Rhône (SE France). In both basins, we set out to understand how river management has affected the composition, sustainability, and restoration potential of the riparian zone at a large spatial scale. We conducted extensive forest inventories and sampled fine sediment depth in regulated, 160-km reaches within both systems, and compared pre- versus post-dam patterns of deposition and linked forest development.

On the Sacramento, where channel migration still occurs and drives new forest development, tree composition shifted across a chronosequence of 110 years. The transition from willow to cottonwood (*Populus*) occurred within 20 years, and the transition to mixed forest started after 50-60 years. On the Rhône, where the river was extensively engineered for navigation and later diverted for hydropower, the pre- versus post-dam surfaces at each site showed less of a shift in species composition, but had more subtle characteristics related to basal area growth and cover of shrubs and vines. Notably, the channelized Rhône had an almost complete absence of small stems of pioneer willows and poplars, portending a long-term dominance by post-pioneer communities in the future. Both rivers showed a strong understory presence on young floodplains by *Acer negundo* (box elder), which is non-native and invasive in Europe, suggesting similar processes of colonization and propagation in both systems. Overall, the Sacramento can serve as a predictive reference system for the Rhône, where significant restoration efforts are underway to improve riparian structure and function in diverted river reaches.

Title: Climate and human forcing of Alpine fluvial processes in the Anthropocene

Presenter/First Author: Stuart N Lane, University of Lausanne, Lausanne,

Presenter/First Author Email: stuart.lane@unil.ch

Co-authors: Maarten Bakker, , , ; Daniela Balin, , , ; Chrystelle Gabbud, , , ; Natan Micheletti, , ,

Published Material: Earlier versions of results were presented at the Riverflow 2014 conference.

Abstract Body: River flow in Alpine environments is likely to be highly sensitive to both: (a) climate change; and (b) human impacts (e.g. flow abstraction). Here we compare river flow and sediment flux of two Alpine drainage basins over the last 7 decades, one basin largely unimpacted by human activities (the Avançon), one strongly impacted by flow abstraction (the Borgne d'Arolla), so as to tease how climate forcing acts in isolation but also combines to impact upon fluvial processes.

First, reconstruction of the Avançon flow and sediment transport capacity shows that variability in temperature, through its effect upon snow accumulation and so the intra-annual distribution of runoff, significantly impacts upon sediment transport capacity. We observe a linkage between this increased river flow, river incision and terrace formation during runs of years that are snowier than average; and sediment accumulation and increases in the active width when warmer. Although changes in basin sediment delivery could also be responsible for these processes, we cannot exclude climate forcing of river flow as a plausible hypothesis for observed river morphodynamics.

Second, for the Borgne d'Arolla, abstraction of flow at intakes has very major impacts upon sediment deposition in the 20 km of studied river downstream. We show a slow-moving sediment wave linked to substantial reduction in the duration of possible sediment transport. But, this human forcing was hard to distinguish from climate forcing over the same period, and an observed increase in sediment transport capacity.

Thus, whilst both climate and human effects can have major impacts upon river flow and hence upon sediment flux and river channel morphodynamics, separating these effects is exceptionally difficult. Management systems have evolved continually both in response to climate forcing but also human forcing itself, and their effects on river dynamics. We need to understand climate and human forcing of Alpine rivers as co-evolving.

Title: Improving Salmon Management with Automated Habitat Characterization and Functional Habitat Connectivity

Presenter/First Author: Mathieu L Roy, University of Montreal, Montreal, QC

Presenter/First Author Email: mathieu.roy@gmail.com

Co-authors: Céline Le Pichon, Irstea, Antony, France; Normand Bergeron, INRS, Quebec, QC, Canada; Marc Mingelbier, ministère des Forêts de la Faune et des Parcs, Quebec, Canada; Jean-Nicolas Bujold, ministère des Forêts de la Faune et des Parcs, Quebec, Canada

Abstract Body: Currently, Atlantic salmon conservation requirements and management targets established by the Quebec Wildlife Service rely on a model linking a physical habitat quality index and the number of migrating smolts monitored for several rivers. The production capacity of other rivers is then extrapolated using estimates of habitat quality based on channel width, substrate and morphohydraulic reach types (pools, riffles, meanders, channels, rapids, lakes). However, accumulating evidence suggest that besides habitat quality, the spatial arrangement of functional habitats patches (i.e. specific to life stages (fry, parr, adult) or function (feeding, shelter, spawning)) affects river production capacity.

Characterizing river habitat and keeping data up to date over decades represent a considerable challenge for provincial wildlife managers, considering the large extent to cover, including thousands of river kilometers remote areas in the North. In this context, increasingly available high resolution areal remote sensing imagery appears as a cost effective opportunity providing continuous data over large extents.

In this study, we developed an automated method to delineate reach types and functional habitat patches using hyperspectral areal remote sensing imagery and digital elevation model analyses. The classification of homogeneous reaches was based on channel width, slope, radius of curvature and relative depth classes. Then, we modeled the connectivity between functional habitats using a least cost approach integrating life-stage specific fish mobility. Our results present quantitative estimates of habitat probability of use based on river habitat spatial arrangement and illustrate the management functionality of the method in improving the estimation of river production capacity.

Title: Impacts of bank stabilization on fish habitat in two contrasted environments

Presenter/First Author: William Massey, Concordia University, Montreal,

Presenter/First Author Email: wmassey0319@gmail.com

Co-authors: Pascale Biron, Concordia University, Montreal, QC, Canada

Published Material: An earlier iteration of these finding were presented at the American Fisheries Society (AFS) annual symposium at Québec city on August 15. Finding will soon be under review. Submission is planned to Earth Surface Processes and Landforms in the month of February.

Abstract Body: Riprap is a form of riverbank stabilization that has a standardized design based on local hydraulic conditions and is commonly used for protecting and repairing road and bridge structures. However, little is known about how streams adjust to such perturbation or how this can affect fish habitat in different fluvial environments. The objective of this study is to assess impacts of riprap on fish habitat quantity and quality through a pairwise comparison of stabilized and non-stabilized stream reaches in two physiographic regions, the St. Lawrence Lowlands and the Appalachian highlands of Montérégie-Est (Quebec). For each stream reach high-resolution measurements of depth and velocity were taken to determine zones of fast, slow, shallow and deep flow, as well as to calculate a hydro-morphological index of diversity (HMID). The reach area proportions of in-stream cover (woody debris, overhanging vegetation, undercut banks, aquatic macrophytes) and habitat units (pools, riffles, runs, glides) were also documented, longitudinally. Fish habitat quality was also assessed holistically, using a Qualitative Habitat Evaluation Index (QHEI). Results demonstrated a significant ($p<0.05$) decrease in the median proportion of woody debris and overhanging vegetation at stabilized reaches in both Lowland and Appalachian environments. Riprapped reaches in the Lowlands also showed significantly lower proportions of pool/glide habitats and higher proportions of riffle/run habitat as well as higher HMID scores. QHEI scores were found to be significantly lower at stabilized reaches for Appalachian streams and higher quality Lowland streams, while stabilized reaches for extremely degraded (straightened) Lowland streams showed higher scores. These results indicate that riprap can significantly alter fish habitat in ways that reduce fish habitat quality and the availability of specific habitat types but also improve habitat quality and diversity in streams which were already degraded.

Title: Bedload sediment transport in gravel-bed rivers: Intermittence and continuum

Presenter/First Author: Andre Roy, University of Waterloo, Waterloo, ON

Presenter/First Author Email: agroy@uwaterloo.ca

Abstract Body:

Understanding bedload sediment transport in gravel-bed rivers remains a challenge for river scientists. Bedload sediment transport is often sporadic and intermittent at various temporal and spatial scales and transport rates do not necessarily increase with increasing hydraulic stresses. Bedload sediment transport occurs mostly during flood events when unsteady flow makes it difficult to obtain simultaneous and continuous records of flow and bedload transport measurements. This paper examines the complex response of bedload transport to turbulent flow. First, we will review the relationships between turbulent flow characteristics and sediment transport rates as observed in a small gravel-bed river in southern Quebec. The measurements were conducted during the rising limb of two flood hydrographs of different magnitudes. Turbulent variables change systematically with discharge through hydraulic geometry relationships. Bedload sediment transport occurred as discrete events in both floods. Among the hydraulic variables, flow acceleration/deceleration at the turbulent scale explained a large proportion of the behaviour of sediment transport rates especially for the less intense flood. This result supports evidence reported in previous studies that flow acceleration/deceleration was important in the mobility of individual gravel particles. Second, this evidence at the turbulent scale will be examined at larger time scales. We have observed that turbulent flow events are clustered in a way that generates larger scale flow pulsations. We have documented such pulsations in several gravel bed rivers at different flow stages. An important question that needs to be addressed is the relationship between these large scale flow pulsations and the dynamics of bedload transport. The impact of flow pulsations on sediment transport may be related to the frequency and temporal spacing of the large magnitude turbulent events that generate high shear stress. These extreme events contribute to the flow acceleration/deceleration patterns observed in flow pulsations and to the emergence of large scale flow properties. This may provide a key to our understanding of the intermittence, intensity and duration of bedload transport events.

Co-authors: Taylor Olsen, University of Quebec at Rimouski UQAR, Rimouski, QC, Canada

Abstract Body: In rivers with high bed load transport, morphological changes result in considerable cost for managing river crossing. In Québec, managers lack the tools to anticipate river change driven by hydrosedimentary dynamics. Simple rules are hard to provide because of river complexity and of contingency in river behaviour hence the need for a framework that is adjustable to both river character and management needs. We propose three fundamental steps that can lead to a relevant diagnostic of hydrosedimentay dynamics in support of river crossing management. The first step provides geomorphological context and first-hand understanding from river styles. The second step details historical trajectories and identifies relevant controls. The third step aims at defining sediment connectivity, from sediment sources to sinks, which can be quantified through sediment budget analysis. Taken together, the three steps provide an efficient understanding of hydrosedimentary dynamics and lead to management strategies that can address sediment-related problems. The 3-step framework will be illustrated using several cases of high sediment load rivers in eastern Quebec where river crossing issues emerge from intense hydrosedimentary dynamics.

Title: Evaluating the contribution of geotechnical and vegetation processes to lateral erosion in a meandering river reach using a holistic morphodynamic model

Presenter/First Author: Yannick Y Rousseau, University of Western Ontario, London,

Presenter/First Author Email: yanrousseau@gmail.com

Co-authors: Pascale Biron, Concordia University, Montreal, QC, Canada; Marco J Van de Wiel, University of Western Ontario, London, ON, Canada

Abstract Body: Numerical models are increasingly being employed to examine the morphodynamics of meandering river channels. Although sinuous channels are typically associated with cohesive soils and vegetated floodplains, few models formally include these two elements. Furthermore, certain models reproduce the meandering planform and migration patterns observed in nature, but they require relaxed physics and rely on simplified floodplain morphology and process representation to study morphological changes at large spatiotemporal scales. As a result, they have a limited ability to quantify the relationships between key variables. The objective of this research is to evaluate the feasibility, relevance, and usefulness of including geotechnical and plant processes in a physics-based morphodynamic model. Two new modules were developed and coupled to the computational fluid dynamics model TELEMAC-2D for that purpose. A geotechnical module relies on a fully configurable universal genetic algorithm to detect unstable slopes in a fluvial valley represented by an unstructured mesh including a single- or multi-threaded channel, and to update terrain topography following planar and rotational slope failures. A vegetation module is coupled to the former to account for the mechanical effects of plant roots on slope stability. Topographic measurements from the semi-alluvial Medway Creek, London (Canada), are used to calibrate and validate the model. The model is then applied to fictive river channels to quantify the contribution of various biophysical conditions and hydrological regimes to river bank retreat rate.

Title: Estimating Bedload Transport in Braided Gravel-Bed Rivers using Structure–from-Motion Photogrammetry and the Morphological Method

Presenter/First Author: Sarah Peirce, University of Western Ontario, London, ON

Presenter/First Author Email: speirce@uwo.ca

Co-authors: Pauline Leduc, University of Western Ontario, London, Canada; Peter Ashmore, University of Western Ontario, London, ON, Canada

Abstract Body: Monitoring bedload transport in gravel-bed rivers, and braided rivers in particular, has been notoriously difficult due to highly dynamic sedimentary processes that result in considerable geomorphic change, both spatially and temporally. This research aims to characterize fluvial geomorphic change, and subsequently bedload transport, using high-resolution repeat surveys from a Froude-scale physical model of a gravel-bed braided river. The overall goal is to investigate the relationship between morphological dynamics and bedload transport rate and test whether reliable bedload estimates can be based primarily on planimetric morphology and dynamics. Specifically, this research is will examine the role of the morphological active width, defined by the bed area experiencing detectable morphological change, and determining its relationship with bedload transport rate and channel morphology. High-resolution DEMs (±2mm vertically) are created of the physical model surface using Structure-from-Motion photogrammetric techniques. Successive DEMs are used to create a DEM of difference from which the morphological active width and volumes of erosion and deposition are used to calculate bedload transport rate. The use of a physical model is ideal for examining these relationships experimentally over a range of river conditions with both tiltable bed (slopes of 1-2%) and adjustable discharge (0.6-3.2 ls^{-1}). The bedload transport rate will be independently monitored using a series of sediment traps at the downstream end of the physical model to verify the relationship to the morphological measurements. These preliminary results will contribute to the theory of bedload transport in braided gravel-bed rivers by characterizing the relationship between bedload transport, morphological change and sedimentary processes.

Title: Deposit geometry and grain sorting in gravel braided rivers

Presenter/First Author: Pauline Leduc, University of Western Ontario, London,

Presenter/First Author Email: pleduc3@uwo.ca

Co-authors: Peter Ashmore, University of Western Ontario, London, ON, Canada

Abstract Body: Braided river dynamics and sedimentary processes involve complex sequences and patterns of erosion/deposition and channel migration. The different grain size, shape or thickness of the deposition layers developed during these processes create a vertical structure within the bed which vary with the river dynamics and influence the bedload transport processes. Quantitative analysis of these interrelations between sedimentary characteristics, river morpho-dynamics and bedload transport need further development. Field measurements can be used to document vertical structure on the river bed and point out layers boundaries, but the time scale and deposition dynamics is not available. We investigated the dynamic formation of the vertical bed structure using a small-scale physical

model of a braided channel. The braided channel was developed at a slope of 1.5% and discharge of 2.1 l/s. The grain size distribution in the model is an approximately 1:30 scaled distribution of medium fluvial gravel with median size 1.3mm (D10 0.3 mm, D90 4mm). Vertical stereo images (with pixel resolution of approximately 1mm) of the dry bed were taken at one hour intervals over 40 hours of flume running time during which a large area of the river was re-worked. DEMs were derived photogrammetrically with mean elevation error of about 4mm. Surface grain size was mapped using calibrated relationship with picture texture value and sieved grain size. Over the 40 hour period the range of elevation and grain size variations over the river bed can be used to analyse deposits dynamics, deposit structure and grain size variation within the river bed.

Title: Physical controls on fine-sediment infiltration into gravel beds.

Presenter/First Author: Jan Franssen, University of Montreal, Montreal,

Presenter/First Author Email: jan.franssen@umontreal.ca

Co-authors: Michel Lapointe, McGill University, Montreal, Canada; Pierre Magnan, Université du Québec à Trois-Rivières, Trois-Rivières, Canada

Published Material: Franssen, J., Lapointe, M., & Magnan, P. (2014). Geomorphic controls on fine sediment reinfiltration into salmonid spawning gravels and the implications for spawning habitat rehabilitation. *Geomorphology*, *211*, 11-21.

Abstract Body: As humans continue the widespread modification of the Earth's terrestrial surface augmented fine sediment loading to river systems is likely to remain an ongoing issue. In gravel-bed streams the impact of increased fine sediment loads on streambed habitats is determined by factors controlling fines infiltration into channel substratum. Much of what we know about the infiltration processes is derived from laboratory studies. Few, if any, field studies have simultaneously investigated the multiple physical factors thought to control infiltration. Here we present the results of a field experiment conducted in a boreal forest stream in Quebec, Canada, that was designed to investigate the influence of the following factors on substrate fines content: (i) substrate pore constriction size, (ii) hyporheic flow, and (iii) the quantity of fines transported across the bed surface (i.e., exposure dose). Our results indicated that the ingress of fines into gravel-beds was primarily a gravity driven process influenced by size thresholds between the infiltrating fine sediment and the size of the substrate interstitial spaces. Results also indicated that fines content at depth was unrelated to fines exposure and that the estimated upward seepage rates at these study sites were well below the threshold velocities that would inhibit the percolation of medium-grained sand into the gravel bed. We discuss the implication of this research for stream habitat rehabilitation and suggest directions for future research.

Title: *Structural comparison of multiple rivers across Canada: the importance of scale for characterizing the river complexity*

Presenter/First Author: Fabien Hugue, McGill University, Montreal,

Presenter/First Author Email: fabien.hugue@mail.mcgill.ca

Co-authors: Michel Lapointe, McGill University, Montreal, QC, Canada

Abstract Body: Ongoing developments in remote sensing and geographical information science are massively improving efficiencies in analyzing earth surface features. Various applications of these techniques are widely used to assess environmental and ecological processes. With the development of new satellite sensors and the lowered cost availability of high resolution multi spectral imagery, fluvial geomorphology is experiencing a revolution in mapping streams both at high resolution and over large spatial extents. Exploiting the power of aerial or satellite imagery is thus particularly useful in Riverscape framework. This study presents a multi-scale remote sensing method that helps describe the hydraulic structures of wetted habitats. Metrics of habitat description are calculated from i) depth maps obtained through spectral analysis on multiple satellite images and ii) complementary modelized velocity maps, in order to assess the spatial structure of the selected rivers. A principal component analysis on the set of metrics was used to cluster river reaches in regards to their "structural signature". We tested our method in a set of 10 Canadian rivers and investigated the link between the local channel morphology and the regional geomorphic contexts. Results highlight the benefits of such a method for characterizing 1) the habitat heterogeneity and 2) the natural (alluvial) versus controlled (non-alluvial) river variability. Results also demonstrate the importance of using remote sensing tools in a multi-river analysis not only for constraint saving in time and onerous field work, but also for uniformly characterize river structures across the country. Applications of this approach can include 1) specific fish habitat detection for regional management*,* 2) understanding how river habitat heterogeneity affects fish distribution and 3) guidance for river restoration site location.

Title: Freshwater Processes and Feedbacks in Baffin Bay and the Labrador Sea

Presenter/First Author: Paul Glen Myers, University of Alberta, Edmonton, AB

Presenter/First Author Email: pmyers@ualberta.ca

Co-authors: Xianmin Hu, University of Alberta, Edmonton, AB, Canada; Amber Marie Holdsworth, University of Alberta, Edmonton, AB, Canada; Laura Castro de la Guardia, , , ; Laura Gillard, , ,

Published Material: Aspects presented at ASOF and FAMOS workshops, as well as Arcticnet meeting.

Abstract Body: Enhanced transport of low salinity water from the Arctic, as well as the Greenland ice cap, is expected to have impacts on the stratification, water formation and circulation in the North Atlantic Ocean. In this presentation, pathways of freshwater in the Canadian Arctic Archipelago, Baffin Bay and the sub-polar North Atlantic Ocean will be examined. Both observational data and numerical modelling will be used. Observational analyses will focus on the Labrador Current where historical sections will be used to estimate freshwater transport, its variability and locations of offshore exchange. The modelling analysis will be based on regional configurations using the NEMO model of the Arctic Ocean, Canadian Arctic Archipelago and the sub-polar North Atlantic. The impact of freshwater input from the Greenland Ice sheet on the circulation and properties of Baffin Bay will be examined. Lagrangian float tools such as Ariane will also be used to examine the pathways for freshwater from both the Arctic as well as the Greenland Ice sheet into the sub-polar North Atlantic in high resolution simulations.

Title: Modelling impacts of opening/closure of Arctic gateways during interglacial stages

Presenter/First Author: Mehdi Pasha Karami, GEOTOP-UQAM, Montreal,

Presenter/First Author Email: pashakarami@gmail.com

Co-authors: Paul Glen Myers, University of Alberta, Edmonton, AB, Canada; Xianmin Hu, University of Alberta, Edmonton, AB, Canada; Anne de Vernal, University of Quebec at Montreal UQAM, Montréal, QC, Canada

Abstract Body: The Canadian Arctic Archipelago (CAA) and the Bering Strait are two of the key gateways that connect the Arctic Ocean to the Atlantic and Pacific Oceans, respectively. Changes in the sea ice-freshwater flux through these gateways have the potential to significantly affect the sea-ice distribution in the Arctic and the salinity in North Atlantic subarctic basins. The relative size of the freshwater fluxes into the Atlantic through the CAA influences the location and intensity of dense water formation which might have important consequences on the strength of the Atlantic meridional overturning circulation. We investigate the impact of opening/closure of the Arctic gateways (due to Tectonic movements or changes in the sea-level) on the sea-ice distribution and water pathways of the Arctic and subarctic North Atlantic during interglacials. We specifically focus on the Baffin Bay and Labrador Sea. An eddy-permitting regional configuration of the NEMO coupled ocean/sea-ice model is used. The regional domain covers the Arctic Ocean and the Northern-Hemisphere Atlantic, with a horizontal resolution of 1/4 degree at the equator (ANHA4). We set-up several sensitivity experiments by closing either one or both of the CAA and Bering gateways to know the individual impacts of each gateway. Boundary conditions are obtained from the global climate models for Holocene and MIS-5. The model results are compared with the paleoclimate data from Arctic and subarctic seas to further understand the climate conditions during interglacial stages.

Title: A few highlights of the late glacial and deglacial history of Baffin Bay and the Labrador Sea

Presenter/First Author: Claude Hillaire-Marcel, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: hillaire-marcel.claude@uqam.ca

Co-authors: Anne de Vernal, University of Quebec at Montreal UQAM, Montréal, QC, Canada; Quentin Simon, UQAM, Montreal, QC, Canada; Olivia T Gibb, GEOTOP (UQAM), Montréal, QC, Canada; Laurence Nuttin, GEOTOP (UQAM), Montréal, QC, Canada; Nicolas Van Nieuwenhove, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Jenny Maccali, GEOTOP (UQAM), Montréal, QC, Canada; Marie-Michèle Ouellet-Bernier, GEOTOP (UQAM), Montréal, QC, Canada

Published Material: Partly presented at the last AGU Fall meeting (the ice-sheet aspect)/Focus here on oceanographic implications

Abstract Body: Recent works, based on gravimetric data (e.g., Paulsen et al., GIJ 2007) provide new insights into the isostatic response of the northeastern American lithosphere to glacial loading and unloading. They point to a multidome Last Glacial Maximum (LGM) Laurentide Ice Sheet (LIS), with ice-divides over Keewatin, New-Quebec and the Foxe Basin-Baffin Land area, feeding large-scale ice streams (Stokes and Tarasov, GRL 2014). Similarly, recent studies of marine cores raised from Baffin Bay and the Labrador Sea led to reconstruct near steady-streaming interrupted by high amplitude, but out of phase surges along the NE LIS margin (cf. carbonate events from Hudson Strait and Baffin Bay; Simon et al., JQS 2014). These studies also point to the potential role of glacio- isostatic re-equilibrium and advection of warm, sub-surface waters in the NW North Atlantic sector, for the triggering of large ice surges, notably those off Hudson Strait. These findings might also imply a slightly lesser LIS-LGM volume than previously assumed (~ 70 m of "eustatic" sea level). However, a compilation of all available information on the isotopic composition of the LIS-ice suggests slightly less negative oxygen isotope composition than the currently assumed mean value (i.e., ~ -25‰ vs - 30‰, vs VSMOW). As a consequence, the overall ice-ocean mass transfer isotopic budgets between the LGM and the Present might require some re-examination. Nevertheless, the reconstruction of paleo-density gradients in the northern North Atlantic marginal basins since the LGM indicates a late attainment of full interglacial conditions, with a "modern-like" Atlantic Meridional Overturning inception at ~ 7.5 (Labrador Sea) and ~ 6.5 BP (western Nordic Seas), but fully emplaced since the mid-late Holocene transition only.

Title: Late Quaternary Stratigraphy of the Baffin Island Slope

Presenter/First Author: Donald Calvin Campbell, Geological survey of Canada, Dartmouth,

Presenter/First Author Email: cacampbe@nrcan.gc.ca

Co-authors: Kimberley Jenner, , , ; Robbie Bennett, , ,

Abstract Body: The Baffin Island Slope (BIS) extends more than 1000 km from Davis Strait in the south to Lancaster Sound in the north. Relatively little is known about lateral variations in the late Quaternary stratigraphy and geological history of the BIS. The adjacent Baffin Island Shelf is incised by 11 transverse troughs that point to a complicated history of sediment supply to the BIS. In this study, 17 piston cores, multibeam bathymetry and high resolution sub-bottom profiler data were used to examine regional variations in the Late Quaternary stratigraphy of the BIS. The shallow seismic stratigraphy of the BIS can be broadly divided between the slope north of Home Bay, where acoustically transparent sediment overlies more reflective sediment, and the slope south of Home Bay, where acoustic penetration is greater and acoustically stratified and chaotic reflections (representing mass transport deposits) are present. Similarly, north of Home Bay, the shallow lithostratigraphy is consistant; cores typically stop in a basal, dark diamict that is overlain by turbidites, stratified ice-rafted deposits, IRD-rich detrital carbonates and hemipelagic sediments. Synthetic seismogram analysis shows that the basal, dark diamict coincides with the regional change to more acoustically reflective deposits on sub-bottom profiler data. South of Home Bay, core samples are generally finer-grained with less diamict but ice-rafted detritus layers are still present. This distinct lateral change in the shallow stratigraphy of the BIS represents differences in the style of proglacial and glacio-marine sedimentation along the slope which may provide important insight into the late Quaternary glacial history of the region. Ongoing research is focused on acquiring age control for the various lithostratigraphic facies; large dateable shell fragments are uncommon in core samples, so analysis of forams and lithostratigraphic correlation with published magnetostratigraphy results will hopefully better constrain the timing of major stratigraphic events.

Title: Magnetostratigraphy of Late Quaternary and Holocene Baffin Bay Sediments

Presenter/First Author: Guillaume St-Onge, University of Quebec at Rimouski UQAR, Rimouski, QC

Presenter/First Author Email: guillaume_st-onge@uqar.ca

Co-authors: Quentin Simon, UQAM, Montreal, QC, Canada; Marie-Pier St-Onge, , , ; Claude Hillaire-Marcel, University of Quebec at Montreal UQAM, Montreal, QC, Canada

Published Material: Recent papers (Simon et al., G3, 2012; St-Onge and St-Onge, JQS, 2014)

Abstract Body: With the potential of recording the dynamics of the Laurentide, Innuitian and Greenland Ice Sheets during the Quaternary, Baffin Bay sediments were cored during several expeditions during the last decades. Unfortunately, the setting of robust chronostratographies in Baffin Bay proved challenging due to several factors including calcium carbonate dissolution during interglacials and the production of isotopically light brines resulting from sea-ice formation, that hampers the use of ^{18}O stratigraphies. Here, we will look into tentative chronostratigraphies of Baffin Bay late Pleistocene and Holocene sequences mostly based on magnetic paleointensity and directional records. In conjunction with radiocarbon dating, geomagnetic field model outputs and the identification of geomagnetic excursions, they provide a chronostratigraphic framework for sedimentary accumulation in Baffin Bay to document Holocene climatic changes and ice sheet dynamics along the Laurentide, Innuitian and Greenland ice sheet margins during the last ice-age.

Title: Surficial geology and glaciomarine geomorphology of Baffin Bay continental shelf sites based on ROV observations, multibeam bathymetry, and acoustic sub-bottom profiles

Presenter/First Author: Evan Edinger, Memorial University of Newfoundland, St John's, NF

Presenter/First Author Email: eedinger@mun.ca

Co-authors: Bárbara de Moura Neves, , , ; Calvin Campbell, Natural Resources Canada, Dartmouth, NS, Canada

Published Material: Biological observations from the same ROV dives were presented at the 2013 and 2014 ArcticNet meetings. Geological results have not been previously presented in any form.

Abstract Body: The continental margins of Baffin Bay were strongly influenced by Quaternary glaciations, which left behind glaciomarine geomorphic features at continental slope depths. We surveyed surficial geology and associated geomorphology of three glacially-influenced environments on the margins of Baffin Bay using a Remote Operated Vehicle (ROV) as part of a broader program on deep-sea corals and sponges. ROV dive locations were guided by multibeam bathymetry, sub-bottom profiles, and fisheries bycatch data. An ROV dive on the Disko trough-mouth fan in 900 m depth in SE Baffin Bay found dominantly mud, at low slopes, with rare exposures of angular cobbles and boulders. Fan lobes were indistinct but recognizable in contour-parallel sub-bottom profiles, but were not readily apparent in multibeam bathymetry. On rill-and-gully morphology of the Home Bay trough-mouth fan at about 750 m depth in SW Baffin Bay, identified from multibeam bathymetry, sand and mud bottoms dominated, with commonly occurring highly angular cobble and boulders. Steeper slopes often, but not always, had greater exposure of cobbles and boulders. A bedrock massif within the Scott Inlet trough at ~600 m depth in W Baffin Bay had exposed bedrock only on the vertical cliff face. This vertical cliff may have been linked to faulting. Atop the massif, bedrock was usually covered by a veneer of sediment, including sand, gravel, and angular cobbles and boulders, but this veneer was not detected in sub-bottom profile. The sediments atop of the massif are probably derived from ice-rafted debris. Glacial megaflutes in sediments were observed in multibeam bathymetry downdrift from another massif within the trough. Hydrocarbon release associated with previously described hydrocarbon seeps at the Scott Inlet site was observed as an oil slick at the sea surface, but no direct evidence of hydrocarbon-related authigenic carbonates was observed during the ROV dive. Although subfossil calcareous deep-sea corals have been collected from the Labrador Sea and SE Baffin Bay, none were observed in western Baffin Bay. The modern benthic faunal composition differed greatly among sites, with greatest differences observed between Eastern and Western Baffin Bay. Faunal composition is probably affected by bottom currents and water mass characteristics, as well as geomorphology.

Title: Neodymium isotopic composition of deep-sea corals from the Labrador Sea: implications for NW Atlantic deep-water masses circulation during the Holocene, MIS 5 and 7

Presenter/First Author: Lucie Ménabréaz, GEOTOP-UQAM, Montreal,

Presenter/First Author Email: menabreaz@sca.uqam.ca

Co-authors: Jenny Maccali, GEOTOP (UQAM), Montréal, QC, Canada; Bassam Ghaleb, Université de Québec à Montréal, Montréal, QC, Canada; Andre Poirier, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Aurélien Blénet, GEOTOP (UQAM), Montréal, QC, Canada; Claude Hillaire-Marcel, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Evan Edinger, Memorial University of Newfoundland, St John's, NF, Canada

Abstract Body: The Neodymium isotopic composition (εNd) of aragonitic deep-sea corals (*Desmophyllum dianthus)* collected off Belle Isle Strait and Newfoundland, at Orphan Knoll (1740 m water depth) and Flemish Cap (1550 m water depth), was investigated to identify changes in the seawater εNd and thus changes in the Northwestern Atlantic deep-water masses circulation during the late Quaternary. These sites, located at depths corresponding approximately to the maximum convection depth of the Labrador Sea Water (LSW) just above the North East Atlantic Deep Water (NEADW) mass, are under the influence of the intermediate to deep-water masses re-circulating in the North Atlantic subpolar gyre. ^{14}C and U-Th dating performed on unaltered specimens selected on the basis of geochemical and mineralogical criterions indicate that they developed during warm periods MIS 1/Holocene, the Bølling-Allerød, MIS 5c and MIS 7a. Comparison between εNd values of 4 modern corals and of ambient seawater at both sites yields a good agreement around a value of – 13.5, indicating that these corals have the potential to reliably record changes in seawater εNd. First results obtained on subfossil corals indicate seawater εNd of around -14 during the Holocene and Bølling-Allerød, -25 during MIS 5c and -17 during MIS 7a. The strongly negative seawater εNd during MIS 5c and MIS 7a reveal an increased imprint of unradiogenic lithogenic sources of Nd derived from Greenland and the Canadian Shield via slope sediment remobilizations and/or an increased Baffin Bay overflow of relatively dense waters, through Davis Strait. Nonetheless, this implies the absence of deep-water formation in the Labrador Sea through the advection of more radiogenic north Atlantic waters during these time periods.

Title: Labrador Sea Water variability over the last 3000 years

Presenter/First Author: Paola Moffa Sanchez, Institute of Marine and Coastal Science, New Brunswick, NJ

Presenter/First Author Email: paolamoffa@gmail.com

Co-authors: Ian R Hall, Cardiff University, Cardiff, United Kingdom

Published Material: 20% of it was published in Moffa-Sanchez et al. 2014 Paleoceanography

Abstract Body: The Labrador Sea is a key location for the Earth's climate system, because it is a major component of the Atlantic meridional overturning circulation (AMOC). Due to intense surface air–sea heat exchange, dense ocean mixed layers are created, forming Labrador Sea Water (LSW), which ventilates the intermediate depths of the North Atlantic and beyond. Various studies have revealed considerable spatial and temporal variability, associated with the formation and meridional transport of this water mass, over the past few decades. Yet, crucially, because of the limited temporal extent of the instrumental records, its longer-term history and interactions with the climate at multidecadal to centennial time-scales remains limited.

In this study, we present new multi-proxy records including sortable silt and foraminiferal assemblage counts and stable istotopes from decadally resolved marine sediment cores recovered from the Eirik (SE Greenland) and Gardar (S. Iceland) Drifts to infer hydrographic changes in the LSW and thus better understand the role that the ocean played in the centennial climate variability over the late Holocene. Our results show coherent changes between the records and suggest a decrease in the formation of LSW with similar timing to the cold periods that have been previously recorded as glacial advances in the circum-North Atlantic at 3000-2500; 1100-1500 and 500-100 yrs BP. These findings strongly indicate that hydrographic changes in the Labrador Sea and the associated variability in LSW formation rates may have played an active role in these climate anomalies.

Title: Integrating hydrogeomorphological concepts in management approaches of lowland agricultural streams in Quebec: Perspectives, problems and prospects.

Presenter/First Author: Alexandre Paradis, Concordia University, Montréal,

Presenter/First Author Email: mc_paradize@hotmail.com

Co-authors: Pascale Biron, Concordia University, Montreal, QC, Canada

Abstract Body: River management in agricultural settings has undergone profound changes in recent years, particularly in the Midwest. In particular, a better integration of hydrogeomorphological principles has led to novel approaches with the two-stage channel design for small agricultural streams being among the best examples of this change. The benefits of these approaches include: decrease of nitrate concentrations in water, better heterogeneity of stream habitat, reduction of field flooding and greater bank stability than the traditional trapezoidal profile typically used in straightened agricultural streams. However, the applicability of these innovative techniques in Quebec remains to be tested. We conducted detailed analyses of streams in agricultural areas located in Montérégie (Quebec) to determine the impacts of a change in the trapezoidal channel profile that would allow for some geomorphological adjustments of a small channel comprised within a larger, fixed one. A particular emphasis was put on the subsurface drainage outlets which often limit the degree of adjustment of these small streams. These impacts are analyzed by hydrodynamic modeling (HEC-RAS) and a hydraulic geometry approach. A crop yield analysis in the fluvial corridor along streams prone to frequent flooding was also conducted. Initial findings confirm the improvement of surface drainage for high magnitude floods, but also identify a potentially endemic problem for Quebec where, due to the rectangular shape of agricultural fields (an inheritance from French settlements), very deep subsurface drainage outlets are in conflict with natural floodplain generation within the straightened channels. Alternative measures to accommodate for natural fluvial adjustments while maintaining drainage efficiency were also explored. One approach would be to create small cavities along the streams that would provide increased heterogeneity and limit the need to dredge agricultural streams over long distances.

Title: Bank and bed stabilization using riprap: geomorphological impacts on embeddedness and implications for fish habitat

Presenter/First Author: Guénolé Choné, Concordia University, Val-Morin,

Presenter/First Author Email: g.chone@yahoo.ca

Co-authors: Pascale Biron, Concordia University, Montreal, QC, Canada; Normand Bergeron, INRS, Quebec, QC, Canada

Abstract Body: Bank and bed stabilization, through riprapping in most cases, is a common and necessary measure to protect infrastructures such as bridges and roads from fluvial erosion. However, banks artificialization may trigger hydrological, biological and geomorphological changes. In particular, in a lowland context, the coarsening of the substrate is a drastic modification from the pristine river state, but it can be mitigated by the embeddedness of riprap with finer sediments. The research objectives of this study are 1) to identify factors that may improve the substrate through embeddedness at riprapped reaches ; 2) to provide an insight on the relevance of artificially adding fine sediment into riprap to increase embeddedness ; 3) to better assess the role of embeddedness on low-flow water stage essential for free passage of fish . Visual estimation of the embeddedness at 42 sites which were recently stabilized with riprap was conducted in the region of Montérégie-Est, Quebec, Canada. Results from a combination of field topography measurements and Lidar data reveal that embeddedness depends on local topography. No temporal trend in embeddedness was observed, indicating that sediment infilling happens quickly under favourable conditions, or does not occur at all depending on conditions. It is consequently argued that artificially adding fine sediment to promote naturalization of the substrate is a worthless operation. In addition, observations show that riprapping is often linked with bed rising which can have a negative effect on low-flow stage, potentially impacting free passage of fish during the summer. A conceptual model is presented displaying interactions between groundwater base flow, surface water stage, artificial bed heightening and embeddedness.

Title: Comprehensive Interpretation of the Ice Sheet-Ocean Current Interaction Around the Baffin Bay

Presenter/First Author: Catalina Gebhardt, Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research Bremerhaven, Bremerhaven,

Presenter/First Author Email: catalina.gebhardt@awi.de

Co-authors: Boris Dorschel, Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research Bremerhaven, Bremerhaven, Germany; Patricia Slabon, Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research Bremerhaven, Bremerhaven, Germany

Abstract Body: Baffin Bay is a marginal sea of the North Atlantic Ocean, bounded by Greenland to the east, Ellesmere Island to the north and Baffin Island towards west, and connected to the Arctic Ocean through Nares Strait and through the Canadian Archipelago. With its location between the Greenland, Innuitian and Laurentide ice sheets, Baffin Bay is a key location in understanding the glacial history of the Arctic region. Several studies from this area have revealed that the development of the ice sheets has been tightly coupled to the oceanic circulation in this area. Existing low-resolution bathymetric data both from the Greenland and Canadian boundaries show fjords with associated cross-trough channels. Bathymetric and sediment echosounder data from *RV Polarstern* expeditions ARK-XXIII/3 (2008) and ARK-XXV/3 (2010) through Lancester Sound and from the Greenland side of the Baffin Bay show a high variety in glaciogenic bedforms, ranging from iceberg scours to moraines, erosional discordances and mass wasting deposits. Bathymetric data from the Canadian fjords show comparable features. In the framework of ArcTrain, a series of expeditions to Baffin Bay is planned for the next couple of years to systematically map key areas, to gain information on the past ocean circulation and hence to develop a better understanding of the dynamics of the Greenland, Laurentide and Innuitian ice sheets, their similarities and differences, and leads and lags in their waxing and waning. This forms a prerequisite for modeling and predicting the future response of the Greenland ice sheet to changing climate and oceanographic conditions. The first expedition MerMet13-48 on *RV Maria S. Merian* is scheduled for summer 2015.

Title: Greenland Ice Sheet Development in the Northeast Baffin Bay Derived From Geo-Morphology Analysis

Presenter/First Author: Patricia Slabon, Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research Bremerhaven, Bremerhaven,

Presenter/First Author Email: patricia.slabon@awi.de

Co-authors: Boris Dorschel, Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research Bremerhaven, Bremerhaven, Germany; Catalina Gebhardt, Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research Bremerhaven, Bremerhaven, Germany

Abstract Body: Understanding the advance and retreat history of the northwest Greenland Ice Sheet (nwGIS) and its interactions with the oceanic circulation is substantial to understand and predict its future development. During past climate warming events, the nwGIS underwent significant changes and its glaciers accelerated with major contribution to global sea level. Analyses of glacigenic seabed features, visible in high resolution bathymetric data, can provide information for the reconstruction of the history of ice sheets and thus can be applied to give insights into the past development of the nwGIS.

Already lower resolution bathymetry (e.g.the International Bathymetric Chart of the Arctic Ocean IBCAO), shows distinct cross-shelf troughs of glacial origin in the northeast Baffin Bay. High resolution multibeam and sub-bottom echosounder data collected during RV Polarstern cruises ARK-XXIII/3 (2008) and ARK-XXV/3 (2010) enhance the bathymetry in this areas and give a better understanding of the glacial processes on the northeast Baffin Bay shelf and slope. During the research cruise MerMet13-48 scheduled for July 2015, additional high resolution multibeam mapping surveys are planned for troughs and inter-trough areas in the Melville Bugt in northeast Baffin Bay.

First results from sub-bottom and multibeam echosounder data show stacked debris flows building up glacial trough mouth fans, stratified deep-sea sediments, iceberg scours and mega-scale glacial lineations on the respective continental rise and shelf. Geo-statistical analyses of these features indicate ice stream developments and ice sheet groundings, advances and retreats in this area. Geo-morphological assessment on various scales further help to reconstruct the glacial history of the northwest Greenland Ice Sheet in order to model its future development.

Published Material: These findings are currently under review by the scientific journal *The Holocene*. A portion of these findings were presented at the *Arctic Change* 2014 meeting in December in Ottawa, ON.

Abstract Body: An increased understanding of the dynamics and variability in Labrador Sea Water (LSW) formation requires assessing past regional hydrographic responses driven by changes in climate and ocean circulation, specifically freshwater outflow through Baffin Bay. The shift from the most recent glacial to postglacial interval with deglacial meltwater influx from surrounding ice sheets provides examples of the breadth of conditions. Here, we reconstruct sea surface conditions based on dinoflagellate cyst (dinocyst) assemblages from four cores collected from Baffin Bay, Davis Strait, and the northwest Labrador Sea. All exhibit a major shift from a polar-subpolar heterotrophic species assemblage tolerating cold and extensive sea ice cover, to assemblages characterized by a higher diversity and the presence of phototrophic taxa associated with North Atlantic waters. Sea surface reconstructions using transfer functions display an abrupt shift from harsh, quasi-perennial ice cover to warmer summer sea surface temperatures and seasonal sea ice cover. This shift occurred at ca. 11.9 cal ka BP south of the Davis Strait sill under the influence of warm North Atlantic waters, while Baffin Bay remained densely sea ice covered. These warmer waters penetrated into Baffin Bay and mixed with the West Greenland Current (WGC) by ca. 7.4 cal ka BP. A major change in Labrador Sea surface conditions occurred at about the same time, when the strong stratification of surface waters weakened, due to the reduction in meltwater supplies from the Laurentide Ice Sheet. This change finally allowed winter convection and the inception of LSW formation. Therefore, these shifts were facilitated by the advection of North Atlantic water and retreat of the Greenland and Laurentide Ice Sheet margins. Since deglaciation, however, these records demonstrate large fluctuations in sea surface conditions possibly controlled by the relative strengths and shifts of the warmer WGC and colder Baffin Island Current.

Title: A High Resolution Chronology of Clastic Supply to the Central Baffin Bay during the Last Deglacial Ice Sheet Melting

Presenter/First Author: Rebecca Jackson, MARUM Center for Marine Environmental Sciences, Bremen,

Presenter/First Author Email: rjackson@marum.de

Co-authors: Michal Kucera, MARUM Center for Marine Environmental Sciences, Bremen, Germany; Ruediger H Stein, Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research Bremerhaven, Bremerhaven, Germany

Abstract Body: The Baffin Bay is a key region for understanding the interaction between ocean circulation and the Greenland Ice Sheet (GIS). Oceanic conditions in the basin are affected by the extent of seasonal sea-ice and changes in the inflow of water from the Labrador Sea and North Atlantic. The input of freshwater from the Arctic Ocean and meltwater from both the Canadian Arctic Archipelago and the GIS also plays an important role. All of these systems have been shown to vary on millennial and centennial timescales, and their state is predicted to change in response to the ongoing Arctic warming trend. However, the complex feedbacks and phase relationships between these systems, as well as how they respond to shifts in climate in the wider region, remain unclear.

During the last deglaciation, the region experienced large magnitude environmental change. We use this interval to investigate periods of increased clastic supply from the melting of the GIS, using two sediment cores from the central Baffin Bay. A novel preparation method allowing AMS 14-C dating of ultra-small samples (0.5 mg) has been used to generate a robust deglacial chronology in both cores. Here, we present profiles of sediment physical and chemical properties for both cores which provide, to date, the highest-resolution continuous record of terrigenous input for the central Baffin Bay, spanning the entire deglaciation.

Results indicate several intervals during which the composition of the clastic fraction shifts; the older episode of detrital input coincides with the timing of Heinrich Event 1 centred around 17ka BP. However, further through the deglacial, the chronology of detrital input appears to be out of phase with Greenland temperatures. An interval of elevated deposition, enhanced clastic supply and thus enhanced meltwater input began in the Younger Dryas stadial at 12.5 ka BP, indicating a fundamentally different relationship between ice-sheet derived clastic supply and Greenland temperature during the late deglacial period.

Title: Paleaoceanographic Changes in Disko Bugt Area in Relation With Human Settlements During the Holocene

Presenter/First Author: Marie-Michèle Ouellet-Bernier, GEOTOP (UQAM), Montréal, QC

Presenter/First Author Email: ouellet.bernier.mm@gmail.com

Co-authors: Anne de Vernal, University of Quebec at Montreal UQAM, Montréal, QC, Canada; Claude Hillaire-Marcel, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Matthias Moros, Baltic Sea Research Institute, Rostock, Germany

Published Material: The results have been published : Ouellet-Bernier, M-M, de Vernal, A, Hillaire-Marcel, C et Moros, M (2014). Paleoceanographic changes in Disko Bugt area, West Greenland, during the Holocene, *The Holocene*, 24(11), p.1573-1583.And presented at the EGU meeting in 2014.

Abstract Body: Palynological and isotopic analyses of a sediment core raised off Disko Bugt (West Greenland) were undertaken in order to document Holocene paleoceanographical changes in the eastern Baffin Bay. The Modern analogue Technique (MAT) applied to dinocyst assemblages provided information on paleo sea-surface conditions (temperature, salinity, sea-ice cover and productivity) whereas isotopic analyses of benthic foraminifera aimed at documenting the "deep" water mass at the site. The paleoceanographic information we obtained is compared with archeological data from the Disko area as compiled by JF Jensen et al. (*Copenhagen University Archaeological Notes*, 1999).

From ~ 10 to ~ 7.3 ka, important discharge of ice and meltwaters from the Greenland ice sheet, mostly through the Jakobshavn Isbrae, resulted in harsh conditions with dense sea-ice cover, low temperature and low pelagic and benthic productivity. Postglacial conditions settled at about 7.3 ka as indicated by a sharp increase in dinocyst diversity and abundance, which corresponds to increase in summer temperatures. Optimal conditions were finally achieved by about 6 ka, i.e. before the first human occupancy dated at about 4.5 ka. The mid- to late Holocene dinocyst data suggest a slight cooling with increased sea ice cover at ~ 4.2-4.0 ka followed by a slight warming, which matches maximum occurrence of Saqqaq people artefacts in Disko area. Sea-surface temperature continued to increase in summer until about 1.8 ka, when a pronounced cooling was accompanied by increased seasonal sea ice cover and salinity, together with a decrease in productivity. The event marked by harsh conditions in surface waters spanned from about 1.8 to 1 ka. It is consistent with a slight increase in $\delta^{18}O$-values in benthic foraminifers at about 2.1-1.1 ka, which also indicate a cooling in subsurface waters and/or lesser meltwater fluxes. This regional event coincides with the main decline in the number of paleo-Eskimo occupation sites in the Disko area. On this basis it might be hypothesized that rough climate conditions and productivity drop contributed together to the regional decline in paleo-Eskimo population.

Title: Surface and sub-surface multi-proxy reconstruction of mid to late Holocene palaeoceanographic changes in Disko Bugt, West Greenland

Presenter/First Author: Matthias Moros, Baltic Sea Research Institute, Rostock,

Presenter/First Author Email: matthias.moros@io-warnemuende.de

Co-authors: Jeremy M Lloyd, Durham University, Durham, United Kingdom; Kerstin Perner, , , ; Diana Krawczyk, , , ; Anne de Vernal, University of Quebec at Montreal UQAM, Montréal, QC, Canada; Marie-Michèle Ouellet-Bernier, GEOTOP (UQAM), Montréal, QC, Canada; Thomas Blanz, University of Kiel, Kiel, Germany; Antoon Kuijpers, Geological Survey of Denmark and Greenland, Copenhagen, Denmark; Anne E Jennings, Institute of Arctic and Alpine Research, Boulder, CO; Andrzej Witkowski, University of Szczecin, Szczecin, Poland; Ralph Robert Schneider, University of Kiel, Kiel, Germany; Eystein Jansen, University of Bergen, Bergen, Norway

Published Material: Poster presents and discusses results of a multi-proxy study in Disko Bugt area, West Greenland. Several data sets (benthic foraminifera: Perner et al. 2011 in QSR, 2013 in The Holocene; Lloyd et al. 2011 in Geology; diatoms of core 343310: Krawczyk et al. 2013 in QSR, dinos of core 343300: Ouellet-Bernier et al. 2014 in The Holocene) are published recently and new data (diatoms, alkenones) are presented.

Abstract Body: We present new surface water proxy records of meltwater production (alkenone derived), relative sea surface temperature (diatom, alkenones) and sea ice (diatoms) changes from the Disko Bugt area in central West Greenland. We combine these new surface water reconstructions with published proxy records (benthic foraminifera -

bottom water proxy; dinocysts – surface water proxy), along with atmospheric temperature (Camp Century ice core). This multi-proxy approach allows us to reconstruct centennial scale mid to late Holocene palaeoenvironmental evolution of Disko Bugt in more detail than previously possible. Combining surface and bottom water proxies identifies the close coupling between ocean circulation (West Greenland Current conditions), the atmosphere and the Greenland Ice Sheet. Centennial to millennial scale changes in the wider North Atlantic region lead to variations in the West Greenland Current (WGC). During periods with a relatively warm WGC, the atmosphere in west Greenland warms and glaciers retreat producing significant meltwater flux to the west Greenland margin. In contrast, during periods of cold WGC the atmosphere cools and glaciers advance. This highlights the longer-term influence of ocean forcing on ice sheet behavior. We also identify links between palaeoceanographic evolution in the Disko Bugt region and the history of human occupation. Cooler oceanographic conditions at 3.5 ka BP support the view that the Saqqaq people left Disko Bugt due to deteriorating climatic conditions. The disappearance of the Dorset people is less clear, but our new data indicate that it may be linked to a significant increase in meltwater flux causing cold coastal conditions at *c.* 2 ka BP. The subsequent settlement of the Norse is clearly associated with climatic amelioration during the Medieval Climate Anomaly and their disappearance linked to harsher conditions at the beginning of the Little Ice Age.

Title: Paleoceanography of marine isotope stage 31 in the northwest North Atlantic

Presenter/First Author: Aurélie Marcelle Renée Aubry, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: aurelieaubry@gmail.com

Co-authors: Anne de Vernal, University of Quebec at Montreal UQAM, Montréal, QC, Canada; Claude Hillaire-Marcel, University of Quebec at Montreal UQAM, Montreal, QC, Canada

Abstract Body: We investigated paleoceanographic conditions during Marine Isotope Stage (MIS) 31 at IODP site 1305, off southwest Greenland in the Labrador Sea, based on the analysis of dinocyst and foraminiferal assemblages, in addition to isotopic measurements in planktic foraminifers as complementary tracers of properties in mesopelagic and epipelagic water masses. The Modern Analogue Technique (MAT) has been applied to reconstruct sea surface conditions using dinocyst assemblages. Low salinity conditions (32-34.5), large seasonal temperature gradients with cool winters (3-6°C) and mild summer (10-15°C) characterized the surface water mass. In contradistinction, the application of MAT to foraminifers assemblages, which are largely dominated by the deep dwelling species *Neogloboquadrina pachyderma* left coiling, indicate very cold conditions both in winter (-2-0°C) and summer (2-4°C), a range consistent with the observed isotopic composition of planktic foraminifers. Hence, the discrepancy between dinocyst vs planktic foraminifer reconstructions suggests strongly stratified, relatively warm surface waters, overlying a cold and more saline intermediate water mass. These results lead to infer conditions unfavorable for convection and intermediate- or deep-water formation in the Labrador Sea during the interval.

First Author Student?: No

Co-authors: Martin Frank, GEOMAR Helmholtz Centre for Ocean Research Kiel, Kiel, Germany; Thomas Blanz, University of Kiel, Kiel, Germany; Ralph Robert Schneider, University of Kiel, Kiel, Germany

Abstract Body: Despite its undisputed importance in the global ocean-atmosphere system, the NW Atlantic is arguably the region of the global ocean where reconstructions of past variations in sea surface temperatures (SST) are fraught with the greatest uncertainty. While alkenone paleothermometry has successfully been applied to reconstruct past SSTs in many parts of the northern Atlantic, including off Iceland and Greenland as well as off Newfoundland and Nova Scotia, previous studies have also highlighted the large scatter of alkenone unsaturation (expressed as the UK37 or UK'37 index) determined from N Atlantic surface sediments around the globally established calibrations of UK37 versus SST.

Here we present a synthesis of 94 previously published and 99 new alkenone unsaturation data from surface sediments in the northern and NW Atlantic. These data will be reviewed in the context of global calibrations of UK37' versus mean annual, SSTs and of regional calibrations that have been developed specifically in an attempt to improve the calibration between alkenone unsaturation and SSTs in the N Atlantic. Scatter around these calibrations, or residuals, will be discussed in the context of ocean frontal systems with large SST gradients, sea surface salinities, sea ice extent, the possible input of allochthonous alkenones from other areas of the Atlantic and even from land, and potential effects of melt water intrusions from the Greenland ice sheet. Neither of these factors, individually or combined, can fully explain the increased scatter around the low-temperature end of UK37' - SST calibration. The largest decrease in uncertainty, however, is obtained by considering alkenone unsaturation in terms of bloom and/or spring-summer SSTs, rather than mean annual temperatures.

Title: Evidence for Meltwater Drainage via the St. Lawrence River in Marine Cores from the Gulf of St. Lawrence, Laurentian Channel and Labrador Sea at the Time of the Younger Dryas

Presenter/First Author: Elisabeth Levac, Bishop's University, Sherbrooke, QC

Presenter/First Author Email: elevac@ubishops.ca

Co-authors: Michael C F Lewis, Geological Survey of Canada Atlantic, Dartmouth, NS, Canada

Published Material: Most of these findings are presently under review in a scientific journal. However, the data from Bay of Islands is not published and not part of that manuscript.

Abstract Body: The debate about the source(s) and paths of meltwater that drained into the North Atlantic Ocean at the time of the Younger Dryas (YD) is ongoing. There are still discussions about the eastern route from glacial Lake Agassiz and predecessor lakes of the Laurentian Great Lakes located along the southeastern edge of the Laurentide Ice Sheet. We

present evidence for meltwater drainage via the St. Lawrence valley from six new sediment cores from Cabot Strait, Laurentian Channel, Scotian Shelf and Labrador Shelf at the time of the YD. Palynological analyses are used to reconstruct sea surface conditions based on dinoflagellate cyst records, and pollen data are used for additional correlation. The reconstructions show distinct drops in salinity, temperature and increased sea ice cover duration within the YD period. In addition to these new records, we present a re-examination of original data and paleoceanographic interpretation of surface waters based on a new analysis of dinoflagellate cyst zonation in combination with an updated chronology supported by new radiocarbon dates and refined calibrations. The intervals corresponding to the YD are clearly defined in the cores and contain strong evidence of lowered salinity, thereby re-establishing the St. Lawrence drainage system as a significant route for inflow of YD meltwater to the North Atlantic, including the Labrador Sea. This inflow does not exclude the possibility for another source of freshwater, possibly via the Labrador Current, as suggested by geographical differences in the duration of cold, low salinity conditions west and east of Laurentian Channel associated with the YD climatic event.

Title: Least Squares Wavelet Analysis

Presenter/First Author: Ebrahim Ghaderpour, York University, Toronto,

Presenter/First Author Email: ebig2@yorku.ca

Co-authors: Spiros D Pagiatakis, York University, Toronto, ON, Canada

Published Material: This is under review by Digital Signal Processing (Elsevier)

Abstract Body: The least-squares spectral analysis (LSSA), an alternative to the classical Fourier analysis, was introduced by Vanicek in order to analyze unequally spaced and non-stationary time series in their first and second statistical moments. When a time series has low or high frequency and amplitude variation over time, however, both the LSSA and Fourier analysis are not appropriate tools for analysis. On the other hand, the classical short-time Fourier transform (STFT) and the continuous wavelet transform (CWT) do not consider the covariance matrix associated with a time series nor do they consider trends or datum shifts. Both, the STFT and the CWT are not defined for unequally spaced time series.

In this talk, we present a new method called the least-squares wavelet analysis (LSWA) that can analyze a non-stationary and unequally spaced time series with high frequency and amplitude variation over time by transforming the time series to the time-frequency domain. The LSWA is a powerful method for analyzing an unequally spaced and unequally weighted time series with associated covariance matrix superseding the well-known wavelet analysis. Several examples from artificial and real time series will be presented to demonstrate the effectiveness of the method.

Title: Stochastic Surfaces in the Least Squares Wavelet Analysis

Presenter/First Author: Ebrahim Ghaderpour, York University, Toronto,

Presenter/First Author Email: ebig2@yorku.ca

Co-authors: Spiros D Pagiatakis, York University, Toronto, ON, Canada

Published Material: This paper is under review by Digital Signal Processing (Elsevier).

Abstract Body: The stochastic significance of peaks of the least-squares spectrum was discussed by Pagiatakis (1999), which we extend to define the stochastic surfaces of the Least-Squares Wavelet Analysis (LSWA) spectrograms that follow the beta distribution. Several examples will be presented to show the stochastic surfaces for the LSWA spectrograms that define confidence levels (usually 95% or 99%) above which spectral peaks in LSWA spectrograms are statistically significant. In the examples, we also show that the spectral peaks must be stronger for higher frequencies to be statistically significant as the number of data points for the segments of a time series decreases in the LSWA.

Title: Principal component analysis of InSAR data

Presenter/First Author: Kristy French Tiampo, University of Western Ontario, London, ON

Presenter/First Author Email: ktiampo@uwo.ca

Co-authors: Pablo J González, University of Leeds, Leeds, United Kingdom; Sergey V Samsonov, Canada Center for Remote Sensing, Ottawa, ON, Canada; Jose Fernandez, Complutense University of Madrid, Madrid, Spain

Published Material: Initial results were presented at Fall AGU, 2013. The final results, to be presented here, are being written up for journal submission in the next few months.

Abstract Body: Geodetic data, the spatial and temporal surface expression of complex geophysical processes in the earth, is being acquired today at unprecedented rates and accuracies. Differential Interferometric Synthetic Aperture Radar (DInSAR) is a satellite remote sensing technique that is used extensively for mapping ground deformation with a high spatial resolution and sub-centimeter precision over a large area. Spatial resolution of the modern SAR sensors ranges from 1 to 20 m over areas from 10x10 km to 200x200 km. Images produced with advanced DInSAR techniques can contain millions of data points. Previous research has demonstrated that an eigenpattern decomposition technique known as principal component analysis (PCA) can be used to identify a unique, finite set of correlated deformation patterns for a given regional network of GPS stations. Similar in nature to the empirical orthogonal functions (EOF) historically employed in the analysis of atmospheric and oceanographic phenomena, the method derives the eigenvalues and eigenstates from the diagonalization of the covariance matrix. After decomposing large data sets into their orthonormal eigenvectors and associated time series, based upon the spatiotemporal relationships that exist in the data, the decomposition can be used to study those modes most responsible for the various signals and their sources or to remove those uninteresting modes in the system. One additional benefit is that these modes are ordered naturally by the predominant spatial wavelength of the signal and can be used to identify the potential anthropogenic, volcanic and tectonic sources responsible for those signals. Here we demonstrate its application to DInSAR data from several different regions and its ability to isolate the handful of important signals in the thousands of data points in remote sensing images.

Title: An integral image approach to performing multi-scale topographic position analysis

Presenter/First Author: John Barrie Lindsay, The University of Guelph, Guelph, ON

Presenter/First Author Email: jlindsay@uoguelph.ca

Co-authors: John C Gallant, CSIRO Land and Water, Canberra, ACT, Australia; Jaclyn Cockburn, University of Guelph, Guelph, ON, Canada; Hazen Russell, , ,

Abstract Body: Digital elevation model (DEM) derived measures of terrain ruggedness and relative topographic position are useful parameters for automated landform classification and are widely applied in soils, vegetation, and habitat mapping. These topographic attributes are inherently scale dependent because they are defined in the context of a local neighborhood. Previous studies have focused on assessing the multi-scale properties of these attributes based on varying roving window sizes, grid resolution resampling, and hierarchical object-based methods. Despite significant advantages, the computationally intensive nature of large-window DEM filtering has limited the varying window size approach from being used to study the scaling properties of topographic position in high resolution and at broad spatial scales.

This study uses integral image and integral histogram based approaches to explore two common measures of relative topographic position, deviation from mean elevation (DEV) and elevation percentile (EP). The approaches were applied to a massive DEM of an extensive, heterogeneous region in eastern North America (40°N to 50°N and 70°W to 80°W). Compared with traditional image filtering techniques, the integral image approach was extremely efficient for calculating DEV, enabling high-resolution multi-scale analysis. A technique, based on a novel multi-scale DEV, was developed for visualizing the scaling characteristics of topographic position using color composite imagery. The information density in these images, provided by the contrast in the dominant scale response of nearby pixels, was very high. The integral histogram approach was similarly highly computationally efficient, enabling EP measurement at scales that are not feasible using traditional methods. However, large memory requirements limited applicability to moderate sized DEMs of low-to-moderate relief landscapes.

Title: Ice Mass Loss Monitoring in the Canadian Arctic: A Study on the Filtering Methods with Release-05 GRACE Data

Presenter/First Author: Iliana Tsalis, University of Calgary, Calgary,

Presenter/First Author Email: itsali@ucalgary.ca

Co-authors: Dimitrios Piretzidis, University of Calgary, Calgary, AB, Canada; Elena Veselinova Rangelova, Univ Calgary, Calgary, AB, Canada; Michael G Sideris, University of Calgary, Calgary, AB, Canada

Abstract Body: The biggest challenge in GRACE gravity data analysis is the signal separation of the GRACE-observed integrated geophysical signals. Due to the geometry of the twin-satellite orbit noise is produced, which is described as long, linear features generally oriented from north to south in the GRACE maps of mass variability. These 'stripes' imply a high degree of correlation in the gravity field coefficients, so spatial noise filtering is needed. As the halfwidth of the filter is increased, the level of smoothing is increased and the amplitude of the stripes decreases, until the pattern of the geophysical signals become apparent, but the magnitude of the geophysical signals is reduced.

In this study, in order to remove the 'striping' effect, a series of miscellaneous filtering methods is applied, tested and evaluated by ice mass loss estimates from previous studies in the Canadian Arctic. The data used include 139 months of GFZ and CSR Release-05 (RL05) GRACE time-variable gravity coefficients, covering the time period 01/2003-10/2014. Monthly gravity coefficients are converted to mass changes and corrected for the Glacial Isostatic Adjustment (GIA) effect.

The filtering methods that have been tested are: (1) Wiener filter (the signal and the error covariance depend only on the spherical harmonic degree), (2) post-processing decorrelation filter followed by Gaussian smoothing (convolution with an isotropic Gaussian smoothing kernel), and (3) non-isotropic smoothing (decorrelation) using the k-filtered five DDK filters RL05 GRACE solutions. We conclude that the general performance of isotropic filters is weak for ice applications.

Title: Wavelet spectral techniques for error mitigation of superconductive angular accelerometer output

Presenter/First Author: Elaheh Mokhtari, University of Calgary, Calgary, AB

Presenter/First Author Email: emokhtar@ucalgary.ca

Co-authors: Mohamed Mamdouh Elhabiby, University of Calgary, Calgary, AB, Canada; Michael G Sideris, University of Calgary, Calgary, AB, Canada

Abstract Body: A superconductive angular accelerometer is an important sensor that often supplements a superconductive angular gradiometer on a moving platform during data acquisition operations.. The gradiometer instrument senses not only gravity gradients, but also various effects of an accelerated coordinate frame (which are introducing major errors). The superconductive angular accelerometer measurements help compensate the main error, which is entering as angular velocity squared in the gradiometer output. While the angular accelerations can be measured, angular velocity squared has to be computed by integration. However, a major difficulty arises when the angular accelerations are noisy because of translational accelerations of the platform and temporal fluctuations of the environment during the operation. These errors are a source of low and high frequency error in the accelerometer output. Therefore, filtering of angular accelerations is necessary before integrating them to produce angular velocities. We have implemented wavelet de-noising and de-trending techniques in order to mitigate these errors. Wavelet results indicate 80% improvement in reducing the RMS noise level compared to the results obtained with traditional Wiener low pass filtering.

Title: Multilinear Filtering of Nonstationary Array Data and Inversion

Presenter/First Author: J A Rod Blais, University of Calgary, Calgary, AB

Presenter/First Author Email: blais@ucalgary.ca

Published Material: The application part on seismic imaging has partially been discussed at CGU 2014 in Banff, AB.

Abstract Body: For various geoscience applications, observations and measurements provide array data that necessitate filtering and inversion for parameters of interest. Although most geophysical processes are nonlinear and nonstationary, simplifications are often implemented in practical data array computations. Starting with linear filtering and inversion of stationary array data, the mathematical convolution can often be generalized to multilinear tensor formulation for filtering and inversion of nonstationary data. Multilinear and tensor algebras can then be exploited to optimize the transformation to conventional matrix algebra and hence take advantage of linear equation solvers available in numerical libraries. These strategies and procedures will be briefly discussed using simple numerical examples with special attention to the computational aspects of Kirchhoff least-squares imaging using seismic data. Some open questions are also included for further research and development.

Title: MATLAB Tools for Earth's Surface Deformation Studies

Presenter/First Author: Mohammad Ali Goudarzi, Laval University, Quebec City, QC

Presenter/First Author Email: mohammad-ali.goudarzi.1@ulaval.ca

Co-authors: Marc Cocard, Laval University, Quebec City, QC, Canada; Rock Santerre, Laval University, Quebec City, QC, Canada

Published Material: Some parts of this poster were already published in GPS Solutions with DOI 10.1007/s10291-012-0296-2, and 10.1007/s10291-013-0354-4, and some parts are presented here for the first time. In this poster, however, we present them as a software suite and focus on their computational aspects rather than the mathematical background, as well as a case study for eastern Canada.

Abstract Body: We developed three software programs for research on Earth's surface deformation studies, including time series analysis, Euler pole estimation, and strain analysis. The first software named GPS Interactive Time Series Analysis (GITSA) is capable of visualizing the input time series, determining and removing jumps and outliers, data interpolation, calculating quality indicators and producing publication quality graphical outputs. Along with computing basic statistics such as mean and variance, it can accomplish the bivariate statistical analysis, residual analysis, and spectral analysis. The second application named Euler Pole Calculator (EPC), estimates the expected velocities for any points on Earth's surface given the relevant Euler pole parameters. It also allows for calculating the Euler pole parameters from observed velocities of a set of sites on the same tectonic plate. The last program named GeoStrain, calculates the crustal strain rates using the least-squares collocation method. It is able to simultaneously determine the signal and noise of the velocities at the observation points with the best possible removal of the observation errors, or any other position with no velocity observation. Furthermore, it allows for calculating strain and rotation rate tensors at any points of interest. The advantage of the software is the fact that it can optionally consider the effect of the vertical velocities on the strain rates.
Although our programs are independent, they make a software suite: the output of each program is the input of another one. While inputs of the first program are the position time series of continuous GNSS sites obtained from a GNSS data processing software, the outputs of the last one are parameters of deformation, e.g., in the form of strain tensors. We developed these programs using MATLAB programming language with a graphical user interface, and released them freely as open source software. MATLAB Parallel Computing Toolbox was used to increase the performance of computationally intensive algorithms on multi-core processors.

Title: Assessment of the SHAO-C Tropospheric Delay Correction Model Over Ethiopia

Presenter/First Author: Yohannes Getachew Ejigu, Retired, Wolkite,

Presenter/First Author Email: john.yohannes200@gmail.com

Co-authors: Gizaw Mengistu Tsidu, Addis Ababa University, Addis Ababa, Ethiopia

Published Material: In the AGU Chapman Conference on Longitude and Hemispheric Dependence of Space Weather at Addis Ababa, Ethiopia, 12–16 November 2012, have been presented in the poster session, but stil can not submitted to any scientific journal publisher.

Abstract Body: Tropospheric signal delay can introduce a considerable error in satellite positioning if it is not properly modeled. In the neutral atmosphere, the average GPS signal delay in the zenith direction can varies from 1.8 m to 2.5 m depending on meteorological conditions and site location. In this work, the spatial and temporal variations of the zenith tropospheric delay (ZTD) over Ethiopia, are analyzed using ECMWF (European Centre for Medium-Range Weather Forecast) pressure-level atmospheric data and compared with ZTD time series for 5-year period from 2007-2011 measured at several GPS stations from the Crustal Movement Observation Network over Great Rift Valley regions of Eastern Africa managed by UNAVCO. A new tropospheric delay correction model, SHAO-C used in China, is evaluated for its performance over Ethiopia. The ZTD along altitude, latitude and longitude is fitted with a second order polynomials at a reference height, and the mean ZTD is modeled directly by a harmonic function together with an initial value and an amplitude in each grid. The coefficients of this modified model are generated using the ECMWF ERA-Interim data at a resolution of 0.75X0.75 degree latitude-longitude grid. The altitude is obtained from high resolution digital elevation model (DEM). The agreement between GPS and model ZTD is found to be very good which reflected in overall average bias between -4.3 cm to -1 cm, and RMSE less than 4.5 cm. The model results are within the requirements of most GNSS navigation or positioning applications in terms of the tropospheric delay correction.

Title: GAPS for Atmospheric Studies (GAPS-ATM): Preliminary Results

Presenter/First Author: Marco Aurelio Moraes de Mendonca, University of New Brunswick, Fredericton,

Presenter/First Author Email: marco.mendonca@unb.ca

Co-authors: Marcelo C Santos, University of New Brunswick, Fredericton, NB, Canada

Abstract Body: Precise Point Positioning (PPP) is a well-established method of satellite positioning data processing. Since late 1990's, several developments have been made in order to take into account the impact of atmospheric effects on the satellite signals such as the ones caused by troposphere and ionosphere. At first, these effects were modelled in order to improve the quality of the estimated coordinates. Lately, by modelling the effects, new researches moved towards correlating the positioning errors with different atmospheric activities. Nowadays, GNSS data is widely used to estimate several different "side" parameters such as water vapor in the atmosphere and electron density. In this work, we use GPS Analysis and Processing Software (GAPS), a PPP software developed and maintained at UNB, to constrain known and nuisance - in this scope - parameters as the receiver's antenna final coordinates, and estimate atmosphere activity indexes. Among many parameters of interest, one can highlight troposphere wet and dry delay components and horizontal gradients, Total Electron Content (TEC) for each satellite in view, Electronic Gradients over time and others. An online platform is under development to allow the user to submit its own GNSS data and antenna coordinates to obtain a processing reporting focusing not on position estimation, but on atmospheric parameters represented in time series, plots and maps. Our first results show that the combination of PPP and the correct constraining of coordinates is a reliable alternative to estimate the atmospheric influence over satellite signals and, hence, estimate the behavior of the atmosphere in several different ways. By developing and implementing new tools on GAPS and focusing on the specific needs of atmospheric researchers, GAPS-ATM shows itself as an innovative and pioneer initiative among the GNSS post-processing packages available commercially or not.

Title: An overview of the UNB Ray-Tracer for geodetic applications

Presenter/First Author: Marcelo C Santos, University of New Brunswick, Fredericton, NB

Presenter/First Author Email: msantos@unb.ca

Co-authors: Felipe G Nievinski, , Presidente Prudente, SP, Brazil

Abstract Body: Ray-tracing through the neutral-atmosphere is an important task to retrieve meteorological parameters from a numerical model. There are several ways of doing it, which implies different representations of the neutral-atmosphere, as well as different ways to integrate through the path. We have developed a ray-tracer that involves alternative models for the ray-path and the atmospheric structure involved in the operation. The ray-tracer is currently in continuous use in the evaluation of zenith delay and one of the Marini coefficients of the Vienna Mapping Functions, generated daily at UNB as a service towards GGOS. This paper overviews the main characteristics of the UNB Ray-Tracer and discusses applications when dealing with integration through numerical weather models for neutral-atmospheric delay modelling. The paper also discusses other uses of ray-tracing in geodesy.

Title: Forecasting the radiooptical properties of the atmosphere

Presenter/First Author: Josep M Aparicio, Environment Canada, Dorval, QC

Presenter/First Author Email: Josep.Aparicio@ec.gc.ca

Abstract Body: The weather forecasting community is both a user and a provider of geodetic products. Numerical weather prediction requires huge amounts of data from a vast number of sources. Most of the traditional measurements are not directly related to geodesy. However, over the last decade, certain highly accurate geodetic products such as Zenith Delay, and particularly satellite radio occultations, have become available in volume and timeliness sufficient to have a significant impact for weather forecast. This is only expected to grow to larger volumes and faster access. We will present the current state of these technologies, plans for the near-term future from the point of view of the meteorological use of these data, and the impact that they have to the accuracy of the weather forecast service.

Also, with the increasing accuracy of meteorological products, as well as with the increasing demands of the geodetic community, the traditional infrastructure and products of meteorology have become relevant for geodesy. Besides certain products that are already used in accurate positioning applications, such as fields of atmospheric pressure load, other quantities such as Zenith Delays, the vertical profile of refractivity, atmospheric horizontal gradients, and atmospheric scintillation are fields that can also be estimated or forecasted, and that can become products for use within the geodetic community. There is therefore place for a two-way relationship between the atmospheric and the geodetic communities.

Title: Inside Tropical Cyclones With GPS: A New Perspective on Their Morphology and Intensity Estimation

Presenter/First Author: Panagiotis Vergados, NASA Jet Propulsion Laboratory, Pasadena, CA

Presenter/First Author Email: Panagiotis.Vergados@jpl.nasa.gov

Co-authors: Zhengzhao Johnny Luo, CUNY City College, New York, NY; Kerry Emanuel, Massachusetts Institute of Technology, Cambridge, MA; Anthony J Mannucci, Jet Propulsion Laboratory, Pasadena, CA

Published Material: These findings were published in the Journal of Geophysical Research - Atmosphere in January 2014, and have never been presented before to the AGU or CGU science meetings.

Abstract Body: Despite the great progress in trajectory forecasting of tropical cyclones (TCs) in the past few years, little progress has been made to their intensity forecasting. Temperature inversions layers at the outflow inside the eyewall of TCs, superimposed on the background upper troposphere, markedly affect the background thermal structure of the upper-troposphere lower-stratosphere (UTLS) region. The temperature difference between the ocean surface and the outflow region defines a TC's thermodynamic efficiency, which is a direct analog of its intensity. Global Positioning System radio occultation (GPSRO) observations offer a unique opportunity to sense the vertical thermal and moisture structure of a hurricane – from its center to the outermost closed isobar – with a vertical resolution of ~100 m. Here, we employ collocated vertical temperature and humidity profiles from the European Center for Medium-range Weather Forecasts Re-Analysis Interim (ERA-Interim) to assess the thermodynamic environment of an ensemble of hurricanes and compare them against GPSRO data sets. Combining GPSRO observations, along with ocean surface temperatures from NASA Modern Era-Retrospective Analysis for Research and Applications (MERRA), we demonstrate how to infer TC intensities using a simplified vortex TC model [*Wong and Emanuel,* 2007]. We analyzed TCs in the time period 2006–2010, and our GPSRO-based TC intensity estimates are found to be quantitatively consistent with best-track values from the Joint Typhoon Warning Center (JTWC) within 1.2–9.0%. This suggests that GPS signals can potentially augment current datasets in TC intensity forecasting, and provide accurate thermal information of a TCs' morphology and strength.

Title: Geophysical Parameters and Geophysical Application Development for Space-borne Polarimetric SAR (Synthetic Aperture Radar)

Presenter/First Author: Wooil M Moon, University of Manitoba, Winnipeg, MB

Presenter/First Author Email: wmoon@cc.umanitoba.ca

Co-authors: Junjun Yin, Tsinghua University, Beijing, China; Duk-Jin Kim, Seoul National University, Seoul, South Korea

Published Material: This research is in progress and a part of the same material will also be presented at the URSI At-RASC conference in later part of May 2015 in Gran Canaria. However, none of the material to be presented was published yet.

Abstract Body: Polarimetric SAR (Synthetic Aperture Radar) is an important microwave remote sensing tool which has increasing new applications in geophysics research. In addition to all weather operation advantages without sun light, it has interferometric applications utilizing the phase information of the backscattered signals. Understanding of geophysical parameters have been particularly important in the development of new geophysics applications for polarimetric SAR. As increasing number of new remote sensing satellites are now launched into Earth's orbit, it is timely to revisit and study various geophysical parameters which are closely related to backscattered microwave signals and their interaction at the surface of Earth.

In this paper, we will first investigate geophysically applicable regions of electromagnetic spectrum and will discuss basic principles of space-borne fully polarimetric SAR (Syntehtic Aperture Radar), in regard to the observation of solid Earth processes such as earthquakes, volcanoes and mass movements at the surface of Earth. In addition, we will also discuss various geophysical parameters which play important roles in the observation of waves, currents and surface winds over Earth's hydrosphere, including oceans and rivers, with radar scattrometer, radar altimeter and polarimetric SAR on-board Earth orbiting platforms. This paper will also discuss the available multiple frequency SAR systems and their applications.

Title: Ionospheric Disturbances after 2010 Merapi Eruption: The Biggest Amplitude of Disturbances by Volcano Eruption

Presenter/First Author: Cahyadi Nur Nur Cahyadi, Institute of Technology, Surabaya,

Presenter/First Author Email: cahyadi@geodesy.its.ac.id

Abstract Body: Global Positioning System (GPS) satellite orbit was located on the 20,000 km above earth surface. Those satellites transmitted two kind of L band signals which were L1 (1.5 GHz) and L2 (1.2 GHz). The signals were transmitted by satellites trough ionosphere then it was received by receiver in the earth surface. Because of this transmission method, we could observe electron density in ionosphere specially F layer which was called by Total Electron Content (TEC). Variation of ionosphere was caused by seismic wave propagation from earthquake, tsunami or volcano eruption. Seismic propagation was composed from three components with different velocities, Raleigh wave (velocity about 4 km/s), Acoustic wave (1 km/s) and Gravity wave (velocity about 0.3 km/s). This research focused on the ionospheric disturbances caused by Merapi volcano eruption which seismic wave was took into account in this variation. Ionospheric disturbances research was done in several topics using GPS-TEC,a comprehensive research about near field Coseismic Ionospheric Disturbance (CID) with Indonesian GPS array (INACORS) was done by [Cahyadi and Heki,2014].

Merapi volcano erupted on the 5 November 2010 on the 19:00 UTC, this was biggest eruption during 1872. Ionospheric disturbances was detected first time on the 18:40 UTC. They were several satellites which observed the disturbances e.g satellite number 6,3, and satellite number 21. The amplitude of the disturbances was about 1.7 TECU which was the biggest amplitude of disturbances caused by volcano eruption. Ionospheric disturbances by volcano eruption was also found in Indonesia for example

2013 Kelud volcano eruption , but the disturbances was smaller than disturbances by 2010 Merapi volcano eruption.

The directivity of the disturbances was located around south-west and north-west of the volcano which was different with CID of the 2011 Sumatra earthquake which directivity of the CID followed geomagnetic field direction. The magnitude of ionospheric disturbances by 2010 Merapi volcano was positive then became normal variation, it was like CID of earthquakes. This characteristic was very different with ionospheric disturbances by Kelud volcano, the later has positive peak variation then was followed by longer oscillation.

Title: Contemporary 3D Velocity Field of Eastern North America based on 14 Years of Continuous GPS Observations

Presenter/First Author: Mohammad Ali Goudarzi, Laval University, Quebec City, QC

Presenter/First Author Email: mohammad-ali.goudarzi.1@ulaval.ca

Co-authors: Marc Cocard, Laval University, Quebec City, QC, Canada; Rock Santerre, Laval University, Quebec City, QC, Canada

Abstract Body: The Saint Lawrence Valley in eastern North America is under intraplate surface deformations and has experienced strong historical and instrumental earthquakes. This shows the probability of occurring earthquakes all along the valley which is an important issue from the seismic hazard point of view. The area is further influenced by the glacial isostatic adjustment (GIA). We study this region using observations of all the available continuous GPS (CGPS) stations in the area as well as some more CGPS stations to the west and south of the valley in order to delineate the GIA process in eastern North America. The data comprise 14 years of continuous GPS daily solutions (8 years on average) from 112 CGPS sites. We use Bernese GNSS software to process the GPS data and our GITSA software for time series analysis to obtain the contemporary three-dimensional velocity field of the eastern North America and their uncertainties. The results clearly show the counter-clockwise rotation of the North American plate with an average velocity of 16.3 mm/yr constrained to ITRF 2008. The repeatability of results is at the level of 1.2 mm/yr for horizontal and 4.7 mm/yr for vertical velocities at the best sites assuming the white noise model. The accomplished noise analysis on the post-fit residuals using both spectral and maximum likelihood estimation methods brings us to obtain more realistic uncertainties for the estimated velocities and distinguish non stable GPS stations. The results show the white plus flicker noise model is the best, and uncertainties are increased with the order of 5~30 times. We discuss limitations in the computed velocities, especially when the possible instability over time causes non-linear behavior in the time series. In this way, 13 stations (out of 112 sites) were identified as stations with non-stable monuments. We also present an ongoing uplift model in the study area using the variogram analysis. At the best sites, the vertical velocities agree with the ICE-5G (VM2) model to within 0.02 mm/yr. However, the model shows a systematic tilt of ±6 mm/yr compared to the ice model in the east-west direction with a vertical hinge line approximately located to the west of Ontario province.

Title: Investigations on the Quality of the GOCE Level 1b Gradiometer Data around the Magnetic Poles

Presenter/First Author: E. Sinem Ince, York University, Toronto, ON

Presenter/First Author Email: seince@yorku.ca

Co-authors: Spiros D Pagiatakis, York University, Toronto, ON, Canada

Published Material: Some amount of this presentation was presented as a poster in the 5th GOCE User Workshop in Paris, in November 2014.

Abstract Body: The latest Canadian Geoid Model was developed based on the combination of GOCE, GRACE, terrestrial and altimetry data. It is observed that the GOCE data have improved the Canadian geoid up to a few centimetres in some regions. Our preliminary investigations on the GOCE Level 1b gradiometer data have shown that GOCE data processing methodology still needs improvements. It is found that GOCE gravity gradients along the satellite track are affected by unknown external sources over Northern Canada and Greenland. These effects can disturb the gravity signal up to three times the expected noise level. In this study, we have attempted to understand the reasons behind these disturbances present in the gradients by using external and GOCE-independent space weather datasets. Solar satellites ACE (Advanced Composition Explorer) and WIND derived interplanetary magnetic and electric field data and magnetic activity data observed by the terrestrial CARISMA (Canadian Array for Real-time Investigations of Magnetic Activity) stations are used for this purpose. We found that GOCE was affected by the increasing short-term solar activity and its corresponding effects around the polar cusp regions. We have investigated both, the GOCE and magnetic activity observations in time, spectral and spatial domain and attempted to eliminate these disturbances from GOCE observations. We believe that any improvement on GOCE data processing can help scientists improve the quality of the global and regional geoid models as well as the processing of other missions' datasets.

Title: Microgravity Effects of Earthquakes in the Cascadia Subduction Zone

Presenter/First Author: Jeong Woo Kim, University of Calgary, Calgary, AB

Presenter/First Author Email: jw.kim@ucalgary.ca

Co-authors: Juergen Neumeyer, University of Calgary, Calgary, AB, Canada; Joseph Alan Henton, Pacific Geoscience Center, Sidney, BC, Canada; Byung-Gon Chae, Korea Institute of Geoscience and Mineral Resources, Daejon, South Korea; Hojjat Kabirzadeh, University of Calgary, Calgary, AB, Canada; Michael G Sideris, University of Calgary, Calgary, AB, Canada; Ik Woo, Kunsan National University, Kunsan, South Korea; Ricky Kao, University of Calgary, Calgary, AB, Canada; Junghae Choi, KIGAM, Daejeon, South Korea

Published Material: The preliminary results were presented at the meeting as a poster, but never been published. This presentaiton contains the updated results with recent data with advanced methodologies.

Abstract Body: An iGrav superconducting gravimeter (SG) and an A10 absolute gravimeter (AG) have been deployed at Pacific Geoscience Centre (PGC) on Vancouver Island, Canada, since 2012. The PGC is situated in the forearc of the northern Cascadia Subduction Zone (CSZ). In this area, a transient surface deformation accompanied by tremor-like seismic signals has been documented with a recurrence interval of 13 to 16 months. This phenomenon, named episodic tremor and slip (ETS), has been interpreted to be associated with slow slip events (silent earthquakes) in the CSZ. To detect the ETS events, the continuous microgravity recordings from the SG were reduced for all known environmental effects including Earth and ocean tides, polar motion, atmospheric pressure and soil moisture. The residual gravity effects were then compared with the GPS-detected ETS.

The gravity effect of the Haida Gwaii earthquake was analyzed. The earthquake occurred near the plate boundary between the Pacific and North America plates on 28 October 2012 with a magnitude 7.8. A large co-seismic gravity change of -2.6 microGal was recorded at the onset of the earthquake. In addition, a significant decrease of gravity was observed for the 15 days prior to the eartquake, and the decrease lasted for 11 days after the earthquake. The distance from the SG to the earthquake center is about 780 km. Compared to the observed co-seismic gravity change of 0.58 microGal whinin a distance of 3.4^o by Imanish et al. [2004] that was confirmed by a dislocation model, it is a significant gravity change. This gravity change can be associated with both subsurface mass redistribution and surface height displacement. For further interpretation, it has to be proved with straightforward seismic and dislocation models. Another earthquake that occurred in a similar region was the southwestern Alaska earthquake (5 January 2013, m7.5), and although it triggered a tsunami warning, it did not show any sign of co-seismic gravity change in the SG recordings.

These studies have shown that identification and assessment of geohazards and geodynamics such as active fault movement, as well as mass changes in geological CO_2 storage, may be possible with continuous monitoring of microgravity with combined SG and AG when the environmental gravity effects and surface displacements are effectively reduced.

Title: Precise Point Positioning for Geodynamics

Presenter/First Author: Marcelo C Santos, University of New Brunswick, Fredericton, NB

Presenter/First Author Email: msantos@unb.ca

Co-authors: João Carlos Chaves, , ,

Abstract Body: Precise Point Positioning is a Global Navigation Satellite System technique that allows the determination of centimeter-level coordinates in an Earth-Centered, Earth-Fixed frame using observations collected by a unique receiver. It requires external information, namely, satellite orbit and satellite clock offsets of better quality than the ones broadcast by the navigation message. It has found tremendous use in the last 10 years, and remains a topic of great development potential. One of the applications is in geodynamic studies. This presentation overviews the principles of PPP and discusses its application for crustal deformation modelling. A full case study will be presented and results compared to geophysical and geometric models.

Title: Real-Time Global Navigation Satellite System Positioning along Canada's Active Coastal Margin: Efforts Directed Toward Support of Tsunami Early Warning

Presenter/First Author: Joseph Alan Henton, Pacific Geoscience Center, Sidney, BC

Presenter/First Author Email: jhenton@NRCan.gc.ca

Co-authors: Herb Dragert, Geological Survey of Canada Sidney, Sidney, BC, Canada; Yuan Lu, Geological Survey of Canada (Pacific), Sidney, BC, Canada

Published Material: Some material presentated at the 2014 AGU Fall Meeting (significant updates expected to be presented at the Joint Assembly).

Abstract Body: High-rate, low-latency Global Navigation Satellite System (GNSS) data are being examined for real-time applications to monitor motions related to large earthquakes in coastal British Columbia. Specific goals for real-time regional geodetic monitoring are: collection of GNSS data with adequate station density to identify the source function for regional earthquakes with M>7.3; robust, continuous real-time analyses of GNSS data with a precision of 1-2 cm and a latency of less than 10s; and display of results with attending automated alarms and estimations of earthquake parameters. Megathrust earthquakes (M>8) are the primary targets for immediate identification, since the tsunamis they generate will strike the coast within 15-20 min. However, large (6.0<M<7.5) normal or strike-slip earthquakes when occurring within the ocean plate offshore could be mistakenly identified as large tsunamigenic events and need to be discriminated from subduction thrust ruptures in order to avoid tsunami "false alarms" and unwarranted mitigation responses.

Results from commercial software packages RTD and RTnet run in-house are compared to real-time precise point positioning streams received from other organizations. Comparison of multiple real-time solutions allows a realistic evaluation of day-to-day software performance especially when faced with adverse conditions such as data gaps or poor satellite geometry. Forward models for scenario earthquakes in this region can "fingerprint" the coseismic displacements expected from various offshore events which allows an evaluation of the effectiveness of the current regional coverage. The present distribution and density of real-time sites is sufficient for aiding the timely estimation of size, location, and nature of a great (M>8) megathrust earthquake. However, current coverage is inadequate for the unambiguous identification of the same parameters for 7<M<8 earthquakes, especially those occurring offshore northern Vancouver Island.

Title: Land Hydrology Monitoring in North America via GRACE and Hydrology Models: A Comparison Study

Presenter/First Author: Dimitrios Piretzidis, University of Calgary, Calgary, AB

Presenter/First Author Email: dimitrios.piretzidis@ucalgary.ca

Co-authors: Elena Veselinova Rangelova, Univ Calgary, Calgary, AB, Canada; Michael G Sideris, University of Calgary, Calgary, AB, Canada

Abstract Body: Monitoring the time-varying gravity field with GRACE satellite can be used to derive information about hydrological processes on the Earth surface. In the area of North America, the GRACE signal is contaminated with the effect of glacial isostatic adjustment (GIA). A study has been done to compare hydrological signals from several global hydrology models and determine the one that is closest to the GRACE-observed hydrology signal.

The set of hydrology models investigated consisted of the available releases of the global and regional hydrology models GLDAS 1.0 and NLDAS 2.0. These models use integrated satellite and terrestrial observations along with different data assimilation methods to derive various land surface states and fluxes. The land surface models used for GLDAS 1.0 were the Noah, CLM, Mosaic and VIC, and for NLDAS 2.0 the Noah, Mosaic and VIC. The recent GRACE CSR Release 05 data were also used. Proper masks were applied to cover Greenland and other areas with strong snow growth signal.

The study was focused on the variability of equivalent water height (EWH) which was computed on 1°-grids. To ensure a fair comparison between the GRACE and hydrology EWH fields, the latter were converted to the spherical harmonic domain and filtered with the same filters that were applied to GRACE. The effect of GIA was then removed from GRACE time-series using the latest GIA models.

The computed EWH fields show good agreement with both GRACE signal and seasonality. The models closest to GRACE EWH signal are the GLDAS NOAH and VIC. In North America the GLDAS NOAH is closest to GRACE signal. On the contrary, the GLDAS CLM present the largest disagreements with GRACE signal. The results also show that the GLDAS VIC model exhibits better agreement with GRACE seasonality. Finally, the performance of NLDAS models is similar for both EWH signal and seasonality.

Title: High-Precision Repeat Gravity Measurements In Riyadh Using Fgl Absolute Gravimeter, Potential Applications For Saudi Arabia

Presenter/First Author: Saad Mogren AlMogren, King Saud University, Riyadh 11451,

Presenter/First Author Email: smogren@ksu.edu.sa

Abstract Body: High-precision repeat Absolute Gravity measurements are lacking for the Kingdom of Saudi Arabia, though there is an urgent need for such measurements considering their scientific importance, tectonic implications and also the size of the country. Presently there is no IGSN71 station within the Kingdom. Not only that; the base and baseline stations established by USGS, through network tie with IGSN stations in Africa way back in 1985, have also become extinct. Considering these aspects, we undertook repeat Absolute Gravity measurements by deploying FGL Absolute Gravimeter, for one locale on the Arabian Platform – King Saud University (KSU) Riyadh, Saudi Arabia. These measurements were continued since June 2008 through December 2014, which consists of a total of 310+ processed repeat data sets, displaying a set scatter of 1.87 – 4.52 µGal, where, the measuring precision is found to range between 0.29 – 0.52 µGal. Its best determined value at the King Saud University Absolute Gravity Base (called; KSU-AGB1) is: 978780044.50 µGal, Lat: 24.72167N, Long: 46.61722E, Elevation: 650.00 m, Set Scatter: 2.77 µGal, Measurement Precision: 0.57 µGal, , Total Uncertainty: 10.53 µGal. Plate I illustrates a typical display record for the FGL Absolute Gravimeter monitored on 7 January 2015 at KSU-AGB1. We recommend that the absolute gravity value reported here for KSU-AGB1 may be considered as the National Gravity Base for Saudi Arabia, and the Absolute Gravity Network in the country may ultimately be linked to this Base value.

Title: Assessment of discontinuities of Helmert's gravity anomalies on the geoid

Presenter/First Author: Ismael Foroughi, University of New Brunswick, Fredericton,

Presenter/First Author Email: i.foroughi@unb.ca

Co-authors: Petr Vanicek, University of New Brunswick, Fredericton, NB, Canada; Robert William Kingdon, Department of Geodesy and Geomatics Engineering, Fredericton, NB, Canada; Michael Sheng, Department of Geodesy and Geomatics Engineering, Fredericton, NB, Canada; Marcelo C Santos, University of New Brunswick, Fredericton, NB, Canada

Abstract Body: Downward continuation of gravity anomalies has been always one of the most problematic steps in geoid computation, which in that, gravity anomalies on topography are transformed down to the geoid. The area of computation is broken down typically into 1°×1° cells, as the Poisson's formulation -the rigorous formulation of the downward continuation problem- is very demanding on computer resources and the solution is sought separately for each cell. The results in individual cells are then fused together. That can be reliably done if there are no discontinuities between the downward continued values in adjacent cells. This implies that continuity of results should be checked and topic of this contribution is one possible approach to such checking.

The proposed method is assessing differences between overlapping adjacent 1°×1° cells; instead of downward continuing gravity anomaly to a 1°×1° cell on geoid, the cell area is increased by 1' strip on each side. Such that cells on the geoid will have 1' overlap on each side, which then offer an opportunity to compare the results from adjacent 1° cells in two adjacent 1'-wide strips. Theoretically the differences should be either zero, or at least negligible if they are less than a low multiple of the standard deviation of observed data. We note that this approach can be used in a variety of problems encountered not only in geodesy but also in other experimental sciences.

Numerical assessment of the potential of this method has been done for mean Helmert gravity anomalies in Auvergne, France. The area limits to -1°<λ<7° and 43°<φ<49°, with standard deviation of about 40 µGal. Discontinuities between downward continued Helmert anomalies are between ±120 µGal. The general behavior of differences suggests that they are random in origin, but more detailed examination shows some biases which may be coming from topography, neglected far zone contributions or differences in the number of iterations in downward continuation process.

Title: Progress Update on the U.S. Gravity for the Redefinition of the American Vertical Datum (GRAV-D) Project and Lessons Learned for Geoid Modelling

Presenter/First Author: Monica Youngman, National Geodetic Survey, Germantown, MD

Presenter/First Author Email: monica.youngman@noaa.gov

Co-authors: Vicki A Childers, NOAA, National Geodetic Survey, Silver Spring, MD; Simon A Holmes, SGT inc., Greenbelt, MD

Abstract Body: The U.S. National Geodetic Survey is collecting airborne gravity with the Gravity for the Redefinition of the American Vertical Datum (GRAV-D) Project to produce a geoid supporting heights accurate to 2 centimeters where possible with a modernized U.S. vertical datum in 2022. This year GRAV-D will approach 50% of the country with airborne data collected to support the geoid, with over 75% of this data complete and publicly available. In this poster we provide an update on data collection status and present areas of known geoid improvement. We also discuss challenges faced when using airborne gravity to improve the geoid over a large, geographically diverse area with varying amounts of corroboratory data.

Title: Continuation of Surface Anomalies to the Geoid in Regions of Negative Heights

Presenter/First Author: Robert W Kingdon, Fugro Airborne Surveys, Ottawa, ON

Presenter/First Author Email: rwkingdon@gmail.com

Co-authors: Petr Vanicek, University of New Brunswick, Fredericton, NB, Canada

Abstract Body: The Poisson integral is a spatial solution to the Dirichlet boundary value problem for the exterior of a sphere. In the context of geoid computation, the Poisson kernel is usually applied to gravity anomalies on the geoid (approximated locally by a spherical surface), to determine gravity values on topography. Conversely, a discrete form of the Poisson integration can be inverted to determine gravity anomalies on the geoid, from gravity values on topography. Direct Poisson integration attenuates high frequencies, while the inverse operation amplifies high frequencies, in accordance with the physics of potential fields.

The Poisson integral as usually implemented, choosing the geoid as the spherical boundary and applying it to gravity anomalies harmonic only above the geoid, cannot be applied to gravity measurements within (below) the geoid. Two methods are herewith proposed to resolve this issue, in the context of continuation of Helmert gravity anomalies. In the first, the Helmert anomalies on topography are converted to a space where they are harmonic above a reference sphere corresponding to the lowest elevation in the area. They are then downward continued to the reference sphere, upward continued to the geoid, and converted back to the Helmert space. In the second, the **B** matrix representing the Poisson integral kernel in its discreet form is partitioned into sub-matrices, separating areas of negative and positive heights. The sub-matrices associated with negative heights are applied to gravity anomalies at negative heights, while the sub-matrices of $\mathbf{B}^{-1}$ associated with positive heights are applied to gravity anomalies at positive heights. Application in a test area over the Dead Sea shows agreement between geoid results from both methods of less than 1.5 cm in regions of negative height, and suggests that the second method is the more accurate.

Title: Determination of the spectral weights of satellite models, and terrestrial and airborne gravity data for local geoid computations – case studies from GSVS11 and GSVS14 area

Presenter/First Author: Yan Ming Wang, NOAA, Boulder, CO

Presenter/First Author Email: yan.wang@noaa.gov

Co-authors: Tao Jiang, Chinese Academy of Surveying and Mapping, Beijing, China

Abstract Body: For local geoid computations, the least squares collocation has been the standard method to combine several sets of gravity data. An alternative is to use the spectral combination which takes into account the error characteristics of each data represented by their error degree variances (EDV). However, the EDV of terrestrial and airborne gravity data are not known; thus limiting wide use of the method in practice. One way to estimate EDV of terrestrial and airborne gravity data is to use statistical models of red and white noise. This paper explores the feasibility of computing EDV directly from gravity data without using the statistic models. The EDV at low degrees are estimated by the aid of a satellite gravity model, while a leave-out-one error estimation technique is introduced to estimate those at the medium and high degrees directly from the local data themselves. The EDV implied spectral weights restrict the satellite models to long wavelength, the contribution of airborne gravity to the medium wavelength, and terrestrial data to the medium to short wavelengths of the gravity field. The spectral weights are applied in local geoid computations in GSVS11 and GSVS14 areas. The study shows not only the contribution of each data set to the geoid in the frequency domain, but also reveals the degree of correctness of the satellite gravity models.

Title: Geoid Determination from Airborne Vector Gravimetry: An Example Using AIRGrav Data from Tanzania

Presenter/First Author: Stephen Ferguson, Sander Geophysics Ltd, Ottawa, ON

Presenter/First Author Email: stevef@sgl.com

Co-authors: Rene Forsberg, Technical University of Denmark - Space, Kongens Lyngby, Denmark

Abstract Body: Airborne gravity measurements have proven to be very useful in geoid computation, both as a sole source of data in areas where access is challenging, and as an addition to ground gravity data in other areas. Until now, measured airborne horizontal gravity components for geoid computation have not been utilized. One of the potential advantages of using horizontal gravity data for geoid determination is the relaxation of requirements for obtaining gravity data over a region larger than the area of interest, often practically impossible in coastal regions, or for countries in the developing world, where gravity data for neighboring countries are often lacking or kept secret.

In this presentation, high-resolution airborne vector gravity data over a large area of Northeastern Tanzania is used to compute new high-resolution geoid models, both with and without the use of horizontal gravity data. The geoid models are computed by remove-restore methods using least-squares collocation and Fourier methods, and these results are inter-compared, as well as compared with other recent geoid models and available GPS/levelling data.

The vector gravity data were acquired in 2012 using a Sander Geophysics AIRGrav system, as part of a large high-resolution multi-parameter survey conducted for the Tanzanian Ministry of Energy and Minerals (Fig. 1). Three large contiguous blocks are used in this study, covering an area of about 180,000 square km (Fig. 1). A larger airborne gravity survey, covering all of Tanzania, was carried out in 2012-13 by DTU Space in cooperation with the Tanzanian Department of Lands, and allows an independent comparison of the geoid results.

Title: Assessments of Recent GRACE and Release 5's GOCE Global Geopotential Models in Canada

Presenter: Marc Veronneau, Natural Resources Canada, Ottawa, ON

Presenter Email: marcv@nrcan.gc.ca

First Author: Jianliang Huang, Natural Resources Canada, Ottawa, ON

First Author Email: Jianliang.Huang@NRCan-RNCan.gc.ca

First Author Student?: No

Published Material: Part of the results (less than 25%) was reported in the AGU Fall 2014 and the 5th user workshop as co-authors.

Abstract Body: The GOCE satellite by European Space Agency was launched on March 17th, 2009, and re-entered the Earth's atmosphere falling into the ocean on November 11th, 2013. Its objectives were to measure the Earth's gravity field with an accuracy of 1 mGal (one millionth of the Earth's gravity) and geoid with an accuracy of 1-2 cm at a spatial resolution of 100 km. Up to 2014, five generations of GOCE-only and GOCE-based satellite geopotential models have been released. In the meantime, satellite-only geopotential models derived from more than 10 years of observation by the ongoing GRACE mission were also released recently. While these satellite-only models only provide the long and medium wavelengths of the gravity field components, an extra-high degree model (EIGEN-6C4) complete to degree/order 2190 has been developed by combing the GRACE and GOCE models with the terrestrial and marine gravity data to improve the determination of the complete Earth's gravity field.

Assessments of the new releases of GRACE- and GOCE-based models are to understand what new and improved gravity information these new GRACE and GOCE models have brought in; what unique contribution of each mission is in term of improving the Earth's gravity field; how accurate these models are in terms of both commission and omission errors; and how the combined model EIGEN-6C4 have improved determination of the full Earth's gravity field. Answers to these questions are necessary for our ultimate goal that is to best use GRACE and GOCE information to improve the geoid model in Canada. This study attempts to address these questions through assessing the recent GRACE models and Release 5's GOCE geopotential models using GPS-Levelling, astronomical deflections of the vertical and gravity data in Canada.

Title: Concerning the Roundabout Method to Downward Continuation and the Evaluation of the Far-zone

Presenter/First Author: Michael Sheng, Department of Geodesy and Geomatics Engineering, Fredericton, NB

Presenter/First Author Email: michaelsheng1@gmail.com

Co-authors: Petr Vanicek, University of New Brunswick, Fredericton, NB, Canada; Robert William Kingdon, Department of Geodesy and Geomatics Engineering, Fredericton, NB, Canada; Ismael Foroughi, University of New Brunswick, Fredericton, Canada; Juraj Janak, Slovak University of Technology, Bratislava, Slovakia; Marcelo C Santos, University of New Brunswick, Fredericton, NB, Canada

Abstract Body: The Stokes-Helmert approach to precise geoid computation is used in the SHGeo software package at the University of New Brunswick. This method uses Stokes's theorem which requires the knowledge of gravity anomalies on a boundary (the geoid); measurements on or above the surface of the Earth must therefore be downward continued to the geoid. The mathematical instability of the downward continuation is well-documented and its effect on the resulting geoid must be considered.

Helmert space differs from the real one by removing topography above the geoid and applying Helmert's second condensation method. It has a similar gravity field to the real space while satisfying the harmonicity of the gravity potential above the geoid as required. Another space that can be used is the No-Topography (NT) space, defined by the Earth after the removal of topography; this causes the field to be much smoother than the real field. The NT anomaly can be downward continued and transformed to Helmert space by accounting for the condensation layer. We call this technique of evaluating Helmert's anomalies on the geoid the 'roundabout' approach compared to continuing Helmert's anomalies directly to the geoid (the 'direct' approach). Results from the roundabout technique should be more accurate due to the smoothness of the NT anomalies.

Applying this approach in Auvergne, France ($44.5° < \varphi < 47.5°$, $1.5° < \lambda < 4.5°$), the results for the roundabout approach after downward continuation are worse than for the direct approach. After testing we found that the NT anomalies are about twice as sensitive to the far-zone contribution than the Helmert ones. By doubling the integration radius for the downward continuation of the NT anomalies, the geoid results from the roundabout approach are comparable to those obtained from the direct approach. The fit to GPS benchmarks in Auvergne is $\sigma = 0.042$m vs. 0.037m. This preliminary work shows that the NT field is worth further investigation.

Title: Updating Bench Mark Coordinates for the New U.S. National Datums

Presenter/First Author: Daniel R Roman, National Geodetic Survey, Silver Spring, MD

Presenter/First Author Email: dan.roman@noaa.gov

Co-authors: Xiaopeng Li, NOAA, Boulder, CO

Abstract Body: The National Geodetic Survey (NGS) maintains the National Spatial Reference Systems (NSRS) within the United States. The NSRS currently includes the North American Datum of 1988 (NAVD 88) for orthometric heights and the North American Datum of 1983 (NAD 83) for ellipsoidal coordinates. Replacing these two datums with new geometric and geopotential datums in 2022 will require many changes in standards, technique, policy, and practices. The approach envisioned is to use GNSS observations in conjunction with online processing tools to obtain geometric coordinates, which would then be interpolated into a high accuracy gravimetric geoid (geopotential) model to determine orthometric heights.

This would mark a move away from traditionally defined bench mark coordinates that currently provide definitive positional control. The NGS Integrated Database (NGSDB) serves as the electronic repository for bench mark data on nearly 500,000 NAVD 88 leveling sites and 80,000 NAD 83 coordinate sites. The role of this bench mark data would then become secondary, serving as a backup in case of catastrophic failure of GNSS access. To be useful then, bench mark data will need to be made consistent with the new datums requiring an adjustment of the positional coordinates in the NGSIDB. These values must be consistent with what would be obtained using a GNSS receiver and the geoid model in the new datums. Backward compatibility will be maintained through knowledge of the coordinates under the older and newer datums, which will be used to produce a transformation model similar to VERTCON and NADCON software.

Title: Practical and Technical Considerations for the Replacement of NAVD 88 and IGLD 85

Presenter/First Author: Dru A Smith, NOAA Natl Geodetic Survey, Silver Spring, MD

Presenter/First Author Email: dru.smith@noaa.gov

Abstract Body: The North American Datum of 1988 (NAVD 88) was co-defined with the International Great Lakes Datum of 1985 (IGLD 85) through the determination of geopotential numbers at some 600,000 passive geodetic control bench marks. Those geopotential numbers were computed from geodetic spirit leveling and surface gravity measurements. Most of the field work was performed in the 1970's and 1980's, though some of the leveling dates from NGVD 29 and CGVD 28.

The primary method by which surveyors and other geospatial professionals access NAVD 88 and IGLD 85 is through the publication of Helmert orthometric heights (for NAVD 88) or Dynamic Heights (for IGLD 85), both derived from geopotential numbers, at passive control. NAVD 88 and IGLD 85 were significant achievements and improvements over previous height systems on the North American continent. However, they have a significant number of disadvantages, including: the general lack of vertical change monitoring; the removal of passive control during construction projects; the inconsistency between marks which move with the crust and those which are deep-driven rods and move only with underlying bedrock; the inconvenience of marks not existing in an area of interest to a surveyor; the propagation of leveling errors over thousands of kilometers and the failure to incorporate 2nd and 3rdorder effects into the original determination of geopotential numbers.

In 2008, the National Geodetic Survey (NGS) formally announced its policy to replace NAVD 88 with a geopotential reference frame implicitly linked to a new geometric reference frame (which will replace NAD 83). The geopotential reference frame will have the data and tools needed to provide to users their orthometric height, dynamic height, deflections of the vertical or acceleration of gravity at any point in the USA or its territories. The orthometric heights will be accessed from CORS stations, a time dependent gravimetric geoid model and GNSS positioning techniques. The dynamic heights will be similarly accessed, but will also rely on a time-dependent surface gravity field.

This talk will focus on the technical and practical considerations surrounding the definition of such a frame, its upkeep and its method of access by geospatial professionals. Topics will include data collection, models, tools, accuracy and sustainability.

Title: Maintaining a National Geoid-Based Vertical Datum

Presenter/First Author: Marc Veronneau, Natural Resources Canada, Ottawa, ON

Presenter/First Author Email: marcv@nrcan.gc.ca

Co-authors: Jianliang Huang, Natural Resources Canada, Ottawa, ON, Canada

Abstract Body: In November 2013, Canada established the Canadian Geodetic Vertical Datum of 2013 (CGVD2013). This new datum is defined by an equipotential surface (W_o =62,636,856 m^2/s^2) and realized by a geoid model (CGG2013), making it compatible with Global Navigation Satellite Systems (GNSS) for positioning. The adoption of CGVD2013 represents a major shift from the old datum CGVD28, which was defined by the mean sea level at selected tide gauges and realised by traditional levelling measurements, and a major impact for the users, who have relied on benchmarks for the last 100 years to conduct their surveys.

The presentation will not only discuss the advantages for Canada to moving to a geoid-based datum, but also discuss the challenges in maintaining such as vertical datum in an era where technology is moving rapidly and data are coming in in large numbers allowing the possibility of a quick turnaround in the release of new realisations of the geoid-based vertical datum. This is quite different as when benchmarks were re-surveyed at a 20- to 30-year cycle or sometime never revisited again, keeping heights very consistent over the years. How to satisfy users who want to live in world as static as possible, but simultaneously providing continuous improvement in the vertical datum to satisfy utmost scientific requirements.

Title: Practical and Technical Considerations for the Replacement of NAD 83

Presenter/First Author: Joe G Evjen, National Geodetic Survey, NOAA, Silver Spring, MD

Presenter/First Author Email: joe.evjen@noaa.gov

Abstract Body: The official U.S. horizontal mapping datum, the North American Datum of 1983 (NAD 83)—in both its definition, as well as the services NGS provides for its access—is in need of improvement. As defined, it is non-geocentric by over two meters and has non-zero, residual plate velocities. Since 1983, increasingly accurate International Terrestrial

Reference Frames (ITRF) have become available and have been adopted by many groups, including Mexico's INEGI and the U.S. National Geospatial-Intelligence Agency.

The U.S. National Geodetic Survey is planning a replacement of NAD 83 with a new ITRF-aligned geometric datum, to be released with a new GNSS-accessible geopotential datum to replace the North American Vertical Datum of 1988. We will discuss recent progress, expected benefits, planned products, services, models, and tools to access the new datum, legislative steps, and impacts and concerns from Federal, State, Private Sectors.

Title: *New Datum CGG2013 applications for DSM-DEM-DTM preparation from earth observation satellites data*

Presenter/First Author: Jay Sagin, Saskatchewan Polytechnic, Saskatoon, SK

Presenter/First Author Email: jay.sagin@usask.ca

Co-authors: Karl-Erich Lindenschmidt, Global Institute for Water Security, University of Saskatchewan, Saskatoon, Canada

Abstract Body: *The high resolution Digital Surface Model (DSM), Digital Elevation Model (DEM) and Digital Terrain Model (DTM), a topographic model of the bare earth-terrain relief (DTM=DEM of the earth surface), are valuable data for many earth studies applications. Many regions, including Canada, lack the high resolution DSM-DEM-DTM. We have compared the DEM obtained from satellite datasets, including Canadian Radarsat-2, German TanDEM-X DEM, and Japanese ASTER. The Bathymetry Model (BM) was development into a DTM compilation by subtracting the BM from the DSM. The high resolution Global Navigation Satellite System (GNSS) collection equipment GPS Pathfinder ProXRT GLONASS (the real-time receiver can achieve decimeter (10 cm) accuracy), with satellite OmniSTAR G2 satellite subscription are used for the field elevation data collection. Calibration and verifications of the DSM-DEM-DTM were done in the research area, North West Territory, by using the new Geoid stations, CGVD2013. The critical points along the road profile with the new Geoid stations and the Slave River, bare rock outcrops, including Slave River upstream, Fort Smith town, and downstream, Fort Resolution town, were used to the height reference. The new updated Geoid CGG2013 stations are used as the main DSM-DEM-DTM reference points. Ice thickness and water depth are measured along the Slave River by auger drilling. The collected field data and processed satellite data with prepared DSM-DEM-DTM are to be used for the ice jam and flood predictions along the Slave River, NWT, Canada.*

Title: Toward the Computation of a Geoid Model of Ghana

Presenter/First Author: Michael Klu, University of New Brunswick, Fredericton, NB

Presenter/First Author Email: michael.klu@unb.ca

Co-authors: Petr Vanicek, University of New Brunswick, Fredericton, NB, Canada; Robert William Kingdon, Department of Geodesy and Geomatics Engineering, Fredericton, NB, Canada; Michael Sheng, Department of Geodesy and Geomatics Engineering, Fredericton, NB, Canada; Ismael Foroughi, University of New Brunswick, Fredericton, Canada; Marcelo C Santos, University of New Brunswick, Fredericton, NB, Canada; Peter John Dare, University of New Brunswick, Fredericton, NB, Canada

Abstract Body: Use of the Global Positioning System (GPS) was introduced to Ghana in the early 1990s. The widespread use of GPS in height-related surveying and mapping activities has made the computation of a geoid model a very important task. In this research, the first gravimetric geoid for Ghana is being computed using the Stokes-Helmert method, developed by the University of New Brunswick (UNB), Canada. This method utilizes a two space solving the associated boundary value problems, including the real and Helmert's spaces. The UNB approach combines observed terrestrial gravity data with long-wavelength gravity information from a Global Gravitational Model (GGM).

All the terrestrial gravity data used in the computation was derived from the Geological Survey Department of Ghana, due to difficulties in obtaining data from BGI and GETECH. The first gravity survey was part of Ghana's contribution to the International Geophysical Year, 1957-1958, and was linked to the gravity network of the neighboring countries and to Potsdam reference system through a connection to Pendulum House, Cambridge, United Kingdom (UK). A least squares adjustment of the gravity survey network was carried out in the UK. Since this first campaign of gravity collection, more data have been added to the gravity database, which now covers between 70 and 80 percent of the country. A GGM is used to pad those areas lacking in terrestrial gravity data.

For the computation of topographic effects on the geoid, the STRM, a Digital Elevation Model (DTM) generated by NASA and the National Geospatial Intelligence Agency (NGA), is being used. Since the terrain in Ghana is relatively flat, the topographic effect, often a major problem in geoid computation, is unlikely to be significant. This first geoid model for Ghana will be computed on a 1'1' grid over the computation area bounded by latitudes 4ºN and 12ºN, and longitudes 4ºW and 2ºE. GPS/levelling heights will be used to validate the results of the computation.

Keywords: Geoid, Stokes' formula, Global Gravitational Model, Topographic effect, Digital Terrain Model

Title: Geodetic versus geologic subsidence rate along the United States east coast: Implications for global isostatic adjustment and effects of ground water extraction

Presenter/First Author: Makan A. Karegar, University of South Florida Tampa, Tampa, FL

Presenter/First Author Email: makan@mail.usf.edu

Co-authors: Simon E Engelhart, University of Rhode Island, Kingston, RI; Timothy H Dixon, University of South Florida Tampa, Tampa, FL

Abstract Body: Subsidence along the Atlantic coast of the United States is the largest amplitude collapse of a pro-glacial forebulge on Earth. High-quality geological records of Holocene relative sea level are now available for the region (Engelhart et al., 2009; Engelhart and Horton, 2012; Kemp et al., 2014). These data provide an independent constraint on Global Isostatic Adjustment (GIA), for comparison to continuous GPS measurements that directly measure net vertical motion of the crust from GIA and other processes. Long GPS time series are now available, allowing precision in the vertical component better ± 1mm/yr. Here, we present an improved vertical velocity field for the eastern seaboard of the U.S. and parts of Atlantic Canada with uncertainty estimates that incorporate time-correlated noise. We demonstrate good agreement between GPS vertical velocities and the geologic rates for most of the U.S. eastern seaboard. Exceptions are most likely related to areas of recent excessive ground water extraction, which affects the GPS vertical rate estimate.

Title: ANALYSIS OF GEOLOGICAL-GEOTHECNICAL RISKS DUE TO GROUNDWATER EXPLOITATION USING SPACE AND TERRESTRIAL TECHNIQUES: LORCA AREA (SPAIN) TEST CASE

Presenter/First Author: Juan F. Prieto, Technical University of Madrid, Madrid,

Presenter/First Author Email: juanf.prieto@upm.es

Co-authors: Jose Fernandez, Complutense University of Madrid, Madrid, Spain; Jose A. Fernandez-Merodo, , , ; Antonio G. Camacho, Institute of Geosciences (CSIC-UCM), Madrid, Spain; Gerardo Herrera, Instituto Geologico Minero Espana, Madrid, CDX, Spain; Mimmo Palano, INGV National Institute of Geophysics and Volcanology, Catania, Italy

Abstract Body: To provide new products and services for the analysis, management and mitigation of the geological-geotechnical risks associated with the exploitation of aquifers in urban areas and their surroundings, are the aims of AQUARISK reseach project. For this purpose multi-sensor (ERS & ENVISAT, ALOS PALSAR, Sentinel, PAZ) satellite Advanced DInSAR and GNSS data fusion will be performed at regional scale to determine the 3D deformation field of the mediterranean arc (Southeast Spain) and also at local scale for a detailed study of the areas of interest. This analysis will permit to detect the temporal evolution of subsidence in those hidrographic basins that suffer the greatest exploitation (e.g. Lorca área at Guadalentin-Segura River Basin). In this area, new in situ monitoring systems will be developped and implemented to carry out a real time monitotoring of the temporal evolution of ground water level and the aquifer deformation in depth. These terrestrial measurement data will be integrated with the remote sensing EO data to determine the 4D deformation field, and to define future climate change based scenarios of the aquifer system response. All this effort will permit to develop, calibrate and validate advanced numerical geomechanical models that will simulate the past-present-future aquifer system response, and to analyze the impact of subsidence on urban structures and infrastructures.

In this framework, AQUARISK will performs research and development on new services & products based on EO multi-sensor satellites data in conjunction with in-situ data; and will promotes the exploitation of EO and in situ data to monitor, model and predict subsidence due to aquifers exploitation in different climatic change scenarios.

A summary of the obtained scientific results and of the works to be carried out in the near future will be presented.

Title: Horizontal Displacement Monitoring In Eastern Ontario

Presenter/First Author: Hadis Samadi Alinia, University of Western Ontario, London, ON

Presenter/First Author Email: alinia_202000@yahoo.com

Co-authors: Kristy French Tiampo, University of Western Ontario, London, ON, Canada

Abstract Body: Eastern Ontario is a region of moderate seismic hazard, an area of ongoing intraplate deformation in the North American plate (Tiampo et al., 2011; Calais et al., 2006). However, the continuous melting of ice sheets during deglaciation today causes horizontal and vertical deformation of the Earth surface near Hudson Bay and to the southern Great Lakes. In this work, new measurements from GPS stations installed in the Portable Observatories for Lithospheric Analysis and Research Investigating Seismicity (SOSN/POLARIS) network, combined with permanent stations that are operated by Natural Resources Canada (NRCan), are analyzed in order to estimate the associated horizontal and vertical crustal motions with accuracies less than mm.

GPS stations of the eastern Ontario networks are distributed sparsely, with a spacing of approximately 250km or more. In this work, several sets of reference stations were processed using Bernese 5.0 and residual time series coordinate changes of each station were compared to the global solutions for crustal motions (http://geodesy.unr.edu/). Comparison of our results with others global solution techniques show an internal accuracy at the level of 0.1 mm/yr. (1 sigma) for horizontal and vertical velocities at the best sites.

The focus of this paper is to present GPS stations horizontal velocities obtained by analyzing their coordinate time series. To achieve this goal, the basic parameters such as mean and variance are estimated then jumps and outliers are detected and eliminated. Correlation coefficients of linear trend, residual analysis, interpolation of spaced data, spectral analysis and wavelength power spectrum are computed. Finally, all of the obtained horizontal velocities are corrected for the North America plate motions (Altamimi et al., 2012) and compared with the predicted glacial isotactic adjustment (GIA) model ICE3G (Tushingham and Peltier, 1991; Peltier, 2004) with different viscosity structures. The horizontal velocities are consistent with the ICE-3G postglacial rebound model with 0.1-0.2 mm/yr. uncertainties, and they provide new insights into the modeled viscosity structure.

Title: CO2 reservoir joint modeling using time lapse micro gravimetry and ground deformation

Presenter/First Author: Hojjat Kabirzadeh, University of Calgary, Calgary, AB

Presenter/First Author Email: hkabirza@ucalgary.ca

Co-authors: Jeong Woo Kim, University of Calgary, Calgary, AB, Canada; Michael G Sideris, University of Calgary, Calgary, AB, Canada

Abstract Body: Geodetics and gravimetric methods have been used for CO2 reservoir monitoring purposes in the past. However they have been employed as a joint process rarely. We use gravity and surface deformation forward modeling in order to show the feasibility of a numerically joint study. A reservoir is considered to be located at 1800 meters depth with 20 meters of thickness. 2.5 million tons of CO2 is injected to this reservoir. This excessive CO2 causes a negative density change in the pore content and consequently a negative gravity anomaly at the surface. On the other hand the positive volumetric changes caused by excessive pressure inside the reservoir results in uplift at the surface. For modelling procedure, subsurface is divided to rectangular portions and two different Green's functions relates the gravity and surface deformation to density and volume changes in each cell. The results show that under these assumptions we can detect -5 µGal gravity change as well as 30 mm of ground deformation just above the injection well. The obtained gravity signal target is well above the precision of Superconductive gravimeters. Superconducting gravimeter supported by absolute gravimeter can provide unique measurements with high resolution (0.05 µGal in time domain). Millimetre scale accuracy of INSAR surface deformation measurements enables the deformation detection due to CO2 injection with a very high accuracy.

Title: Constraints Provided by Ground Gravity Observations on Geocentre Motions

Presenter/First Author: Yves J G Rogister, EOST École et Observatoire des Sciences de la Terre, Strasbourg,

Presenter/First Author Email: Yves.Rogister@unistra.fr

Co-authors: Anthony Mémin, , , ; Severine Rosat, IPGS-EOST, Strasbourg, France; Jacques Hinderer, Institut de Physique du Globe Strasbourg, Strasbourg Cedex, France; Marta Calvo, CNRS EOST, Strasbourg, CDX, France

Abstract Body: The geocentre motion is the motion of the centre of mass of the entire Earth, considered an isolated system, in a terrestrial system of reference. Up to now, geocenter motions have been derived from positioning measurements only. We propose a new approach to constrain these motions by using ground gravity measurements. We first derive a formula relating the harmonic degree-1 Lagrangian variations of the gravity, the harmonic degree-1 vertical displacements of the station and the displacements of the whole Earth's centre of mass. The relationship is independent of the nature of the Earth deformation and is valid for any source of deformation. We impose no constraint on the system of reference, except that its origin must initially coincide with the centre of mass of the spherically-symmetric Earth model. Next, we consider the geocentre motion caused by surface loading. In a system of reference whose origin is the centre of mass of the solid Earth, we obtain a specific relationship between the gravity variations at the surface, the geocentre displacement and the load Love number h'_1, which demands the Earth's structure and rheological behaviour be known. We show that an annual gravity signal of 400 nGal (100 Gal = 1 m/s^2) associated with a geocenter motion of 1 mm is above the noise level of the superconducting gravimeter (SG) in Strasbourg, France. Given that, we investigate if the present network of SGs co-located with positioning measurements can detect the annual variation of the geocenter motion.

Title: Archaeomagnetism as Geoarchaeology: Using Mineral Magnetic and Palaeomagnetic Measurements to Understand Behaviour, Palaeoenvironmental Change, Occupation Intensity and Fire Use on Palaolithic Sites from South Africa, Australia and China.

Presenter/First Author: Andy IR Herries, La Trobe University, Bindoore, VIC

Presenter/First Author Email: a.herries@latrobe.edu.au

Published Material: Brown et al. 2009. Science. various media outlets. (Pinnacle Point) and various archaeological meetingsHerries and Fisher, 2010. J. Human Evolution. (PInnacle Point) and various archaeological meetingsCurnoe et al. 2012. Plos One. (Red Deer Cave).the remaining material fromSouth Africa and Australia has not been presented and is unpublished.

Abstract Body: The term Archaeomagnetism is generally synonymous with Archaeomagnetic Dating and the use of geomagnetic secular variation data for understanding the age of sites. However, in a broader sense it should be used to include the use of mineral magnetic and palaeomagnetic measurements on archaeological sites as part of the field of geoarchaeology. It should also be undertaken with a multi-disciplinary perspective in mind and in combination with other geoachaeological methods such as micromorphology and geochemistry. A number of studies have undertaken this approach but archaeomagnetism in this sense remains an underutilized method within the realms of archaeological science despite being able to inform archaeologists about a range of different processes including palaeoenvironmental change, site formation processes and human behavior through fire use and pyrotechnology. To illustrate the potential of archaeomagnetism to the Palaeolithic time period, a range of case studies will be shown that illustrate this. This will include work on the hominin bearing site of Red Deer Cave in China, the Middle Stone Age Pinnacle Point Caves and Erfkroon Later Stone Age site in South Africa and a range of site contexts in Australia. From the Pinnacle Point Caves and caves in Western Australia mineral magnetism in conjunction with micromorphology has been used to understand fire use and inferences for site occupation intensity. At other cave sites in South Africa, Australia and at the Red Deer Cave in China mineral magnetism has been used to show climatic change, including evidence for millennial scale changes during the Holocene and late Pleistocene. At Pinnacle Point archaeomagnetism has also been succesfully used to identify the oldest evidence for the heat treatment of stone by early humans to make stone tools and this work has been continued in Australia. At Erfkroon potentially early Later Stone Age hot rock technology has been identified and in conjunction with work on Australian Clay Balls this will be used to illustrate the need for experimental archaeology as a fundamental part of archaeomagnetic analysis.

Title: Iron isotopes as a new tool for old metals tracing

Presenter/First Author: Jean Milot, GET Géosciences Environnement Toulouse, Toulouse,

Presenter/First Author Email: jean.milot@get.obs-mip.fr

Co-authors: Franck Poitrasson, Universidade de Brasilia-IRD, Brasilia, Df, Brazil; Sandrine Baron, Laboratoire TRACES, Toulouse, France; Marie-Pierre Coustures, Laboratoire TRACES, Toulouse, France; Caroline Robion-Brunner, Laboratoire TRACES, Toulouse, France

Abstract Body: Geochemical and isotopic analyses are well known tools for old metal provenance studies and ancient trade networks reconstitution. For relevant archaeological interpretation, the metallurgical processes have to be taken into account and analyses must be performed on ores, slags and produced metal. Classically, trace elements analyses are used for ferrous metals provenancing (Coustures *et al*., 2003), whereas lead isotopic analyses are used for non-ferrous metals (Stos-Gale *et al*., 1997; Durali-Mueller *et al*., 2007). However, these two techniques show limitations. Indeed, trace elements analyses of ferrous artefacts are performed on slag inclusions which induces significant deterioration of archaeological pieces. Moreover, a very pure metal does not contain any slag inclusions. Concerning lead isotopes analyses, distinct mining districts may have a homogeneous isotopic composition while ores from the same mine can show a heterogeneous isotopic composition. This may induce some questionings for provenance issues (Baron *et al*., 2014). These limitations underline the need to develop new tracers as a complement to the existing ones.

For the first time, iron isotopes are used for old metals characterization and provenancing. To develop our method, we analyzed material from reduction experiments and metallic artefacts clearly constrained by archeology and by multi-elemental analyses. The isotopic ratios ^{57}Fe /^{54}Fe and ^{56}Fe/^{54}Fe were quantified using a Multi Collector Inductively Coupled Plasma Mass Spectrometer after sample dissolution and Fe purification.

Our first results show that iron isotope compositions of ores, slags and metal are homogeneous for each iron ore reduction experiments. Moreover, iron isotopes allow to distinguish iron ores from different sources which were undistinguishable using lead isotopes. It demonstrates here that whereas iron isotopes remain unaffected by the ferrous metallurgical process, they can become a powerful tool for provenance studies.

Title: Interpreting the Different Scales of Ceramic Paste Compositional Datasets: Archaeological Perspectives and Scales of Analysis.

Presenter/First Author: Yves Monette, University of Montreal, Montreal, QC

Presenter/First Author Email: yves.monette@umontreal.ca

Published Material: Part of the presentation uses material from my PhD thesis also published in the Journal of Archaeological Science (2007) and one example on fire assay crucibles was published in 2013 in Applied clay Science.

Abstract Body: Over the past 20 years, ceramic paste chemical analysis has become common practice in archaeology. Chemical data obtained through a variety of analytical methods is either used to answer questions of provenance, pin-point the source of raw materials, highlight trading routes and patterns or simply to characterise a ceramic container and reveal some of its deeply buried secrets. The variety of research questions that one can tackle via a robust chemical dataset covers a large angle.

Through a selection of case studies making use of geochemical data, this paper explores the multiple scales of analysis of ceramic pastes through wide to narrow archaeological perspectives. The selected examples will present European and colonial ceramic materials dated from the 16th-19th Century time period. Form the broad observations to the very small scale study, we will look at the 16th and 17th centuries worldwide diffusion of highly refractory fire assay crucibles, at the chemical characterization of potters ceramic wastes in a regional perspective, and have a look at an early 19th Century pottery production were multiple production series can be identified.

Moving forward in the demonstration, we will highlight the interplay between the scales of analysis and the archaeological perspectives, and their mutual influence on the reality we are trying to capture.

Title: Using Microfossils to Observe the Occupancy of Pre-Historic Peoples: the Value of Non-Pollen Palynomorphs

Presenter/First Author: Nicholas Riddick, Brock Univ, St Catharines, ON

Presenter/First Author Email: riddick.nicholas@gmail.com

Co-authors: Andrea Krueger, Brock Univ, St Catharines, ON, Canada; Francine M G McCarthy, Brock Univ, St Catharines, ON, Canada; Olena Volik, University of Waterloo, Toronto, Canada

Abstract Body: Microfossils, particularly pollen grains, have been used to address archaeological questions since the early 1900's. Their use has expanded beyond their original application to date archaeological remains. A classic example is the response of various microfossil groups (diatoms, rotifers, fungal spores, dinoflagellate cysts and pollen) to several periods of human occupation around Crawford Lake, Ontario. While Euro-Canadian land clearing, farming and logging (identified by abundant ragweed pollen) added nutrients to the lake, the Iroquois occupation (identified by cultivar pollen and spores of their pathogenic fungi) had the greatest impact on the lake ecosystem. These higher abundances are observed more than once between ~A.D.1286–1486, indicating cycles of habitation of the village. Similarly, the distribution of palynomorphs (acid resistant microfossils) in small lakes on the Penetanguishene Peninsula and in Severn Sound, Ontario reveals distinct Euro-Canadian and Wendat (Huron - ~A.D.1450–1650) occupation zones, both characterized by an increase in algal microfossils (particularly eutrophic taxa) as well as non-arboreal pollen. Ongoing studies in Lake Simcoe have identified evidence of Wendat occupation in the Orillia region, where the palynological signature is supported by measurements of increased nutrient and heavy metal concentrations in pre-European sections of the core. The abundance of algal palynomorphs in our samples clearly records cultural eutrophication, but because most pollen analysts use acetolysis to "clean up their preparations", the more susceptible non-pollen palynomorphs are destroyed. Analysis of samples from Smith's Bay (Lake Simcoe) pre- and post- acetolysis treatment show a loss of most desmid species (particularly Staurastrum spp.) and small, thin-walled dinoflagellates, for instance, whereas Pediastrum appear to be unaffected. Geoarcheologists are urged to avoid acetolysis and examine the non-pollen palynomorphs in their "pollen" slides, thus getting broader insights into anthropogenic impact than by relying on the pollen alone.

Title: The Geochemical Provenance of Pre-Contact Copper Artifacts from the Gaspereau Lake Area, Nova Scotia: Analytical Approaches, Challenges and Interpretation

Presenter/First Author: Jacob J Hanley, Saint Mary's University, Halifax, NS

Presenter/First Author Email: jacob.hanley@smu.ca

Co-authors: Jessica Whattam, Saint Mary's University, Halifax, NS, Canada; Catherine Cottreau-Robins, Nova Scotia Museum, Halifax, NS, Canada; Christopher RM McFarlane, University of New Brunswick, Fredericton, NB, Canada; W. Bruce Stewart, Cultural Resource Management Group Ltd., Halifax, NS, Canada; Mike Sanders, Cultural Resource Management Group Ltd., Halifax, NS, Canada

Abstract Body: In-situ microanalysis of archaeological materials by laser ablation ICP-MS is rapid and virtually non-destructive compared to bulk techniques (XRF, NAA), allowing compositional variability to be assessed at high spatial resolution. We used LA-ICPMS to compare trace element concentrations in 28 copper artifacts (worked natural “nuggets”) from the Gaspereau Lake area of Kings County, Nova Scotia to natural samples from Michigan (7 deposits) and Nova Scotia (3 deposits) providing constraints on geological provenance.

Intra- and inter-sample variations in trace element concentrations at hand sample and deposit scales are <20% (relative) whereas previous NAA and XRF data is compromised by contaminating mineral inclusions in the copper that cannot be excluded in the large sample volumes required for these methods. Comparison of patina and fresh metal show systematic enrichments in Zn, Sn, Fe, As and Au in patina and S, Sb, Co, Ni and Ge in fresh copper matrix; however, this fractionation resulting from oxidation does not impact composition sufficiently to limit the use of fresh copper or even patina in provenance studies.

Eight of the artifacts were derived from 2 principle copper sources on the Bay of Fundy coast that can be easily differentiated from one another by their contrasting Ag/Pb ratios. (Cap D’Or and Margaretsville-Victoria Beach). The remaining 20 artifacts are not from the Bay of Fundy, or any Michigan sources (enriched in As relative to Fundy) and comprise 5 distinct yet geographically unidentified provenance groupings.

Preliminary results reassert the importance of local (Fundy) copper to pre-contact period indigenous peoples of Nova Scotia and the Maritimes, and negate the Lake Superior model. The diversity of copper sources indicated has significance in the broader context of territorial procurement of copper, and trade relationships between groups of aboriginal peoples in the Atlantic Northeast.

Title: Geoarchaeology of the ancient harbour bassin of Ostia, Rome, Italy

Presenter/First Author: Jean Philippe Goiran, CNRS, Lyon,

Presenter/First Author Email: jean-philippe.goiran@mom.fr

Co-authors: Ferréol Salomon, University of Southampton, Southampton, United Kingdom; Cecile Vittori, , , ; Ilaria Mazzini, , , ; Laura Sadori, , , ; Jonatan Christiansen, , , ; Angelo Pellegrino, , ,

Abstract Body: For the first time we prove, by the use of corings, the location of the basin harbour of Ostia. The study of the stratigraphic sequence of Ostia basin is based on multidisciplinary geoarchaeological approach that integrate 17 radiocarbon dates obtained on 12m of stratigraphy. Three units can be distinguished: pre-harbour, harbour and post-harbour. (i) The pre-harbour is a fluvial-marine environment dated between the 9th and 8th BC: this is the paleo-mouth of the Tiber. (ii) The base of the harbour sequence is characterized by a facies of dark grey silty clay: this is a quiet area in connection with both the river and the sea. It starts at the earliest in the middle of the 4th c. BC (360 BC) and is attested until no later than the end of the 3rd c. BC (205 BC). At that time the depth of the basin reached 6m below roman sea level. This unusual depth is very significant for the time and implies that seagoing vessels could access the basin. (iii) The summit of the harbour sequence is marked by yellow sands brought by floods of the Tiber. The protective role of the basin decreases between 165 BC and 5 AD and depth is no longer than 2.5m under the ancient marine zero. Most seagoing ships cannot access it anymore. (iv) The basin loses its function at the beginning of the imperial period because its depth was only 60 cm between 45BC and 25 AD and about 30cm between 80 and 230 AD.

Title: Archaeology and Geomagnetism: Investigating the Earth's Magnetic Field in Italy during the Neolithic Period. New Data from the Portonovo Archaeological Site (Marche, Italy)

Presenter/First Author: Evdokia Tema, University of Turin, Torino,

Presenter/First Author Email: evdokia.tema@unito.it

Co-authors: Enzo Ferrara, Istituto Nazionale di Ricerca Metrologica, Torino, Italy; Pierre C Camps, CNRS &University Montpellier 2, Montpellier, France; Cecilia Conati Barbaro, Sapienza Università di Roma, Roma, Italy; Simone Spatafora, Istituto Nazionale di Ricerca Metrologica, Torino, Italy; Thierry Poidras, CNRS &University Montpellier 2, Montpellier, France

Abstract Body: Archaeomagnetic data from ancient baked clays is a precious source of information about the past variations of the Earth's magnetic field. Thanks to archaeomagnetic records from well dated archaeological artefacts it is possible to reconstruct the geomagnetic field variations in the past and better understand its behaviour. On the other hand, once a detailed secular variation path is established for a certain area, reliable archaeomagnetic dating is possible. In order to enrich the Italian reference database and extend it back in time, we present here the results of an archaeomagnetic study carried out on three Neolithic ovens excavated at the archaeological site of Portonovo (Marche, Italy). The discovered structures are a rare example of well preserved domed ovens from the Early Neolithic period, dated based on archaeological information and radiocarbon dating. Standard thermal demagnetization procedures were used to determine the archaeomagnetic direction registered by each oven during its last firing and their archaeointensity was determined with the multi-specimen procedure (MSP-DSC). Both directional and intensity results are of high quality and they clearly show an intensity low during the Neolithic period. These new results, that are the first full geomagnetic field vector data available for this period in Italy, have been compared with other contemporaneous data from Europe and with global geomagnetic field models. Independent archaeomagnetic dating of the three ovens has been also performed using the SCHA.DIF.8k model. The obtained results are in excellent agreement with the radiocarbon dates, confirming that all ovens belong to the Neolithic period and were almost contemporaneously used. The new results importantly enrich our knowledge of the geomagnetic field during the Neolithic period that is poorly covered by data, not only in Italy but in the whole Europe and show that archaeomagnetic dating can provide accurate results even for prehistoric periods.

Title: Geochemistry of Ancestral Mi'kmaw Ceramics from Southern Mainland Nova Scotia: Constraints on Pottery Pathways

Presenter/First Author: J. Victor Owen, Saint Mary's University, Halifax,

Presenter/First Author Email: victor.owen@smu.ca

Co-authors: John D. Greenough, University of British Columbia, Okanagan, Kelowna , BC, BC, Canada; Megan Himmelman, , , ; Stephen Powell, , ,

Published Material: full-length paper was submitted to Geoarchaeology in Oct. 2014. It is still in review.

Abstract Body: The mineralogy and bulk chemical compositions of 33 potsherds (14 shell-tempered, 19 grit-tempered) and local sediments (sand and clay, where present) from six ancestral Mi'kmaw sites across southern mainland Nova Scotia were determined, and are compared to samples from a long-used aboriginal site near Pinkey's Point at the mouth of Bear River (BdDk-1), in the Annapolis Basin. Mineralogical criteria link several of the sherds to local raw materials (e.g., grit); biotite has the same range of X_{Mg} values, and monazite similar Ce:Nd:La ratios, as the same minerals in nearby Devonian granitoid rocks, and rare garnets have morphologies and compositions consistent with those found in these granitoid rocks and their metasedimentary host rocks. The presence of biotite granodiorite clasts (and their mineralogical constituents) in the grit-tempered potsherds from the sites described here link this pottery to the Bear River/Annapolis Basin area. This inference is supported by multidimensional scaling (MDS) of the bulk compositional data for the sample suite. Shell-tempered samples, however, lack the granodiorite clasts that largely control the trace element signature of the grit-tempered samples, so they are geochemically distinct even where evaluated exclusive of shell components (Ca, Sr). Although we cannot discount an Annapolis Basin origin for them, geochemically, this linkage remains tenuous. We postulate that granodiorite-tempered pottery from the Annapolis Basin was distributed to other sites in the province via navigable waterways, including the the Mersey River corridor southeast to the Atlantic coast, and the Annapolis River to the northeast.

Title: The Challenges of Research at Varying Geological Spatial Scales for the Geoarchaeological Study of Prehistoric Stone Tool Quarry Sources

Presenter/First Author: Adrian Burke, University of Montreal, ,

Presenter/First Author Email: adrian.burke@umontreal.ca

Published Material: Some archaeological and geological examples used in the presentation have been published or are in press. Other examples represent new data from other ongoing research projects. The paper is an overview of our long term research approach and program.

Abstract Body: It is commonplace for geologists to work at various spatial and time scales. The geoarchaeologist must add to this research the variable scales at which humans interact with each other and the environment. This represents an added level of complexity in the analysis, description and interpretation of geoarchaeological data. This paper focuses on the lithic raw materials that humans and their ancestors have used for more than 2 million years to manufacture cutting and scraping tools. The material to make these tools is not geologically ubiquitous, being primarily limited to highly siliceous, conchoidal rocks like cherts, flints, quartzites, rhyolites, and obsidian. Hunter-gatherers, and later settled agriculturalists, used many different geological sources both in primary bedrock and secondary surficial settings. On any given prehistoric site in North America it is common to find lithic raw materials that come from the area surrounding a site, from a regional setting (<100 km) and from further afield, sometimes over 1000 km distant. Some of these materials were obtained by going directly to a bedrock source and extracting the material at a quarry, while other materials were obtained through trade with neighboring groups. It is therefore imperative that the archaeologist know with precision where the materials come from in order to reconstruct past patterns of group movement in a territory, and also to understand the interaction between groups through trade. In this paper I present examples from aboriginal sites in northeastern North America dating from the earliest Paleoindian occupations to the time of European contact to demonstrate how the geoarchaeologist must continually adjust the scale of analysis depending on the time period, the culture studied, or simply the lithic material and its specific technological qualities. This has significant impacts on geoarchaeological fieldwork, sampling, and subsequent geochemical analyses.

First Author Student?: No

Co-authors: Carl-Georg Bank, University of Toronto, Toronto, ON, Canada

Abstract Body: The Bestwood Valley, an archaeological complex located near the town of Kathu, South Africa, covers an area of about 700 by 1200 m and is dated to the Early Stone Age based on the type varieties of local handaxes, blades, and other lithic tools. The valley consists of ironstone hills of cobble sized clasts (many of which are the archaeological artefacts) grading into a flatter area of red siliceous sands blown in from the Kalahari desert. Our study attempts to compare different geophysical data sets, and depth from two ground-truthing excavations, collected in summer 2014. Analysis of a dozen 500 m long GPR lines across the valley give a good sense of sand thickness in the northern part of the valley; the sand becomes too thick in the southern part to produce radar reflections. Seismic refraction data were collected using 4.5 Hz vertical geophones on two crossing 100 m lines and show clear first arrivals. A magnetic walking survey shows very large (>1000 nT) variations in total field amplitude over short (10s of meters) distances near the edges of the sand fill, these variations become less pronounced towards the center of the valley. We are currently working on determining how signatures of the three different methods may relate to the sand thickness, and how the magnetic

amplitude and wavelength may be used in areas where GPR becomes ineffective.

Title: Mapping historic charcoal production fields from excavation to landscape scale

Presenter: Thomas A Raab, BTU Cottbus, Cottbus,

Presenter Email: raab@tu-cottbus.de

First Author: Anna Schneider, Brandenburg Technical University Cottbus, Cottbus,

First Author Email: schneida@tu-cottbus.de

First Author Student?: No

Co-authors: Melanie Takla, Brandenburg University of Technology Cottbus–Senftenberg, Cottbus, Germany; Alexandra Raab, Brandenburg University of Technology, Cottbus, Germany; Florian Hirsch, BTU Cottbus, Cottbus, Germany; Horst Rösler, Brandenburgisches Landesamt für Denkmalpflege und Archäologisches Landesmuseum, Zossen, Germany

Published Material: Parts of the presented findings were presented in other scientific meetings and were recently published in journal articles: - Methods and results of manual mapping of kiln sites are described in Raab, A., Takla, M., Raab, T., Nicolay, A., Schneider, A., Rösler, H., Heußner, K.U., Bönisch, E., 2015. Pre-industrial charcoal production in Lower Lusatia (Brandenburg, Germany): Detection and evaluation of a large charcoal-burning field by combining archaeological studies, GIS-based analyses of shaded-relief maps and dendrochronological age determination. Quaternary International, doi: 10.1016/j.quaint.2014.09.041.- The automatic mapping method is described in a (technical) paper in Schneider, A., Takla, M., Nicolay, A., Raab, A., Raab, T., in press. A template matching approach combining morphometric parameters for automated mapping of charcoal kiln sites. Archaeological Prospection. doi: 10.1002/arp.1497.In addition to this material, we will present recent and unpublished results of archaeological excavations, the application of the automated mapping routine, and of microdrone-based aerial photography.

Abstract Body: In the forefield of the open-cast mine Jänschwalde (north of Cottbus, Germany), archaeological excavations have revealed one of the largest charcoal production fields described so far. As remains of the historic charcoal kilns, small mounds of sediment rich in charcoal fragments and ash cover the soil surface. We applied a combination of methods for mapping such kiln relicts across a range of scales, in order to analyze the spatial distribution of kiln sites and to improve the understanding of historic forest use systems.

In archaeological excavations in the mine forefield, the geometry of kiln relicts could be studied in high detail. We used a microdrone to record high-resolution photographs of excavation sites for the documentation of kiln site ground plans and other traces of historic land use. Based on airborne laser scanning elevation models, kiln site mapping was extended to areas beyond the mine forefield. Manual digitization from shaded relief maps was used for mapping kiln sites in further woodland areas surrounding an historic ironwork north of Cottbus. An automated mapping approach based on template matching was developed to detect charcoal production fields on a larger scale, and was applied for an area of about 1000 km^{2}up to now.

In archaeological excavations, about 900 kiln sites have been documented on an approximately 17 km^2 large area. Excavation documentations and aerial photographs show variations in the kiln site ground plans. By manual digitization from Shaded Relief Maps, more than 5000 kiln sites with diameters up to 29 m were detected in the 32 km^2 area of the royal forest Jänschwalder Heide north of Cottbus. First results of mapping for larger areas indicate similar densities, but smaller diameters of kiln sites in other charcoal production fields; and show that charcoal production is a so far underestimated component of the land use history in many areas in the Northern European Lowlands.

Title: Constraints on the Geochemical Provenance of Refined Copper and Brass Artifacts from the Gaspereau Lake Area, King's County, Nova Scotia: Insights into the Metallurgical and Trace Element Systematics of European Contact-era Trade Alloys

Presenter/First Author: Jacob J Hanley, Saint Mary's University, Halifax, NS

Presenter/First Author Email: jacob.hanley@smu.ca

Co-authors: Glen Hodge, , , ; Catherine Cottreau-Robins, Nova Scotia Museum, Halifax, NS, Canada; Christopher RM McFarlane, University of New Brunswick, Fredericton, NB, Canada; Graham D Layne, Memorial University of Newfoundland, St John's, NF, Canada; W. Bruce Stewart, Cultural Resource Management Group Ltd., Halifax, NS, Canada; Mike Sanders, Cultural Resource Management Group Ltd., Halifax, NS, Canada

Abstract Body: During the 16th and 17th centuries, copper and copper alloys were key trade materials with considerable spiritual and functional significance to indigenous peoples. A collection of 9 copper-based archaeological artifacts from the Gaspereau Lake area of Kings County, Nova Scotia were analyzed by a variety of microanalytical methods in order to constrain the European origin of the contained metals, providing insight into the timing and nature of trade activities between the indigenous peoples of the Atlantic Northeast and European explorers/settlers, and geographic constraints on ore sources for the production of the metal alloys.

The artifacts range in composition from pure (refined) copper to gilding metal, bronze, and a variety of brass alloys. Refined copper coinage of known European provenance (Sweden, Spanish Netherlands, England, Hungary) and age (spanning a ~300 year period) were characterized by SEM-EDS to provide a reference provenance data set for the range of bulk and "speiss" inclusions (contaminant inclusions formed during smelting) expected in refined copper from the period bracketing European exploration of North America. The majority of speiss compositions ranged from single element (Pb) to complex alloy compositions (Pb-As-Sb-Fe-Sn-Ni-Ag). Similarities in speiss composition exist between Swedish and Spanish coinage (containing Cu sourced from Sweden) minted from 1560 to 1680 and three of the artifacts. Preliminary LA-ICPMS data indicate that Sb/As ratios in the artifacts may be used to differentiate Swedish from central European sources of Cu, owing to the presence or absence of specific sulfosalt minerals in the original mined ores. Preliminary Pb isotope data from the Pb-bearing speiss inclusions (by SIMS) shows that whereas ~pure Cu artifacts with minimal speiss contamination sit closer to compositional fields for the primary Swedish site of Cu production (Falun deposit, Great Copper Mountain), artifacts composed of brass alloys or heavily contaminated with Pb-rich speiss have Pb isotope compositions overlapping with the Central European sources in Poland and Germany, suggesting a non-Swedish source for Cu or Zn required for brass production, and/or Pb-bearing flux used during Cu smelting. The Pb isotope heterogeneity of the Falun deposit is also being evaluated.

Title: *From the source to the object : tracing the archaeological materials using LA-ICP-MS. The example of stone ornaments in the ancient societies.*

Presenter/First Author: Anne Baron, University of Montreal, Montreal,

Presenter/First Author Email: anne.baron@netcourrier.com

Co-authors: Bernard Gratuze, CNRS/Université d'Orléans, Orléans, France; Claude Chapdelaine, Université de Montréal, Montréal, QC, Canada

Published Material: Baron Anne 2011, title of oral communication*: Exploitation des roches noires à l'âge du Fer : vers une restitution des systèmes de production et de diffusion;* Proceedings of the International Colloquium Production-Distribution-Economy. Settlement and economic processes in the La Tène period, 28-30 oct. 2011, Nonnweiler (Saar) , *Universitätsforschungen zur prähistorischen Archäologie*, Baron Anne 2012: Provenance et circulation des objets en roches noires (« lignite ») à l'âge du Fer en Europe celtique (VIII^{ème}-I^{er} s. av. J.-C.), British Archaeological Report, Oxford, 589 p.

Abstract Body: Ancient societies used various natural resources to make many artefacts (ornaments, tools, weapons), especially lithic resources. Current research is mainly dedicated to the study of chipped stone tools such as flint or obsidian, but the study of other kinds of rocks is less developed. We focus here on the case of "soft" rocks (such as black shale, soapstone, serpentinite) used mainly to make ornaments. The study of these rocks constitutes a real scientific challenge: i) from an archaeological point of view, the geological sources and the distribution away from these sources of the artefacts is unknown, consequently this poses a difficulty in reconstructing ancient economic or cultural exchange networks; ii) from an analytical point of view, these materials are difficult to characterize due to their heterogeneity. The lack of systematic characterization studies has impeded the construction of relevant reference data and therefore to establish precise relationships between the archaeological objects and the geological resources exploited. Consequently, interdisciplinary research is essential because raw material characterization forms the basis of any provenance study. However, the destruction of archaeological objects constitutes a major limiting factor. The use of Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS) which allows to carry out nearly invisible micro samplings was chosen as it presents several advantages. Its application to stone artefacts has provided promising results. Two examples of two kinds of "soft" rocks will be presented in order to show the relevance of this method and the results obtained: i) on ornaments made of black shales by the Celts of Europe (8th to 1st century B.C.) and ii) on soapstone beads made by the Iroquoians of the Saint Lawrence Valley in Quebec (15th & 16th centuries).

Title: X-ray microfluorescence, microradiography and tomodensitometry provide a broader view of the archaeological space.

Presenter/First Author: Geneviève Treyvaud, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Varennes,

Presenter/First Author Email: Genevieve.Treyvaud@ete.inrs.ca

Co-authors: Pierre Francus, Inst Nat Recherche Sci, Québec, QC, Canada

Abstract Body: Archaeologist faces multiple pressing questions while being in the field. What is the composition of the different soil layers and what are their laterals extend? What modifications have been made by human occupation? Is it possible to measure, identify and characterize this space in order to evaluate the potential of the archaeological site? The Itrax core scanner allows acquiring geochemical data and high-resolution radiographs from sediment without loos or destruction of material to be analysed. This instrument rapidly and continuously conducts the analysis of sediment samples, such as half cores or u-channels, allowing to retrieve geochemical profiles variations and to visualize the presence of archaeological material. Tomodensitometry (CT-scanning) is a process which uses X-ray equipment to produce three-dimensional representations of components both externally and internally with a sub millimeter resolution. Thanks to it non-destructive nature, its high precision and its speed, medical CT-scans allows to capture in 3 D the deposits architecture of sediment bodies and archaeological artefacts. Applications of these high precision instruments are numerous and various in Archaeology: chemical and physical characterization of archaeological deposits, study of *chaînes opératoires*, characterization and identification of the archaeological collection, bio-anthropology, zooarcheology et dendrochronology.

Title: Geochemical fingerprints of paleo-environmental changes and paleo-pollution in the sedimentary archives of the Roman harbor of Ephesus (Turkey)

Presenter/First Author: Hugo Delile, Université Lumière Lyon 2, CNRS UMR 5600, 69676 Bron, France, Lyon,

Presenter/First Author Email: hdelile@gmail.com

Published Material: Delile, H., Blichert-Toft, J., Goiran, J.-P., Stock, F., Arnaud-Godet, F., Bravard, J.-P., Brückner, H., & Albarède, F. (2015). Demise of a harbor: A geochemical chronicle from Ephesus. Journal of Archaeological Science, 53, 202–213.

Abstract Body: At the end of the 1st c. BC, Ephesus became the Roman capital of Asia Minor and the most important commercial, religious, and cultural center of the area. To shed light on the paleo-environmental evolution of the harbor, including potential anthropogenic fluxes, we measured major and trace element concentrations, including heavy metals, Pb isotope compositions, and ^{14}C ages of ancient harbor sediments from a 12 m long sediment core drilled in the Roman basin of Ephesus. Using these data together with sedimentological data, grain size distribution analysis, and Principal Component and Factor Analyses, we reconstituted the paleo-environment of the harbor basin.

We ascribe observed shifts in the geochemical and sedimentological parameters to the deltaic progradation of the Cayster River (Küçük Menderes) towards the west. A single major disruptive event located at 550 cm core depth (1st BC/AD) significantly affected the ventilation of the harbor water body resulting is oxygen deficit (anoxia). It appears that either passage of the river mouth to the west of the harbor basin or avulsion of the river towards the north was responsible for this abrupt environmental change.

While concentrations of metallic trace elements are well correlated with the oxygenation conditions of the harbor water body throughout the core, the Pb isotope compositions of leachates and residual fractions attest to possible anthropogenic influx in only the uppermost part of the core. The geologically and geochemically informed parameters T_{mod}-µ-κ (derived from the time-integrated measured Pb isotope compositions) are exogenous to the Eastern Mediterranean basement (Pb age-depth model >200 Ma). Searching our European and Circum-Mediterranean Pb isotope database (>6800 samples) we find that Pb ores used at Ephesus during the late Middle Ages came from Western Europe (France, Germany, England) consistent with archeological and historical data indicating that at that time the main active European mines were those of Germany and England.

Title: Rock-Magnetic Proxies of Dredging and Flood Events in Portus, the Ancient Harbor of Imperial Rome

Presenter/First Author: Agathe Lisé-Pronovost, La Trobe University, Fitzroy,

Presenter/First Author Email: a.lise-pronovost@latrobe.edu.au

Co-authors: Guillaume St-Onge, University of Quebec at Rimouski UQAR, Rimouski, QC, Canada; Andy IR Herries, La Trobe University, Bindoore, VIC, Australia; David Heslop, Australian National University, Canberra, Australia; Ferréol Salomon, University of Southampton, Southampton, United Kingdom; Jean Philippe Goiran, CNRS, Lyon, France

Published Material: Part of it was presented at the Casthe meeting 2014.

Abstract Body: Exceptionally high average accumulation rates (up to 1 cm/a) were recently reported in the ancient harbor of Rome, Portus, which was constructed on the Tiber delta (Tyrrhenian Sea) during the first century AD and filled with fine sediments during the first millennium AD. With such rapid harbor infill, Romans had to dredge sediments to allow passage. Dredging complicates the work of geoarchaeologists by introducing chronostratigraphic hiatuses and reworked sediments that are not readily identifiable in extruded sediment cores. Here we present high-resolution physical, rock-magnetic and paleomagnetic data from an undisturbed piston core in order to better constrain the chronostratigraphy of Portus.

Core CPS-1 contains ca. 4 m of harbor sediment and was recovered in the *canale Traverso*, an artificial paleochannel that linked the Tiber River to the harbor. High-resolution analyses were performed, including CT scanning, high-resolution digital imaging, density measurement by gamma ray attenuation, spectrophotometry, magnetic susceptibility, hysteresis properties, natural, anhysteretic and isothermal remanent magnetizations. The CT scans, digital images and data reveal a dredging scar within laminated harbor mud and overlaid by 0.8 m of reworked sediment. A hyperpycnal flow deposit (0.6 m) was also identified using magnetic susceptibility, paleomagnetic inclination and ferrimagnetic grain size and coercivity indicators. The rock-magnetic signature of these dredging and flood events contrast with the background harbor sediment, which is dominated by low coercivity magnetic minerals, stable natural remanent magnetizations and inclinations varying around the expected geocentric axial dipole, suggesting a genuine geomagnetic signal. The precise identification of an event-corrected harbor sequence combined with high-precision radiocarbon dating and possible paleomagnetic dating are useful to better constrain the chronostratigraphy at Portus and highlight the potential of rock-magnetism and paleomagnetism for geoarchaeology.

Title: Timinig of Volcanism and initiation of rifting in Omo-Turkana Depression southwestern Ethiopia: Evidence from Paleomagnetism

Presenter/First Author: Asfaw Erbello, Adama Science and Technology University, Adama,

Presenter/First Author Email: asfawmesi@gmail.com

Co-authors: Tesfaye Kidane, Addis Ababa University, Addis Ababa, Ethiopia; Francis Harold Brown, University of Utah, Salt Lake City, UT

Abstract Body: This Paleomagnetic study was carried out on Gombe Group basalts from the lower Omo Valley in southwestern Ethiopia. The objective of the study is to narrow a wide ranged previous geochronological data about timing of volcanism and initiation of rifting in the area. 80 oriented core samples were taken from nine sites. Pilot specimens were subjected to alternating field (AF), thermal demagnetization (TH) and acquisition experiments. The Natural Remnant Magnetization (NRM) direction comprises two vector components in most samples. The first component of magnetization was easily erased at 5 to 25mT AF and 120°C to 250°C TH demagnetization. A step wise increasing application of magnetic field to selected specimens revealed a saturation magnetization at about 300°C. The magnetization curve results from the acquisition experiment together with TH demagnetization of the same specimens and AF demagnetization results indicates that titanomagnetite is the dominant magnetic carrier. About 50% of magnetization is removed between Temperature ranges of 250^{0}C and 430^{0}C suggesting that pseudo single domains as a primary carrier of magnetic remanence. From total sites, six sites show reversed polarity and two sites show normal polarity. The normal and reversed polarities are antipodal to one another. The overall mean direction for reversed polarity is (D_S=186.1, I_S=-1.9,K_S=38.8, α_{95}=10.9) where as the remaining two sites with normal polarity yield (D_S=348.4, I_S=4.6, K=378.9, α_{95}=12.9).By using the available upper age control of Moiti tuff and Naibar tuff which have never been noted to be intruded by the Gombe Group basalts; Gombe basalts are correlable with the late Gilbert Chron of Cande and Kent (1995). Comparison of this result with the petrographically and geochemically similar basalts (Haileab *et al.,* 2004) in northern Kenya reflects the same polarity. Paleomagnetic data presented in this paper and previous age data results indicates, Gombe Group basalts in southwestern Ethiopia and Northern Kenya erupted during a short period geological time between 4.18Ma and 4.02Ma.Recent paleomagnetic study (Kidane, 2014) of sediments from the base of the rift is also similar with Gombe Group. This suggests that the present architecture of the basin might have been attained soon after the emplacement of the Gombe Group basalt.

Title: Mapping Petroleum Migration Pathways Using Magnetics

Presenter/First Author: Rabiu Abubakar, Imperial College London, London,

Presenter/First Author Email: r.abubakar09@imperial.ac.uk

Co-authors: Mark A Sephton, Imperial College London, London, United Kingdom; Alastair Fraser, Imperial College London, London, United Kingdom; Jonathan S. Watson, Imperial College London, London, United Kingdom; Trevor Almeida, , London, United Kingdom; Paul Southern, University College London, London, United Kingdom

Abstract Body: We report the formation of magnetic minerals in petroleum reservoirs. Eleven wells from Wessex- Basin in Dorset, southern England, were sampled from the British Geological Core Store, across the main reservoir unit; Bridport Sandstone and the overlying Inferior Oolite, which forms the caprock. Sampling was carried out based on physical evidence of oil stain and a high magnetic susceptibility reading. The samples were chemically extracted to determine which were naturally stained with hydrocarbon and which were not. Magnetic analysis was carried out on all the samples: this including hysteresis analysis at low temperatures (5-15K) and room temperature, and low-temperature thermogmagentic analysis. The results indicated a marked increase both in abundance and strength of magnetic materials in samples found to be stained by hydrocarbon.

Title: Palaeomagnetic Analysis on Late Bronze Age Pottery from Santorini: New Data from the Akrotiri Excavation and Estimation of the Deposition Temperatures of the Minoan Pyroclastic Products.

Presenter/First Author: Evdokia Tema, University of Turin, Torino,

Presenter/First Author Email: evdokia.tema@unito.it

Co-authors: Elena Zanella, University of Torin, Torino, Italy; Fco Javier Pavon-Carrasco, Istituto Nazionale di Geofisica e Vulcanologia, Roma, Italy; Despoina Kontopoulou, , Thessaloniki, Greece; Spyros Pavlides, , ,

Published Material: The results presented here have been submitted for publication in Geophysical Journal International and the submitted paper, entitled: " Palaeomagnetic analysis on pottery as indicator for the pyroclastic flow deposits temperature: New data and statistical interpretation from the Minoan eruption of Santorini, Greece" by Tema et al. is currently under review.

Abstract Body: Palaeomagnetic analysis on Late Bronze Age pottery from Santorini was carried out in order to estimate the thermal effect of the Minoan eruption on the pre-Minoan habitation level. Carefully selected pottery fragments found on the surface of the pre-Minoan palaeosol and covered by the first pyroclastic products of the Minoan eruption have been collected and studied. Samples come from five sites situated at the central and south part of the island while for the first time palaeomagnetic results on ceramic fragments from the Akrotiri archaeological site are presented. Stepwise thermal demagnetizations reveal that most of the samples carry a two-component remanent magnetization. The deposition temperatures of the first pyroclastic products have been estimated by the maximum overlap of the re-heating temperature intervals given by the individual fragments at site level. A new statistical elaboration of the temperature data has also been proposed, calculating at 95% of probability the re-heating temperatures at each site. The obtained results show that the precursor tephra layer and the first pumice fall of the eruption were hot enough to re-heat the underlying ceramics at temperatures between 160 and 230 ^{o}C in the non inhabited sites while the temperatures recorded inside the Akrotiri village are slightly lower, varying from 130 to 200 ^{o}C. The decrease of the temperatures registered in the human settlements suggests that there was some interaction between the buildings and the pumice fallout deposits while the buildings debris layer caused by the preceding and syn-eruption earthquakes has probably also contributed to the decrease of the temperatures experienced by the ceramics.

Title: Paleomagnetic Dating of the Genesis of the Early Cretaceous Aliva Zn-Pb Ore Deposit, Northern Spain

Presenter/First Author: David T A Symons, University of Windsor, Windsor, ON

Presenter/First Author Email: dsymons@uwindsor.ca

Co-authors: Fernando Tornos, CSIC-INTA, Madrid, Spain; Kazuo Kawasaki, University of Toyama, Toyama, Japan; Francisco Velasco, , , ; Idoia Rosales, , ,

Published Material: paper submitted

Abstract Body: The Aliva Mississippi Valley-type (MVT) Zn-Pb deposit is hosted in strata of the 309±3Ma (Late Carboniferous) Picos de Europa limestone formation in the Picos de Europa Unit of the Cantabrian zone. Paleomagnetic analyses of 193 specimens from 23 sites in MVT mineralization and surrounding dolomite gives a characteristic remanent magnetization (ChRM) with a paleopole at 80.7°N, 268.1°E (A_{95} =5.3°) that resides mainly in magnetite-titanomagnetite with minor pyrrhotite. A negative fold test shows that the ChRM postdates Variscan orogenic deformation at >95% confidence and that the ore is not syngenetic or syndiagenetic. Plausible tectonic corrections indicate further that the Aliva MVT deposit: 1) resides in dolomitzed zones in olistoliths of the Picos de Europa limestone that slumped into the overlying 305±1Ma Lebena shale formation during Variscan orogenesis; 2) was formed epigenetically at 112±8 Ma (Early Cretaceous) as Iberia rotated away from Eurasia to open the Bay of Biscay, most likely from rift-related hydrothermal fluids ascending into Iberia's coastal margin; and, 3) was tilted 10°±3° downward to the north by N-S compression as Iberia collided with Eurasia during the Oligocene-Miocene Pyrenean Orogeny.

Title: Great Slave Lake Supergroup paleomagnetism:Local rotations, apparent polar wander, true polar wander, or anomalous geodynamo?

Presenter/First Author: XinXin Xu, Yale University, New Haven, CT

Presenter/First Author Email: xinxin.xu@yale.edu

Co-authors: David AD Evans, Yale University, New Haven, CT; Ross Nelson Mitchell, Yale University, New Haven, CT; Wouter Bleeker, Geological Survey of Canada, Ottawa, ON, Canada; Paul F Hoffman, Organization Not Listed, Washington, DC

Published Material: 20% Fall AGU 2013

Abstract Body: Previous paleomagnetic studies of Slave Craton, in northwestern Canada, revealed a sinuous apparent polar wander (APW) path referred to as the Coronation Loop, wherein paleomagnetic poles oscillate over 110° with ages ranging from ca. 1900 to 1850 Ma. We collected paleomagnetic samples across a broad region in the East Arm of Great Slave Lake (GSL), in order to determine if the rotations documented by the Coronation Loop are due to local structural anomalies, craton-scale tectonic motions or peculiar characteristics/behavior of the Orosirian geomagnetic field. Samples were collected at ~3m stratigraphic resolution over 700m of continuous homoclinal sections of the Tochatwi (red sandstone), Portage Inlet (mainly red siltstone), and Pearson (gray basalt) Formations. Paleomagnetic remanence commonly includes post-folding overprint signals of the Mackenzie Diabase (1270 Ma), which outcrops nearby, or the Hudsonian orogeny s.l. (1850-1750 Ma). We isolate a dual-polarity characteristic remanent magnetization (ChRM) direction that is generally shallow North or South in tilt-correct coordinates. Near the Portage Inlet / Pearson Formation contact, we sampled at several localities across folds that are likely related to movement on the McDonald fault at ca. 1850-1800 Ma; the ChRM passes the fold test at >99% statistical level. However, we observe ChRM declinations to vary by tens of degrees across the Christie Bay stratigraphy, even within homoclinal sections. This suggests that some of the previously recognized discordance of the GSL poles is due to APW, or perhaps geodynamo variations, as opposed to local structural rotations. If due to APW, whether it represents oscillatory true polar wander (as suggested by Mitchell et al., 2010, Precambrian Research) awaits similarly detailed paleomagnetic records from other cratons through this time period.

Title: Preliminary Magnetic Studies of the Helen Mine 'Kill Zone' Soils, Wawa, Ontario, Canada

Presenter/First Author: Maria T Cioppa, University of Windsor, Windsor, ON

Presenter/First Author Email: mcioppa@uwindsor.ca

Co-authors: Ayca Yurtseven Sandker, UNIVERSITY OF WINDSOR, Windsor, ON, Canada

Abstract Body: As part of a larger study on using magnetic properties to examine mining-related pollution in Canada, the present-day distribution of iron-oxides emitted from the closed Helen Mine iron sintering plant near Wawa (Ontario, Canada) has been investigated. In this area, the vegetation cover has been severely disturbed, thus providing an excellent setting to investigate variations in magnetic properties. A total of 50 sites were sampled on cross-sections perpendicular (X-X') and parallel (Y-Y') to the dominant wind direction in order to investigate magnetic properties as a function of both wind direction and distance from the source. The *in-situ* surficial magnetic susceptibility (measured using a Bartington MS2D) decreased away from the source. Remanence and hysteresis measurements (2G Cryogenic Magnetometer, Magnetic Measurements VFTB) suggest that the primary magnetic mineral was magnetite; however, a biplot of IRM_{-100mT}/SIRM vs ARM_{40mT}/SARM indicated minor greigite. The laboratory analysis also showed that the highest susceptibility was not observed at the surface but in the subsoil. Similarly, magnetic spherules were not observed in magnetic extracts from the topsoil samples (0-5cm) but samples from the subsoil (5-10cm) contained magnetic spherules (2μm-10μm). EDS analysis shows that the spherules contain high weight percentages of Fe (up to 85%) and O (up to 48%), with some samples showing minor concentrations of other elements (e.g. Al, Ti, Mg). The vertical distribution of magnetic spherules and susceptibility could be due to vertical migration or to post-mining soil development.

Title: Saddleback Basalt as a Terrestrial Analog to Highly Magnetized Martian Crustal Rocks

Presenter/First Author: Kathryn J Murdock, Univ. of Mass. Amherst, Beverly, MA

Presenter/First Author Email: kmurdock@stonehill.edu

Co-authors: Laurie L Brown, University of Massachusetts Amherst, Amherst, MA

Abstract Body: The magnetic anomalies detected from rocks located in Mars's southern hemisphere have led to extensive investigations into the mineral assemblage and crystal size of the apparent host rock -- basalt -- and the ancient magnetic field Mars had at 4Ga. The lack of a currently active field on Mars indicates that remanence is the source. Investigations are of two types: investigating the rocks themselves, with an hypothesis that a unique mineral assemblage and/or grain size within the rock allow for it to acquire and retain high magnetization, thus different than most terrestrial basalts; or investigating the original magnetic field on Mars which was able to magnetize basalts with strong and stable remanence. The main purpose of this study is to identify a variety of terrestrial basalts to determine if any have the magnetic properties necessary for high magnetization for long periods of time. Samples were taken from diverse locales including divergent plate boundaries, hot spots, continental volcanic complexes, and volcanic arcs. While the terrestrial samples shared similar geochemical characteristics with Martian samples, the magnetic properties were not comparable and did not have, and most likely not retain, high magnetization over billions of years. However, one flow within the Saddleback Basalt located in southern California has a fairly high magnetization for an Earth basalt and could be analogous to the highly magnetized Martian basalts. This is an interesting development due to the fact that currently the Saddleback Basalt is used to simulate the regolith on Mars for rover missions. NRM values for the Saddleback range from 0.1238 – 43.201 A/m with an average of 3.697 A/m. Hysteresis measurements indicate small PSD-sized grains. Magnetic susceptibility ranges from 0.151 to 5.77 x10^-2 with an average of 1.286x10^-2. The results of this study may indicate the Saddleback Basalt could be a better analog to Martian crustal rocks than previously thought.

Title: New Paleomagnetic Secular Variation records from various lakes on the Tibetan Plateau

Presenter/First Author: Torsten Haberzettl, Friedrich Schiller University of Jena, Jena,

Presenter/First Author Email: Torsten.Haberzettl@uni-jena.de

Co-authors: Karoline Henkel, Friedrich Schiller University of Jena, Jena, Germany; Thomas Kasper, Friedrich-Schiller-University, Jena, Germany; Junbo Wang, ITP Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China; Marieke Ahlborn, Friedrich Schiller University of Jena, Jena, Germany; Youliang Su, IGG Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China; Erwin Appel, University of Tübingen, Tübingen, Germany; Guillaume St-Onge, University of Quebec at Rimouski UQAR, Rimouski, QC, Canada; Joseph Stephen Stoner, Oregon State Univ, Corvallis, OR; Gerhard Daut, Friedrich Schiller University of Jena, Jena, Germany; Liping Zhu, ITP Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China; Roland Maeusbacher, Friedrich Schiller University of Jena, Jena, Germany

Abstract Body: To understand the dynamics of the paleo-geomagnetic field requires detailed observations around the globe. Suitable paleomagnetic records on the Tibetan Plateau (TP) and adjacent areas are, however, extremely scarce. Here, we derive paleomagnetic records from independently radiocarbon dated sediments from various lakes on the TP. Studied through alternating field demagnetization of u-channel samples, characteristic remanent magnetization (ChRM) directions document

similar inclination patterns in multiple sediment cores for the late Holocene. Comparisons to existing records from a varve dated sequence from the Makran Accretionary Wedge, Lakes Issyk-Kul and Baikal, and a stack record from East Asia reveal many similarities in inclination. This regional similarity demonstrates the high potential of inclination to compare records over the Tibetan Plateau and eventually date other Tibetan records stratigraphically. Paleomagnetic Secular Variation (PSV) similarities over such a large area (>3,000 km) might indicate a large-scale core dynamic origin rather than small scale processes like drift of the non-dipole field often associated with PSV records. In addition, a record covering the past 15.8 ka cal BP was derived from sediments from Tangra Yumco, a large lake on the southern-central Tibetan Plateau. This new record reveals many similarities to the inclination record from of Lake Baikal, which is the only record in the “vicinity” reaching that far back in time. In the near future, these studies will be extended by a new record from Taro Co (250 km west of Tangra Yumco) covering almost 30,000 years.

Title: 9000 years of archeomagnetic field intensity variations in the Middle East

Presenter/First Author: Yves Gallet, CNRS, Paris,

Presenter/First Author Email: gallet@ipgp.fr

Co-authors: Miquel Molist, SGR SAPPO, Prehistory Department, Universitat Autonoma de Barcelona, Barcelona, Spain; Agnes Genevey, CNRS / Université Pierre et Marie Curie, Paris, France; Erwan Thebault, LPG, UMR CNRS 6112, Université de Nantes, Nantes, France; Maxime Le Goff, Institut de Physique du Globe, Paris, France; Anna Gomez Bach, Universitat Autonoma de Barcelona, Barcelona, Spain; Xavier Clop, Universitat Autonoma de Barcelona, Barcelona, Spain; Beatrice Robert, , , ; Stanislava Akimova, , , ; Inga Nachasova, , ,

Abstract Body: Thanks to its rich archeological and historical heritage, the Middle East offers the possibility to travel back through the geomagnetic field history over most of the Holocene. Archeomagnetic studies conducted up to now were mainly focused on the Bronze and Iron Age archeological periods, allowing a better characterization of the regional geomagnetic field intensity behavior for the last 3 millennia BC. These studies have revealed significant field intensity variations, and in particular a series of intensity maxima between c. 2600 and 2500 BC, between c. 2300-2000 BC, around 1500 BC and at the very beginning of the first millennium BC. These studies have further shown that the beginning of the first millennium BC was most probably marked by the highest geomagnetic field intensity detected so far during the Holocene. Archeointensity data available for the pre-Bronze Age period remain scarce. However, several possibilities exist to sample archeological sites older than 3000 BC. This is particularly true for the 6th and 7th millennia BC, which saw the development of the Hassuna and Halaf cultures throughout the northern Mesopotamian region. We will mainly discuss our recent acquisition of new archeointensity results dated to between c. 7000 and c. 5000 BC from two Syrian archeological sites (Tell Halula and Tell Masaikh). These results were obtained from 225 pottery fragments using the Triaxe protocol, which takes into account both the thermoremanent magnetization anisotropy and cooling rate effects on intensity determinations. We will then report on a geomagnetic field intensity variation curve for the Middle East encompassing the past 9000 years, which makes it presently the longest known regional archeomagnetic intensity record.

Title: Building and Using Archeomagnetic Field Models

Presenter/First Author: Gauthier Hulot, Institut de Physique du Globe de Paris, Paris,

Presenter/First Author Email: gh@ipgp.fr

Co-authors: Alexis Licht, Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Université Paris Diderot, UMR 7154 CNRS/INSU, Paris, France; Yves Gallet, CNRS, Paris, France; Andrey Khokhlov, Russian Academy of Sciences, Moscow, Russia; Ilya Kalashnikov, Institute of Physics of the Earth, Russian Academy of Science, Moscow, Russia; Erwan Thebault, LPG, UMR CNRS 6112, Université de Nantes, Nantes, France

Published Material: Part of the talk will rely on previous work published in Licht, A., Hulot, G., Gallet, Y., Thébault, E., Ensembles of low degree archeomagnetic field models for the past three millennia, *Phys. Earth Planet. Int.*, 224, 38-67, 2013, doi :10.1016/j.pepi.2013.08.007

Abstract Body: Since the publication of the first global archeomagnetic field models in the late 1990s, considerable efforts have been made in collecting reliable archeomagnetic, volcanic and sedimentary data, assembling these data in documented compilations and producing improved global models of the geomagnetic field over part or most of the Holocene. These efforts have led to the publication of several families of models now used for quite a wide range of applications. How these models are being built, the way they are intended to be used and the issues encountered during the modeling process, however, can differ from one model to another. It is important for the community willing to use these models to be aware of these differences, in particular when using these models as input to test geophysical properties, or newly acquired data. In this talk, we will report on our own ongoing experience in building such models and discuss the advantages and limitations of the models currently available, as well as the way forward to further improve models.

Title: Exploring high latitude geomagnetic field behaviour in the northern hemisphere over the past four millennia

Presenter/First Author: Andreas Nilsson, University of Liverpool, Liverpool,

Presenter/First Author Email: andreas.nilsson@geol.lu.se

Co-authors: Richard T Holme, University of Liverpool, Liverpool, L69, United Kingdom; Mimi J Hill, University of Liverpool, Liverpool, L69, United Kingdom

Abstract Body: Geomagnetic field observations at the Earth’s surface provide a powerful probe of the dynamics of the top of the core, and ultimately of the whole geodynamo. Field reconstructions for the present day are characterised by the two pairs of intense high latitude flux patches at the core mantle boundary, which are approximately symmetric about the equator. These so-called *flux lobes* have remained relatively stationary over the past four centuries, which has been interpreted in terms of mantle control on the geodynamo. The recently published pfm9k family of models, based on palaeomagnetic data, suggests a more dynamic field behaviour on millennial times scales, predicting dominant westward drift of flux lobes over the past 4000 years. These models were intentionally smoothed in time (approximately averaged over 400 years) to address the large chronological uncertainties and also often low temporal resolution of the sedimentary palaeomagnetic dataset. Here we will investigate ways to increase the temporal resolution of the models with an emphasis on using selected high-resolution sediment records from mid to high latitudes in the northern hemisphere. The results are used to inform the robustness of the pfm9k model predictions and provide new insights into the millennial scale behaviour of the geomagnetic field.

Title: NZPSV1k and NZPSV10k: New Palaeosecular Variation Master Records for New Zealand – Applications for Dating and Field Modelling

Presenter/First Author: Gillian M Turner, Victoria University of Wellington, Wellington,

Presenter/First Author Email: gillian.turner@vuw.ac.nz

Co-authors: Gino de Gelder, Victoria University of Wellington, Wellington, New Zealand; Jamie D Howarth, GNS Science-Institute of Geological and Nuclear Sciences Ltd, Lower Hutt, New Zealand; Annika Greve, Victoria University of Wellington, Wellington, New Zealand; Rimpy Kinger, Victoria University of Wellington, Wellington, New Zealand; Ruth Corkill, , , ; Andreas Nilsson, University of Liverpool, Liverpool, United Kingdom; Sean Fitzsimons, University of Otago, Dunedin, New Zealand

Published Material: My presentation at the recent Dec 2014 AGU meeting, San Francisco included the raw data. The current presentation contains further analysis and the development of master records.

Abstract Body: We present new palaeosecular variation master records for New Zealand on both archaeological and Holocene timescales. These have been compiled using continuous data from the detrital remanent magnetization of lake sediment cores with high-resolution C-14 based chronology, and are constrained and calibrated using directions and absolute palaeointensities obtained from the thermoremanent magnetizations of archaeological materials and volcanic rocks. All data has been “migrated” to a standard geographical location (40°S, 175°E) using a virtual geomagnetic pole (VGP) transformation. By a reciprocal VGP process, the master records can be used to calculate accurate palaeosecular variation records for all locations within the New Zealand region. The new record improves upon and extends by a factor of five the existing 20 year-old record. The geomagnetic field alternates between active periods of high amplitude swings from 12000 to 8000 BP and over the past 4000 years, and a relatively inactive period from 8000 to 4000 BP. The current field (Dec = 21.5° E, Inc = - 65.4°, F = 55.4 mT at 40°S, 175°E) represents a rare steep and easterly extreme in direction, but is close to average in intensity. The palaeointensity record mirrors to some extent the variation of the virtual axial geomagnetic moment seen in the global dataset, but shows some notable differences. We investigate the use of the archaeomagnetic master record as a dating tool, and the effect of including the Holocene record in global spherical harmonic-based field models.

Title: Holocene Southern Atlantic Earth's Magnetic Field Variations

Presenter/First Author: Monika C Korte, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam,

Presenter/First Author Email: monika@gfz-potsdam.de

Co-authors: Ute Frank, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam, Germany; Norbert R Nowaczyk, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam, Germany; Thomas Frederichs, University of Bremen, Bremen, Germany; Maxwell Christopher Brown, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam, Germany

Published Material: The new data have been presented at recent AGU and SEDI meetings. First, very preliminary modelling results using all the data have partly been presented at fall AGU 2014.

Abstract Body: Sediment records of past Earth's magnetic field resolving variations in the southern hemisphere during the Holocene are sparse to the present day. Spherical harmonic field models provide magnetic field component predictions for the whole globe, but might show too little or even unreliable spurious structure in the regions not constrained sufficiently by data.

We have carried out paleomagnetic investigations of sediment cores from six locations at southern hemisphere and equatorial latitudes to better constrain field variation shown by global models in particular in the southern Atlantic region. Lakes Chamo and Chew Bahir are located in Ethiopia. Marine records ODP 1078 and 1079 lie off the coast of Angola, GeoB6517-2 and ODP 1076D are located in the Congo Fan and M35003-4 is situated southeast of Grenada in the Tobago Basin. In addition to the paleomagnetic work all cores were subjected to a comprehensive set of rock magnetic measurements. Age-depth models based on radiocarbon dating were determined for the Ethiopian sites. For all the marine cores, published age-depth models were available from earlier climatic studies at these sites.

We include the new records in millennial scale global models of the CALSxk type. We discuss magnetic field variations in the southern Atlantic region as shown directly by the data and as described by new and previous models. We conclude that robust variation structures are emerging but some characteristics of records and models require further investigation. Even more new data are important to improve the reliability of global models regarding southern hemisphere field variations.

Title: Long-Term Character of Paleomagnetic Secular Variation from the Southern Hemisphere over the last Glacial Cycle – Evidence from ODP Leg 202- Chile Margin

Presenter/First Author: Steven Lund, University of Southern California, Los Angeles, CA

Presenter/First Author Email: slund@usc.edu

Abstract Body: Paleomagnetic secular variation (PSV) records from Sites 1233-1235, ODP Leg 202, Chile Margin (35°-40°S) provide a reproducible look at full-vector PSV variability (both intensity and directions) for the last 70,000 years. The paleointensity records correlate strongly with equatorial paleointensity records from Indonesia and mid-latitude Northern Hemisphere records from the Atlantic Ocean. But, beyond that, there are significant differences in the regional character of PSV in the various regions. Indonesia and the North Atlantic show a Laschamp excursion that is Class 1, characterized by out-of-phase millennial-scale cyclicity, while Chile sees a Laschamp Excursion that is Class II, characterized by in-phase directional variations and local full-polarity reversal. Indonesia and Chile see a Class 1 excursion in MIS 4 (~62, ka), but none is noted in the North Atlantic Ocean. PSV in Chile and the North Atlantic follows a distinctive decrease in amplitude for 30,000 years after the Laschamp Excursion; but it is not obvious that such is noted in Indonesia. These directional differences occur within a context of similar intensity variations. This spatial character should provide insight into the spatial-scale of coherent flux regeneration within the outer core.

Title: Attempting to Pierce the Metamorphic Veil in the Grenville Orogen of the Canadian Shield

Presenter/First Author: David J Dunlop, University of Toronto, Toronto, ON

Presenter/First Author Email: dunlop@physics.utoronto.ca

Abstract Body: The Grenville Province of the Canadian Precambrian Shield is a mélange of tectonic domains and terranes, containing Archean as well as Proterozoic rocks and assembled in a series of collisions with successive margins of the main Laurentian craton. The details of the accretionary events are obscured by the deep burial and consequent metamorphism of most presently exposed domains and terranes – the Grenvillian metamorphic veil. Post-metamorphic erosional uplift and cooling were extremely slow: cooling from 550ºC to 250ºC typically required 200-300 million years. Although it has proven extremely difficult to "see through" the Grenvillian orogeny to the magnetic record of pre-metamorphic events, partial thermoremanent magnetizations (pTRMs) acquired as different grain-size fractions of magnetite (and on occasion hematite) cooled through their blocking temperatures provide a record of post-metamorphic apparent polar wander (APW). Time calibration of this post-metamorphic Grenvillian APW path is provided by $^{40}Ar/^{39}Ar$ plateau ages of minerals like hornblende, actinolite, biotite, muscovite, plagioclase and K-feldspar with known closure temperatures to Ar diffusion and on occasion also by U/Pb ages of sphene. The partnership between isotopic thermochronology and paleomagnetism has been very successful in delineating the 1000-800 Ma APW of "Grenvillia" – and by implication the rest of Laurentia, since the accreted terranes were firmly welded to the craton prior to uplift. Despite quibbles about the details of the Grenvillian polar track, this part of the Laurentian APW path remains better documented than that of almost any other Precambrian time interval, younger or older. The multiple pTRM overprints are also amenable to determination of paleofield intensities (occasionally two paleointensities of different ages for a single rock), the main uncertainty being the correction to be applied for slow cooling in nature compared to that in laboratory heatings and coolings.

Title: Paleomagnetism and U-Pb Geochronology of the Western End of the Grenville Dyke Swarm: Rapid Changes in Paleomagnetic Field Direction at ca. 585 Ma Related to Polarity Reversals

Presenter/First Author: Henry C Halls, University of Toronto, Toronto, ON

Presenter/First Author Email: henry.halls@utoronto.ca

Co-authors: Alan Lovette, University of Toronto, Toronto, ON, Canada; Michael A Hamilton, University of Toronto, Toronto, ON, Canada

Published Material: A paper in the Journal *Precambrian Research* has just appeared on line. The paper is an invited one to present these findings.

Abstract Body: A paleomagnetic study of the western end of the ~585 Ma Grenville dyke swarm shows that individual dykes are characterized by high coercivity and unblocking temperature magnetizations that can differ in direction by as much as 90°. Field tests including baked contact studies and the continuity of paleomagnetic direction along dyke strike, suggest that the magnetizations are primary. Precise U-Pb baddeleyite dating on these dykes indicates that changes in magnetization direction of ~90° occur in less than 4 million years, and their close temporal association with reversals of the axial dipole field suggest that certain dykes are recording a paleo-equatorial dipole field as a transitional field between opposite polarity states. This equatorial field may be local and related to a core disturbance beneath the Sutton plume, the source of the dyke swarm. The documented instability in the Earth's field occurs less than 10 Myr before the first recorded appearance of macroscopic multi-cellular organisms on Earth, inviting speculation that an extended period of frequent magnetic reversals may play a part in faunal evolution.

Title: Ediacaran Paleomagnetism of Well-dated Units in Laurentia and West Avalonia: Implications for Models of Oscillatory True Polar Wander, Equatorial Dipoles and Rapid Continental Drift

Presenter/First Author: Kenneth L Buchan, Geological Survey of Canada Ottawa, Ottawa,

Presenter/First Author Email: kbuchan@nrcan.gc.ca

Co-authors: Michael A Hamilton, University of Toronto, Toronto, ON, Canada; Joseph P Hodych, Memorial University, St. John'S, NL, Canada

Abstract Body: Ediacaran paleomagnetic data from Laurentia are complex, with inclinations of presumed primary remanences that differ by up to 90° or more, often within single geological units. These unusual data have been variously interpreted as due to magnetic overprinting, very rapid continental drift, one or more episodes of oscillatory ~90° true polar wander (TPW), or unusual behaviour of the geomagnetic field such as an equatorial dipole. Here we review the Laurentia data in the 615-565 Ma period. The ages assigned to steep and normal components, if they are primary, appear to require at least two full oscillations during the period in question. There is growing evidence (especially from the Grenville and Rideau dyke swarms for which 9 precise U-Pb baddeleyite ages are now available) indicating that the magnetic directional changes are much too rapid to accommodate either rapid drift or TPW (using current theoretical models). In addition, the paleomagnetic data do not always conform to an equatorial dipole model in which paleopoles should differ by 90°. We also review the paleomagnetic data from well-dated (606-570 Ma) Ediacaran units of the West Avalonia microcontinent, which appear to be simpler than those from Laurentia. Unlike Laurentia units, individual units of West Avalonia usually carry a single presumed primary remanence direction (of dual polarity), rather than two discrete remanence directions or directions that are streaked along a great circle that might record rapid TPW. Large directional (mainly declination) changes *between* units are usually interpreted as due to block rotations, but alternatively could reflect TPW or unusual behaviour of the magnetic field. However, the corresponding paleopole changes are significantly less than the 90º expected for an equatorial dipole model. Taken together, the Ediacaran Laurentia and Avalonia data do not appear consistent with current models of oscillatory TPW, an equatorial dipole or unusually fast drift.

Title: The Nature of the Ediacaran to Early Cambrian Geomagnetic Field

Presenter/First Author: Richard K. Bono, University of Rochester, Rochester, NY

Presenter/First Author Email: rkbono@gmail.com

Co-authors: John Anthony Tarduno, University of Rochester, Rochester, NY

Abstract Body: A rotation of the entire solid Earth by 90°, in what has been called an inertial interchange true polar wander (IITPW) event, has been linked to the significant increase in biotic diversity during Ediacaran to early Cambrian (~635-530 Ma) times. Evidence for the IITPW event has been suggested by previously reported nearly orthogonal directions from the Sept-Îles (ca. 565 Ma) intrusion (Quebec, Canada) on the basis of whole rock analyses. We have demonstrated that only one direction (shallow) is carried by single domain magnetic grains and thus can be considered primary (Bono and Tarduno, Geology, 2015). Moreover, we find that the

geomagnetic field was reversing during cooling of the intrusion; the small spatial scales on which we see antipodal directions suggest a rapid reversal rate. New Total Thermoremanent Magnetization paleointensity experiments on single feldspar crystals from the Sept-Îles intrusion imply a very low field value, somewhat lower than values recorded by single feldspars from Jurassic basalts (Tarduno and Cottrell, JGR, 2005). The high geomagnetic reversal rate and low geomagnetic field intensity that characterize a portion of the Jurassic (ca. 165 Ma) may be an analog for field behavior during the Ediacaran to early Cambrian. We will discuss further paleointensity experiments aimed at testing this hypothesis.

Title: Paleomagnetism of Paleoproterozoic Rocks from Lofoten, Norway: Can They Provide a Baltica Pole for 1.8 Ga?

Presenter/First Author: Laurie L Brown, University of Massachusetts Amherst, Amherst, MA

Presenter/First Author Email: lbrown@geo.umass.edu

Co-authors: Suzanne A McEnroe, Norwegian University of Science and Technology, Trondheim, Norway

Published Material: 10% of the information (magnetic properties of the anorthosite samples) was published in a chapter of IAGA Special Sopron Book Series, Vol 1, in 2011.

Abstract Body: Paleoproterozoic rocks including paragneisses and AMCG suite rocks dominate the landscape in the southern Lofoten islands of Norway, sandwiched between the Scandinavian Caledonides to the east and offshore Mesozoic basins to the west. Published geochronology on the AMCG suite and the metamorphism of the gneisses they intrude range from 1.9 to 1.8 Ga, suggesting tectonic activity in this area was coincident with the formation of the supercontinent Columbia. Twenty-seven sites were drilled into these rocks from Moskenesøy and Flakstadøy to investigate their paleomagnetic character and possible determination of a Paleoproterozoic pole for Baltica. Magnetic susceptibility for all the 27 sites averages 6.95 x 10^{-2} SI, but only one site has a low susceptibility (5.4 x 10^{-4}); all other sites have susceptibilities greater than 1 x 10^{-2}. NRM values range from 0.5 A/m to 4.6 A/m, with an average of 2.0 A/m. Hysteresis properties of at least one sample per site indicate MD magnetite is the predominant oxide, but demagnetization studies show that a high coercivity phase is commonly present and is likely the source of the stable remanence. Both normal and reversed polarities, nearly antipodal, are observed, with a mean direction of I = -48.0° and D= 209.4° (α_{95} = 9.1°, N = 22) with a corresponding (inverted) paleopole at 47°N, 154°E. The paleolatitude from this study (61°) puts the current northwestern side of Baltica at high latitudes at this time, similar to published reconstructions for Columbia, although the Lofoten pole longitude is displaced some 65° from other Sveconorwegian poles.

Title: METAMORPHIC AND STRUCTURAL INSIGHT FROM INVESTIGATIONS OF ELUSIVE AEROMAGNETIC ANOMALIES WITHIN THE CANADIAN SHIELD

Presenter/First Author: Jeffrey Robert Webber, The University of Vermont, Burlington, VT

Presenter/First Author Email: jwebber@geo.umass.edu

Co-authors: Laurie L Brown, University of Massachusetts Amherst, Amherst, MA; Michael L Williams, University of Massachusetts, Amherst, MA

Published Material: Some of these findings have been publlished in Tectonophysics and were presented at NE GSA and GSA previously. However, new material is will be presented.

Abstract Body: The acquisition of aeromagnetic data across the Canadian shield lead to a renaissance of Precambrian geology, from which crustal scale structures and lithotectonic domains where defined, correlated, and placed within a plate-tectonic framework. However, many local aeromagnetic anomalies do not directly correlate to changes in mapped lithology and are often overlooked. We suggest that many anomalies may reflect aspects of the metamorphic and structural history of a region that may be used to gain insight into crustal processes beyond simple map correlations. An excellent location to investigate this relationship is the the Chipman domain of the Athabasca granulite terrane due to the occurrence of significant aeromagnetic anomalies across a relatively homogeneous tonalitic batholith. The western portion of the domain is defined by a large plateau of elevated total field intensity. Volumetrically minor mafic dikes, lozenges, and schlieren hosted by the 3.2 Ga tonalite occur throughout the domain and display significant variations in magnetic susceptibility with observed values in excess of 0.5 SI to below 0.0005 SI. Although low magnetic susceptibilities occur throughout the entire domain, elevated values are restricted to the west. Investigations of isothermal remanent magnetization acquisition curves and analytical petrology indicate that variations in the volume percent of magnetite are likely responsible for most of these anomalies. Furthermore, the occurrence of magnetite is likely a function of metamorphic reactions, some of which involve hydration / dehydration. Two-dimensional finite element modeling of aeromagnetic anomalies supports the characterization of six petrophysically distinct domains with representative magnetic susceptibilities. We suggest that the western and eastern portions of the Chipman domain experienced distinct metamorphic histories that are expressed by the regional aeromagnetic data. Further characterization and modeling of magnetite-producing and consuming reactions will enable the correlation of local petrophysical observations to larger scale interpretations.

Title: The geodynamo as recorded in Archean and Hadean zircons

Presenter/First Author: Rory Danielle Cottrell, University of Rochester, Rochester, NY

Presenter/First Author Email: rory.cottrell@rochester.edu

Co-authors: John Anthony Tarduno, University of Rochester, Rochester, NY; Richard K. Bono, University of Rochester, Rochester, NY

Abstract Body: Isotopic studies of nitrogen (Marty et al., Science, 2013) suggest a lack of the fractionation expected if the early atmosphere was eroded by the early, intense solar wind in the absence of magnetic shielding. Recent estimates of core thermal conductivity and mantle evolution modeling, however, question the presence of a geomagnetic field prior to ~3.5 Ga. To investigate this paradox, we are developing techniques to test the presence/absence of Hadean-Paleoarchean magnetic fields through measurement of zircons from the Jack Hills

metaconglomerate (Yilgarn Craton, Western Australia). Magnetic force microscopy shows the presence of single-domain magnetic inclusions within the zircons. An ultra-sensitive 3-component DC SQUID magnetometer (noise floor, 10^{-11} emu) that has been optimized for single silicate crystal studies is used for these experiments. We choose zircons with initial natural remanent magnetizations between 1-3 x 10^{-9} emu for analyses. These select samples have been handpicked from a sample crush, and examined with transmitted and reflected light microscopes to exclude specimens with visible cracks or large opaque inclusions. Thellier-Coe and total thermal remanent magnetization experiments using a CO_2 laser system have been designed to obtain paleointensity estimates while limiting potential laboratory-induced alteration. We employ a routine that stacks multiple orthogonal component magnetizations at each demagnetization step to reduce measurement noise. After paleointensity analysis, these samples are then analyzed with a Sensitive High Resolution Ion Microprobe (SHRIMP) to obtain age information. We will present data from our ongoing analyses, and discuss the potential of measuring even weaker samples using a SERF magnetometer, currently under development by the University of Rochester and TwinLeaf LCC.

Co-authors: Eleonora Regattieri, , , ; Giovanni Zanchetta, University of Pisa, Pisa, Italy; Ilaria Isola, INGV, Pisa, Italy; Luca Lanci, University of Urbino, Urbino, Italy

Abstract Body: Speleothems are considered excellent archives for the Earth's Magnetic Field changes in the past, as they are able to continuously record its variations, can be easily dated, and acquire a mostly "instantaneous" magnetic remanence at a high-resolution timescale. The latter ensures the possibility to detect short and/or high-frequency events, thus providing high-quality Paleosecular Variation (PSV) data. Unfortunately, the low magnetic intensities often characterizing speleothems limit their study. Here we present a paleomagnetic study performed on a flowstone from Rio Martino cave (Western Alps, Italy). U/Th dating of the flowstone indicates that its deposition started at the beginning of the Holocene. The flowstone is characterized by high magnetization intensity, due to the metaophiolites in the area, which provide the magnetic detrital input. The collected 60 cm-long core was cut in small slices, 3 mm-high, permitting a 60 yr time resolution. Magnetic measurements point at detrital magnetite as the remanence carrier. The Characteristic Remanent Magnetization (ChRM), isolated after stepwise AF demagnetizations, is well defined, with Maximum Angular Deviation (MAD) lower than 10°. Relative paleointensity was obtained by analysis of the Arai diagrams. Regression lines always provided a correlation coefficient lower than 0.850. Paleomagnetic directions and paleointensity data allow reconstruction of the PSV curves during the Holocene for the area. The results are compared to the Italian archaeomagnetic SV curve and to the regional and global geomagnetic field models. The comparison shows that the Rio Martino flowstone has faithfully recorded the Earth's Magnetic Field in the past. The obtained high resolution results, together with the high quality dating, provide promising data both for the detection of short time geomagnetic field variations and completion of past regional PSV curve, where well-dated data are scarce.

Co-authors: Yves Monette, University of Montreal, Montreal, QC, Canada

Abstract Body: New archeointensity data were obtained in Quebec from twelve groups of ceramic and brick fragments dated from the early 17th to late 19th century AD. These data were derived using the Triaxe magnetometer and a tailored experimental protocol. The results show a decrease in intensity in Quebec between the 17th and the early 18th century, followed by an increase until 1900. Similar variations are predicted in Quebec City by the gufm1 geomagnetic field models regardless of whether the calibration uses the assumption of a strong, low or null linear decrease of the dipole moment between 1600 and the mid-19th century AD. However, the amplitudes of the predicted variations appear lower than those displayed from the new data, the latter showing a marked minimum during the 18th century. These new results, together with previous data obtained in France and Brazil, argue in favor of an oscillatory behavior rather than a linear evolution of the dipole moment between 1600 and 1850.

Title: Holocene Paleomagnetic Secular Variation: What Relationships Between Mid and Polar Latitudes tell us About Geomagnetic Dynamics

Presenter/First Author: Joseph Stephen Stoner, Oregon State Univ, Corvallis, OR

Presenter/First Author Email: jstoner@coas.oregonstate.edu

Co-authors: Brendan T Reilly, Oregon State University, Corvallis, OR; Leah B Ziegler, Oregon State University, Corvallis, OR; Timothy Cook, , , ; Pierre Francus, Inst Nat Recherche Sci, Québec, QC, Canada; François Lapointe, Inst Nat Recherche Sci, Québec, QC, Canada; Mark B Abbott, University of Pittsburgh Pittsburgh Campus, Pittsburgh, PA; Nicholas L Balascio, Lamont - Doherty Earth Observatory, Palisades, NY; Raymond S Bradley, Univ Massachusetts, Amherst, MA

Published Material: As a synthesis, part of these results have been published, but the understanding that will be presented has not.

Abstract Body: Longitudinal comparisons of high quality, high resolution, and independently dated archeomagnetic and paleomagnetic secular variation (PSV) records from the NE Pacific (Alaska & Hawaii), North America, North Atlantic, and Europe during the Holocene show generally coherent multi-centennial to millennial scale variations of specific PSV parameters. These observations illuminate two primary alternating modes (although there are likely others), which we have called the European

mode (EM) and North American mode (NAM) because of their consistency with the late Holocene and historical time average field morphologies, respectively. Here we further explore how alternations between these modes compare with observations made at locations sensitive to the geomagnetic field derived from the Arctic tangent cylinder. High resolution paleomagnetic records obtained from a series of cores retrieved from two Ellesmere Island lakes (Sawtooth Lake, 79º21 N, 83º56 W and Lower Murray Lake, 81°34 N, 69°54 W) with varve based chronologies allow us to define regional PSV and paleointensity (PI) patterns for the last ~5 kyr. Although PSV and PI derived at these polar latitudes are both distinct from those observed at mid latitudes and prediction made from global field models, consistencies in timing suggest that these records are dynamically related. This duality is illustrated by variations in virtual geomagnetic pole (VGP) latitude, where those derived from polar latitude sites are both in phase and out of phase with those derived from mid latitude sites and global reconstructions. Axial VGP latitudes are observed during EM and NAM maximums, whereas mid latitude and global reconstructions show axial VGPs during NAM and maximum tilt during EM. It is also illustrated by patterns of PI where repeating progression of PI highs and lows are observed mid and polar latitudes. Together these define coherent oscillations showing that geomagnetic behavior in the tangent cylinder is distinct from, but influenced by, large scale oscillations in flux observed at mid latitudes.

Title: Late Pleistocene and Holocene Paleomagnetic Records from the Gulf of Alaska: Preliminary Results of IODP Expedition 341 Sites U1418 and U1419

Presenter/First Author: Julie Heggdal Velle, University of Quebec at Rimouski UQAR, Rimouski, QC

Presenter/First Author Email: julie.velle@uqar.ca

Co-authors: Guillaume St-Onge, University of Quebec at Rimouski UQAR, Rimouski, QC, Canada; Joseph Stephen Stoner, Oregon State Univ, Corvallis, OR; Matthias Forwick, University of Tromsø, Tromsø, Norway; Alan C Mix, Oregon State University, Corvallis, OR; Maureen H Davies, The Australian National University, Canberra, Australia

Abstract Body: During IODP Expedition 341 in the Gulf of Alaska, Sites U1418 and U1419 were drilled in the upper part of the Surveyor Fan and on the continental shelf edge, respectively. These Sites recovered exceptionally expanded records containing information on climatic, oceanographic, glacial, tectonic and geomagnetic field changes in the eastern North Pacific region over at least the last 60 kyr. As a first step in evaluating the potential of the sediments of Sites U1418 and U1419 to record a reliable relative paleointensity (RPI) signal, the shipboard natural remanent magnetization (NRM) at 20 mT was normalized by magnetic susceptibility and compared with the shipboard inclination record. At Site U1419, two intervals of low normalized intensity and reversed inclination were recovered with preliminary ages consistent with the Laschamp and Norwegian-Greenland Sea geomagnetic excursions at ~ 41 and ~ 61 ka, respectively. U-channel and discrete sample studies to verify these observations are ongoing. A first series of u-channels from Site U1418 were analyzed using stepwise alternating field demagnetization to further clarify the shipboard paleomagnetic observations. These data indicate that a strong, well-defined, single component magnetization with maximum angular deviation (MAD) values generally lower than 5^{o} is preserved. Moreover, alternating gradient force magnetometer analyses at Site U1418 imply that the sediments at the Site consist mainly of low coercivity minerals in the pseudo-single domain range. These preliminary results indicate that the Gulf of Alaska sediments preserve a promising high-resolution paleo-geomagnetic record. The shipboard data will be complimented by more detailed u-channel studies in order to establish a stratigraphic framework and investigate geomagnetic field dynamics during the Late Pleistocene and Holocene.

Title: A new archaeointensity dataset from the SW Pacific: implications for global geomagnetic field models

Presenter/First Author: Andreas Nilsson, University of Liverpool, Liverpool,

Presenter/First Author Email: andreas.nilsson@geol.lu.se

Co-authors: Mimi J Hill, University of Liverpool, Liverpool, L69, United Kingdom; Richard T Holme, University of Liverpool, Liverpool, L69, United Kingdom; Elliot Hurst, University of Liverpool, Liverpool, United Kingdom; Gillian M Turner, Victoria University of Wellington, Wellington, New Zealand; Peter Sheppard, University of Auckland, Auckland, New Zealand

Published Material: Preliminary archaeointensity results were presented at the AGU Fall Meeting in 2014.

Abstract Body: Palaeomagnetic data from the southern hemisphere are sparse, in particular absolute intensity data. To improve global geomagnetic field models and to answer key questions about the millennial scale behaviour of the geodynamo, more data are needed from this region. We present new archaeointensity data from a collection of ceramics from the SW Pacific Islands including Fiji, Tonga, Papua New Guinea, New Caledonia and Vanuatu covering the past 3000 years. The microwave method has predominantly been used with a variety of experimental protocols including IZZI and Coe variants. Standard Thellier archaeointensity experiments using the IZZI protocol have also been carried out on selected samples. The data are presented and compared to regional predictions from the recently published pfm9k family of geomagnetic field models. We explore the influence of the new data on constraining global geomagnetic field models and investigate possible analogies to the present field and the South Atlantic Anomaly. We discuss the physical implications as well as the robustness of these new results.

Title: Paleomagnetism in South East Australia from Archaeological Artefacts, Lava Flows and Lake Sediments

Presenter/First Author: Agathe Lisé-Pronovost, La Trobe University, Fitzroy,

Presenter/First Author Email: a.lise-pronovost@latrobe.edu.au

Co-authors: Andy IR Herries, La Trobe University, Bindoore, VIC, Australia

Published Material: Oral presentation at the 2014 Australian Archaeology Association meeting (Cairns, December 2014)

Abstract Body: Late Quaternary paleomagnetic data from the Southern Hemisphere is limited. One reason for this is because archaeological artefacts, lava flows and most high-resolution sedimentary sequences are found on and near the continents and islands, which represent only about one fourth of the Southern Hemisphere surface. The Australian continent is one of these regions and despite its long human occupation since ca. 50,000 cal BP and abundant materials likely suitable for archaeo- and paleomagnetic studies including fireplaces, heat retainers, heat treated stone tools, bricks, kilns, pottery, ovens, lake sediment and volcanic rocks, it remains poorly documented. Here we present archaeo- and paleomagnetic results derived from a variety of burnt archaeological artefacts (from ca. 25,000 to 15,000 cal BP and since 4000 cal BP), young

lava flows (ca. 35, 000 and 30,000 cal BP) and lake sediments (since ca. 250,000 cal BP) from south-east Australia. Standard procedures of alternating field and thermal demagnetization as well as Thellier-Coe archaeointensity determinations with partial thermoremanent magnetisation checks on selected lava flows and archaeological samples were performed at The Australian Archaeomagnetism Laboratory (TAAL). The results reveal generally strong and stable remanent magnetisation, often displaying single components that are ideal for palaeointensity determinations. Some of the archaeological materials also display complex heating histories informing on the formation, firing conditions and usage of the campfires. This was further investigated with experimental cobbles and clay balls heat retainers in order to document the magnetic remanence acquisition under different firing conditions. The new paleomagnetic direction and intensity data from southeast Australia are compared with global reference curves, geomagnetic field models and the nearest available records. Altogether the results highlight the great potential of archaeo- and paleomagnetic research in Australia for better understanding past behaviour of the Earth's magnetic field in the Southern Hemisphere and for building the first Australian Archaeomagnetic Dating Reference Curve.

Title: Recording and dating geomagnetic reversals, events and excusrions in palaeokarst and pseudokarstic deposits from southern Africa and Australia

Presenter/First Author: Andy IR Herries, La Trobe University, Bindoore, VIC

Presenter/First Author Email: a.herries@latrobe.edu.au

Co-authors: Tom Mallett, La Trobe University, Bundoora (Melbourne), Australia; Peter Kappen, , ,

Abstract Body: This paper outlines the use of caves and palaeokarstic deposits for the recording and dating of high resolution Plio-Pleistocene geomagnetic field data from the southern hemisphere; including magnetic reversals, events and excursions. Examples are given of recently discovered high resolution magnetic reversals in palaeocave sediments from South Africa, including the base of the Olduvai SubChron and an event at ~2.047-2.005 Ma based on the direct uranium-lead dating of the speleothem. This is somewhat younger than recent estimates for the Huckleberry Ridge excursion based on other methods, but older than estimates for the Pre-Oluvai excursion at ~1.977 Ma. Two short geomagentic field events are dated to slightly later than 2.069 and 1.959 Ma at a second cave and could incorporate both the Huckleberry Ridge and Pre-Olduvai excursions. However, in all cases full normal polarity directions are recorded, suggesting these are perhaps events, not excursions. In an older flowstone, another event is recorded and dated to between 2.38 and 2.24 Ma, suggesting that it relates to the older Réunion event at ~2.20 Ma. X-ray fluorescence microscopy and X-ray absorption spectroscopy at the Australian Synchrotron has been used to map iron within the speleothems, identify areas of potential recrystalisation and identify the main magnetic minerals present. This work, combined with palaeomagnetic and mineral magnetic analysis indicates that while the remanence is carried by detrital magnetite, this constitutes only a few percent of the overall iron mineralogy within the speleothems. This work indicates that recystalisation can have an effect on the palaeomagnetic signal in spelothem and so it is important to evaluate this through thin section analysis. Micromorphology has also been used to evaluate the potential effects of sedimentary structures on the geomagentic field data recorded from cave sediments. This work shows the great potential of Pliocene and Pleistocene cave deposits for recording geomagnetic field data in high resolution as well as the direct dating of reversals, events and excursions, but also highlights the difficulties and new challenges faced in this work. The potential of younger pseudokarstic sea caves are also highlighted, including the direct dating of the Punaruu Event (1.11 and 1.09).

Title: Improving our Knowledge of the Geomagnetic Field Intensity in South America: New Archaeointensity Data from Potsherds Derived from Three Archaeological Sites in Ecuador.

Presenter/First Author: Emilio Herrero-Bervera, University of Hawaii at Manoa, Honolulu, HI

Presenter/First Author Email: herrero@soest.hawaii.edu

Co-authors: Evdokia Tema, University of Turin, Torino, Italy; J. Stephen Athens, International Archaeological Research Institute (IARII), Honolulu, HI

Abstract Body: Archaeomagnetic data from the south hemisphere are still very scarce and most of the global geomagnetic field models suffer from this lack of data as well as from their uneven geographical distribution. In this study we present new archaeointensity data from three dated prehistoric archaeological sites in northern highland Ecuador (South America). Potsherd fragments come from the archaeological excavations of Atuntaqui, Otavalo (towns), Mounds and La Chimba (named after the hacienda were it is located), dated at 571 BP, 651-622 BP and 2586-2120 BP respectively, based on available radiocarbon dating. Successful archaeointensity data have been obtained from thirty five potsherds using the Thellier-Coe protocol. Rock magnetic experiments including low-field versus temperature (k-T) plots, Isothermal Remanent Magnetization (IRM) acquisition curves, as well as hysteresis loops and back-fields, have been performed in order to characterize the magnetic behavior of the samples and determine their main magnetic carriers. The Curie temperatures indicate the presence of at least two magnetic mineral phases (i.e. 220-255^{o}C and 560-590^{o}C), with predominant Curie temperatures typical of magnetite. The results of the magnetic grain size analyses suggest the presence of particles in the Pseudo-Single Domain (PSD) range, according to the distribution on the modified Day et al. diagram (Dunlop 2002 a and b) for magnetite. The successful absolute palaeointensity determinations yielded archaeointensity values of 43.9 ± 1.4 μT for Atuntaqui, 37.6 ± 0.8 μT for Otavalo Mound 3 (upper charcoal lens, ca 622 years old BP), 29.6 ± 1.1 μT for Otavalo Mound 3 (lower charcoal lens, 651 years old BP) and 38.0 ± 3.1 μT for La Chimba. The new results are in good correlation with archaeomagnetic data from the Palpa area in South Peru, located within a 900 km radius around the Ecuadorian sites in question. These data are the first archaeointensity results from Ecuador for the last 1500 years and aim to enrich our knowledge of the geomagnetic field intensity variations in the south hemisphere, together with previously published data from South America.

Title: The history of the South Atlantic Anomaly as viewed from southern Africa: Potential influences of the African LLVSP on the geodynamo

Presenter/First Author: John Anthony Tarduno, University of Rochester, Rochester, NY

Presenter/First Author Email: john@earth.rochester.edu

Co-authors: Eric Blackman, Univ of Rochester, Rochester, NY; Thomas Niel Huffman, University of the Witwatersrand, Johannesburg, South Africa; Michael Keith Watkeys, University of Kwazulu Natal, Durban, South Africa; Rory Danielle Cottrell, University of Rochester, Rochester, NY

Abstract Body: A broad low intensity area in Earth's recent magnetic field spans the southern Atlantic Ocean, Africa and South America. This is

commonly called the South Atlantic Anomaly (SAA). The SAA allows a relatively close approach of Earth's radiation belts, affecting spacecraft operations. The low magnetic intensity decreases the efficiency of magnetic shielding in the region, which can influence atmospheric ozone. Many believe the SAA is linked to the dramatic decay of the dipole geomagnetic field intensity during the last 160 years, and the growth of a reversed core flux patch beneath South Africa. Some have even speculated Earth is heading toward a geomagnetic field reversal. But understanding these phenomena within the context of longer-term geomagnetic history has been limited by a lack of Southern Hemisphere archeomagnetic data. We have recently presented the first archeomagnetic data from Iron Age sites of southern Africa (∼1000-1650 AD) (Tarduno et al., 2014). Magnetic data show a sharp intensity drop at ∼1300 AD, at a rate comparable to modern field changes in the SAA (but to lower values). These changes motivated our conceptual model whereby the recurrence of low field values reflects magnetic flux expulsion from the core, promoted by the unusual core-mantle boundary composition and structure beneath southern Africa defined by seismology (specifically the African Large Low Velocity Seismic Province, or LLVSP). Because the African LLVSP is a longstanding structure, we expect this region to be a steady site of flux expulsion, and perhaps the triggering site for reversals, on time scales of millions of years. Here we discuss our ongoing efforts to extend the archeomagnetic record from southern Africa back in time, and further develop the flux expulsion- African LLVSP hypothesis.

Title: Frontiers in Planetary Dynamos Through High-Performance Computing

Presenter/First Author: Bruce A Buffett, University of California Berkeley, Berkeley, CA

Presenter/First Author Email: bbuffett@berkeley.edu

Abstract Body: High-performance computing has enabled scientific breakthroughs in our understanding of planetary dynamos. While current numerical models still fall far short of reaching realistic values for the viscosity of liquid metal, the goal of producing fully turbulent dynamos may be within reach on the world's largest computers. To achieve this goal we have undertaken a series of performance and accuracy benchmarks on a large supercomputer (XSEDE Stampede). We have used the results to identify approaches that enable numerical dynamo models to run efficiently on 10^5 compute cores. Dynamo codes included in the benchmark exercise include a variety of numerical methods (spectral, finite difference, finite element, and hybrid methods) and rely on different strategies for domain decomposition. Our analysis of the results suggests that spectral methods can achieve the required efficiency using a two-dimensional domain decomposition. Estimates for scalability of a new community dynamo code called {\it Rayleigh} are presented and used to define the parameter regime that should be feasible on present-day computers. We also describe an ongoing project through the DOE INCITE program to run planetary dynamo models on Mira, the fifth fastest computer in the world.

Title: High Resolution Geodynamo Simulations with Strongly-driven Convection and Low Viscosity

Presenter/First Author: Nathanaël Schaeffer, ISTerre, Grenoble,

Presenter/First Author Email: nathanael.schaeffer@ujf-grenoble.fr

Co-authors: Alexandre Fournier, Institut de Physique du Globe de Paris, Paris, France; Dominique Jault, University Joseph Fourier Grenoble, Grenboble, France; Julien Aubert, Institut de Physique du Globe, Paris, France

Published Material: These findings will also be presented at the EGU meeting in april 2015.They have already been presented in two workshops in 2014.No paper has been submitted yet, but I hope it will be submitted by then !

Abstract Body: Numerical simulations have been successful at explaining the magnetic field of the Earth for 20 years. However, the regime in which these simulations operate is in many respect very far from what is expected in the Earth's core. By reviewing previous work, we find that it appears difficult to have both low viscosity (low magnetic Prandtl number) and strong magnetic fields in numerical models (large ratio of magnetic over kinetic energy, a.k.a inverse squared Alfvén number).
In order to understand better the dynamics and turbulence of the core, we have run a series of 3 simulations, with increasingly demanding parameters. The last simulation is at the limit of what nowadays codes can do on current super computers, with a resolution of 2688 grid points in longitude, 1344 in latitude, and 1024 radial levels.
We will show various features of these numerical simulations, including what appears as trends when pushing the parameters toward the one of the Earth.
The dynamics is very rich. From short time scales to large time scales, we observe at large scales: Inertial Waves, Torsional Alfvén Waves, columnar convective overturn dynamics and long-term thermal winds. In addition, the dynamics inside and outside the tangent cylinder seem to follow different routes.
We find that the ohmic dissipation largely dominates the viscous one and that the magnetic energy dominates the kinetic energy. The magnetic field seems to play an ambiguous role. Despite the large magnetic field, which has an important impact on the flow, we find that the force balance for the mean flow is a thermal wind balance, and that the scale of convective cells is still dominated by viscous effects.

Published Material: Title: "Canonical Models of Geophysical and Astrophysical Flows:Turbulent Convection Experiments in Liquid Metals" Authors: A.Ribeiro, J-L Guermond, J.M Aurnouunder revision, Metals Paper

Abstract Body: System-scale magnetic fields are observed to develop in galaxies, stars, planets, moons, and even asteroids. In all these systems, magnetohydrodynamic dynamo action occurs via the conversion of the kinetic energy of flowing electrically-conductive fluids into magnetic field energy. Generated by the motion of the electrically-conductive fluid, dynamo fields typically evolve on length and time scales related to the underlying flows. \\

Present-day numerical models do not yet model dynamo action in liquid metals with a thermal Prandtl number, $Pr <1$ and a magnetic Prandtl number, $Pm \ll 1$. Metal dynamo simulations should become possible, though, within the next decade. In order then to better understand the turbulent convection phenomena occurring in geophysical or astrophysical fluids and next-generation numerical models thereof, we present here canonical, end-member examples of thermally-driven convection in liquid gallium, first with no magnetic field or rotation present, then with the inclusion of a background magnetic field and then in a rotating system (without an imposed magnetic field). In doing so, we demonstrate the essential behaviors of convecting liquid metals that are necessary for understanding and for building accurate, robust models of magnetohydrodynamic processes in $Pm \ll Pr < 1$ geophysical and astrophysical systems. \\

Title: A Sparse Fully Spectral Method for Simulations in Spherical, Cylindrical and Cartesian Geometries

Presenter/First Author: Philippe Marti, University of Colorado -- Boulder, Boulder, CO

Presenter/First Author Email: philippe.marti@colorado.edu

Co-authors: Michael A Calkins, University of Colorado, Boulder, Boulder, CO; Jonathan M Aurnou, University of California Los Angeles, Los Angeles, CA; Keith A Julien, Univ of Colorado--Boulder, Boulder, CO

Published Material: Preliminary results where presented at the AGU fall meeting 2014.

Abstract Body: Due to the complexity of core flow problems, they need to be tackled from all possible angles. Direct Numerical Simulations (DNS), asymptotically reduced models and lab experiments allow for the investigation of different aspects related to core dynamics. While a majority of DNS studies are performed in spherical geometries, reduced models and lab experiments often involve Cartesian and cylindrical geometries as well; thus requiring efficient numerical methods that are applicable to a variety of coordinate systems. Furthermore, for numerical stability, accuracy and performance, the linear terms of the governing equations need to be treated implicitly. For example, the explicit treatment of the Coriolis force leads to a stringent timestep constraint. We have developed a fully spectral coding framework that is capable of solving a variety of equation sets in many different geometries. Depending on the geometry, it uses a combination of Chebyshev series, Fourier series and spherical harmonics for the numerical discretization. By using the quasi-inverse method, our approach produces very sparse matrices that allow for the efficient solution of very large coupled systems of equations. We will present our coding framework as well as nonlinear results for different geometries.

Title: Generation of magnetic fields by large-scale vortices in rotating convection

Presenter/First Author: Celine Guervilly, University of Leeds, Leeds,

Presenter/First Author Email: c.guervilly@leeds.ac.uk

Published Material: Part of this work has been presented at the 2014 fall meeting of the AGU.

Abstract Body: Recent computational studies have described the formation of large-scale vortices in rotating turbulent convection in planar geometry. These vortices, which are long-lived and depth-invariant, form by the merger of convective thermal plumes. In this presentation, we will show that for magnetic Reynolds numbers below the threshold for small-scale dynamo action, such flows can sustain large-scale magnetic fields - i.e. fields with a significant component on the scale of the system.

Title: Core Merging After Giant Impacts and Core Stratification in the Late Stages of Earth's Formation

Presenter/First Author: Maylis Landeau, Johns Hopkins University, Baltimore, MD

Presenter/First Author Email: landeau@jhu.edu

Co-authors: Peter Olson, Johns Hopkins University, Baltimore, MD; Renaud Deguen, Institut de Mécanique des Fluides de Toulouse, Toulouse, France; Ben Hirsh, Johns Hopkins University, Baltimore, MD

Published Material: Findings partly (about 50 %) reported at fall AGU meeting 2014.

Abstract Body: The fluid dynamics of core merging after giant impacts during planetary accretion provides constraints on core stratification, early magnetic field generation and metal-silicate equilibration. The energy released during giant impacts, such as those thought to have formed Earth's Moon and the crustal dichotomy on Mars, likely resulted in melting of the impactor and much or all of the protoplanet's mantle. Under these conditions, the liquid core of the impactor migrates through a fully-liquid magma ocean, and merges with the protoplanet's core.

We present experiments on liquid blobs released into another liquid consisting of two immiscible layers, representing the magma ocean and protocore, respectively. In contrast with the laminar flow in numerical simulations, liquid impact experiments can produce turbulence, as expected during core formation. The released liquid is immiscible in the upper layer, miscible in the lower layer, and denser than the upper layer. We characterize the impact at the immiscible interface varying the upper layer depth and the released fluid density. With a shallow upper layer, the relevant regime for giant impacts, a turbulent cloud of released and upper liquid penetrates in the lower layer, collapses and spreads at the immiscible interface. This behavior contrasts with direct core merging found in impact simulations, and suggests that, because of turbulence, metal-silicate chemical equilibration extends deep inside the protocore. Experimental scalings for low-density releases suggest that compositional stratification is likely in the aftermath of core formation, and the stratified layer detected by seismology at the top of Earth's core is compatible with a moon-forming impact. By implication, the early core dynamo had to overcome compositional stratification to initiate.

Title: Revisiting Earth's Thermal Evolution: A Solution to the Mantle and Core Paradoxes

Presenter/First Author: Peter E Driscoll, University of Washington Seattle Campus, Seattle, WA

Presenter/First Author Email: ped13@uw.edu

Abstract Body: Recent discoveries relating to the thermal and magnetic history of the Earth have revealed that a solid surface and a dynamo generated magnetic field have persisted over almost all of its history. However, the geochemically inferred radioactivity and geodynamically inferred heat loss efficiency predict wide spread mantle melting, a "thermal catastrophe", only 2−3 Ga. Similarly, paleomagnetic observations that indicate a geodynamo as old as 3.4 Gyr are at odds with the "new core paradox", which claims insufficient energy to drive the ancient geodynamo prior to inner core nucleation ~ 1 Ga in light of recent revisions to the thermal conductivity of the core. We present a single solution to both paradoxes that invokes a high core heat flow of ~13 TW, a low mantle secular cooling rate of ~13 TW, and an inner core age of ~800 Myr. By including light element depression of the core solidus as the inner core grows and enriches the outer core, core radioactivity is inferred to be ~1 TW or less. This new model has important implications for the history of the geodynamo, including a switch from top driven thermal convection to mixed thermo-chemical convection following inner core nucleation. We propose that this switch is evident in existing paleomagnetic observations.

Title: On the Secular Variation of Saturn's Magnetic Field

Presenter/First Author: Sabine Stanley, University of Toronto, Toronto, ON

Presenter/First Author Email: stanley@physics.utoronto.ca

Co-authors: Jeremy Bloxham, Harvard Univ, Cambridge, MA

Abstract Body: Saturn's nearly axisymmetric observed magnetic field is problematic for dynamo theory and requires unique processes occurring in its dynamo generation region. The leading explanation is that zonal flows in a stably stratified layer surrounding the dynamo source region attenuate the non-axisymmetric components of the field. Here we demonstrate an important theoretical consequence of this axisymmetrization process: the secular variation of the axisymmetric field components must be extremely slow. Observational evidence suggests this may be the case for Saturn. In addition, we present numerical dynamo simulations that reproduce the observed axisymmetry of Saturn's field and confirm the extremely slow secular variation rates in highly axisymmetric models. A consequence of this result is that we can use time variation of the axisymmetric field to learn about the non-axisymmetric field components which are not observed in present data from Cassini.

Title: Connection of a ^{90}Sr Groundwater Plume with Local Tree Swallows

Presenter/First Author: David R Lee, AECL, Chalk River, ON

Presenter/First Author Email: leed@aecl.ca

Published Material: Some of this material was presented at the 2013 GSA meeting in Denver, emphasizing the methods used to quantify mass flux of Sr-90 into the littoral zone. This submission, however is an update. It will feature the findings of 2013 and 2014 and the linkage between tree swallows and the local groundwater system.

Abstract Body: We traced the movement of a strontium-90 (^{90}Sr) plume from source to tree swallows. The source was leakage from a nuclear fuel storage pool. Swallow nest boxes were placed so parent birds would feed their nestlings with insects that emerged from sediments in the ^{90}Sr groundwater discharge zone and from sediments in background control sites. Nest boxes were observed regularly during nest building, egg laying, brooding, hatching and fledging. When nestlings were 12-days-old, one nestling from each of 12 nests at sites labelled with ^{90}Sr (as a result of groundwater discharge) and one nestling from each of two nests at background sites were taken under a Federal Permit and an approved animal care protocol. Gross beta concentrations in the bone and body of nestlings were consistent with the proximity of the nest boxes to the ^{90}Sr-groundwater discharge area. Lower leg samples from nestlings from the ^{90}Sr-labelled site had 7 to 9 times more gross beta radiation than whole bodies, consistent with the expectation that the excess radioactivity was due to ^{90}Sr concentrated in bone. Gross beta of the lower legs vs. bodies for all 14 samples were highly correlated ($r^2 = 0.94$). Although the paucity of control site nestlings prevented statistical comparisons, a preliminary conclusion is that there was no reproductive impairment of swallows at ^{90}Sr-labelled sites. Conservative estimates of internal doses, due to 5 Bq $g^{-1}$of ^{90}Sr/^{90}Y in maximally burdened nestlings, were 8 uGy hr^{-1}as compared with 40 uGy hr^{-1}, which is an internationally recognized benchmark for protection of riparian and terrestrial animals. This study marks an initial effort to perform a biota- dose assessment of ^{90}Sr groundwater plumes where these plumes constitute a nutritional connection between the groundwater system and the local ecology. Future work will use tree swallows to assess the potential for offsite transfer of ^{90}Sr in edible waterfowl and to quantify radioecological effects, if any.

Title: Geophysical and Hydrological Investigation of Rock Glacier in the Canadian Rockies

Presenter/First Author: Alexandra Mozil, University of Calgary, Calgary,

Presenter/First Author Email: alexandra.zheltikova@yandex.ru

Co-authors: Laurence R Bentley, University of Calgary, Calgary, AB, Canada; Masaki Hayashi, University of Calgary, Calgary, AB, Canada

Abstract Body: Anticipated climate warming will lead to increases in the global temperature and evapotranspiration. These changes will affect the peak of the mountain river runoff by shifting it to earlier in the year, away from the peak demand of summer and autumn. The effects of global warming may be buffered by groundwater that is stored temporarily in overburden material such as talus, moraine and rock glaciers, before discharging into mountain streams. Therefore, it is important to understand the contributions of these landscape units to the hydrological cycle in alpine watersheds in order to predict consequences of the climate warming for these natural water reservoirs.

In this project, a rock glacier in the Helen Lake Creek watershed in Banff National Park, Alberta was explored using electrical resistivity tomography, seismic refraction and ground penetrating radar. The main objectives were to identify the presence of ice in the subsurface, determine the depth to bedrock and trace the pathways of groundwater water flow.

Resistivity images showed areas with large resistivity values indicating possible ice locations. Seismic refraction data was consistent with a two-layer system with the velocity range of the lower layer typical for the bedrock. Ground penetrating radar data were consistent with the seismic refraction and resistivity interpretations by showing reflections at the bedrock boundaries.

The geophysical data indicate the location of the bedrock surface, groundwater flow paths and ice in the rock glacier. Their role in the storage and release of water to sustain the late-summer base flow in Helen Lake will be discussed.

Title: The future risk and uncertainty of livelihood development of the villagers on banks of the Lower Mekong Basin (LMB), Cambodia

Presenter/First Author: Serey Sok, Royal University of Phnom Penh, Phnom Penh,

Presenter/First Author Email: sokserey@gmail.com

Published Material: In Cambodia, the Lower Mekong Basin (LMB) represents 86% of its territory and 32.3% of its population is living in. This paper examines current and past risk and uncertainty (2000-2010) faced by villagers regarding resources scarcity; natural hazards and climatic change; man-made activities and catastrophes; and socio-economic impacts. The recent and likely future trends in livelihoods of the past 10 years (2011-2020) and over the next decade (2011-2020) are then explored under plausible scenarios of natural resource conditions. The upper, middle, and lower parts of the River are selected for different characteristics with a sample of 548 households. The upper part is Ramsar and the lower part is Mekong Delta, which borders Laos and Vietnam, respectively. The primary data collection methods are applied including field survey and other participatory tools. The study reveals that villagers are threaten by (1) resources scarcity, natural hazards, climatic change, and socio-economic impacts; (2) man-made activities cause severe catastrophes and make livelihoods become uncertain; (3) lack of suitable infrastructures results in low agricultural productivity and increases hazard impacts; (4) there is dependency on water-related recourses without alternative livelihoods and low adaptation capacity leads villagers to high poverty and vulnerabilities within this decade; and (5) future trends over the next decade remain risky and uncertain to the poor, when development is only influenced by growth, but not sustainable development.

Abstract Body: In Cambodia, the Lower Mekong Basin (LMB) represents 86% of its territory and 32.3% of its population is living in. This paper examines current and past risk and uncertainty (2000-2010) faced by villagers regarding resources scarcity; natural hazards and climatic change; man-made activities and catastrophes; and socio-economic impacts. The recent and likely future trends in livelihoods of the past 10 years (2011-2020) and over the next decade (2011-2020) are then explored under plausible scenarios of natural resource conditions.

The upper, middle, and lower parts of the River are selected for different characteristics with a sample of 548 households. The upper part is Ramsar and the lower part is Mekong Delta, which borders Laos and Vietnam, respectively. The primary data collection methods are applied including field survey and other participatory tools.

The study reveals that villagers are threaten by (1) resources scarcity, natural hazards, climatic change, and socio-economic impacts; (2) man-made activities cause severe catastrophes and make livelihoods become uncertain; (3) lack of suitable infrastructures results in low agricultural productivity and increases hazard impacts; (4) there is dependency on water-related recourses without alternative livelihoods and low adaptation capacity leads villagers to high poverty and vulnerabilities within this decade; and (5) future trends over the next decade remain risky and uncertain to the poor, when development is only influenced by growth, but not sustainable development.

Title: Water budget imbalance and error source for Canada's major drainage basins

Presenter/First Author: Shusen Wang, Natural Resources Canada, Ottawa, ON

Presenter/First Author Email: shuwang@NRCan.gc.ca

Published Material: PART of the presentation was recently accepted by Hydrological Process.

Abstract Body: Assessing water budget closure helps identify knowledge gaps, data quality issues and research needs for better understanding the water cycle and water resources. This study assessed the 30-year (1979-2008) water budget closure for 19 large drainage basins in Canada covering an area of 3.5 million km^2, or about 35% of the entire Canadian landmass. Datasets recently developed for precipitation (P), land surface evapotranspiration and water surface evaporation from the land surface model EALCO, in situ streamflow measurements, and total water storage (TWS) from the GRACE satellite observations were used for the assessment. The objectives are to quantify the magnitudes of the water budget imbalance (e) over Canada and to assess the sources of errors. Results show that the water budget was closed within 10% of the P on average for all the basins. The e showed a general pattern of positive values in the south and negative values in the north and mountainous regions. The positive and negative values of e among the 19 basins were largely offset and the all-basin average e was close to zero. Water imbalance in the north and mountainous regions were large mainly due to inaccurate precipitation. There are 11 basins showing significant trends in TWS over 2003-2008, which accounted for 31% of their e on average. As such, long-term average ET calculated using surface water budget approach (i.e., ET=P-Q) might induce large errors. Improvements in the observation network, data quality assurance, and spatial models for P are critical for further improving the water budget closure.

Co-authors: Saltanat Sadvakasova, , , ; Talgat Usmanov, , ,

Abstract Body: Reduction of surface runoff in the Irtysh River Basin in recent decades is leading to disastrous consequences on the aquatic

ecosystem in the region. As a result of the runoff reduction the Bukhtarma reservoir and connected Lake Zaysan are experiencing dramatic problems with water availability. The major tributary is the Black Irtysh River with the upstream located in China. The research work is based on data collected for the period 1960 to 2014. We used the water fluctuations of river runoff, water levels and water release from the Bukhtarma reservoir. Scenarios of the future changes were analyzed with analyses of the natural and anthropogenic impacts on the water availability fluctuations on the Bukhtarma reservoir. With the water intake from the Irtysh River estimated at 2 km^3 per year, flow decreases by 21.8% compared to the natural conditions in average watered years. When water subtraction is equal to 3 km^3 per year, river flow during the dry year can be reduced by 69.0% compared to the natural conditions.

Title: Coupling System Dynamics and SahysMod Models for Participatory Soil Salinity Management in the Rechna Doab Region, Pakistan

Presenter/First Author: Jerome Boisvert-Chouinard, McGill University, Montreal, QC

Presenter/First Author Email: jerome.boisvert-chouinard@mail.mcgill.ca

Co-authors: Johannes Halbe, McGill University, Montreal, QC, Canada; Jan F Adamowski, McGill University, Montreal, QC, Canada

Abstract Body: The principles of Integrated Water Resource Management outline the importance of stakeholder participation in water management processes, but in practice, there is a lack of meaningful engagement in water planning and implementation, and participation is often limited to public consultation and education. When models are used to support water planning, stakeholders are usually not involved in their development and use, and the models commonly fail to represent important feedbacks between socio-economic and physical processes.

This paper presents the development of a holistic model of the Rechna Doab basin in Pakistan, that simulate socio-economic and physical processes related to soil salinity management. The model consists of two sub-components: a System Dynamics (SD) model, and a physically based model. The SD component was developed in collaboration with key stakeholders in the basin, and was coupled with SahysMod, a soil salinity model. The coupled models were used to assess the environmental and socio-economic impacts of different management scenarios proposed by stakeholders.

Results indicate that coupled SD – physically-based models can be used as effective tools for participatory water planning and implementation. The participatory modeling process provides a structure for meaningful stakeholder engagement, and the models themselves can be used to transparently and coherently assess and compare different management options.

First Author Student?: No

Co-authors: Jay Sagin, Saskatchewan Polytechnic, Saskatoon, SK, Canada

Abstract Body: The geomorphological changes of the Ural River in the West Kazakhstan have been studied by our group during the dozens of years. The number of outstanding floods in the Ural River has been registered during the observations, in 1914, 1922, 1923, 1931, 1940-1942, 1946-1948, 1957, 1970, 1993-1995. The main factors determining the high floods are due to rapid snow melting, high runoff due to the small hydrologic conductivity of the frozen soil. The historical river bed studies with the application of the earth observation satellites (EOS) were applied for this research work. The historical cartographic and EOS images were used to determine the river bed positions at different time slices with analysis of the river bed evolution changes. The estimated shifts, meandering intensification of the Ural River were modeled. The magnitude and speed of the river bed shifts have been determined with geomorphological dynamics, including meandering, bifurcating, straight lined intensity changes. The analysis of river beds evolution with river bed morphology changes were analyzed by the nature and intensity of river bed deformations due to natural and anthropogenic processes. Detection of regional patterns in the development of river bed adjustments and their forecast estimates give the opportunity to analyze the probability of certain geomorphological changes for the prevention of the adverse consequences. The future research work is planned with the data applications from EOS KazEOSat-1. The KazEOSat-1 is a high-resolution observation satellite, which was built by Astrium for the Space Company Garysh Sapary of the Republic of Kazakhstan. KazEOSat-1 satellite was launched in the first quarter of 2014 (KazEOSat on 30 April 2014 and KazEOSat-2 is planned to be launched on 20 June 2015). KazEOSat-1 satellite provides high-quality panchromatic, 1 m, and four multispectral channels, 4 m, for a wide range of applications. KazEOSat-2 satellite provides medium-quality five multispectral channels, 6.5 m, for a wide range of applications. The current stage of the satellite's data applications for geomorphological research work is also to be discussed. The research results are used for the long-term forecasts of river bed regime changes.

Title: The Hydrological Challenges of Scale Dependency

Presenter/First Author: Howard S. Wheater, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: howard.wheater@usask.ca

Abstract Body: From the earliest beginnings of Hydrology, the scale dependence of catchment response has been explicitly recognised, for example in regional analyses of flood frequency and unit hydrograph response. And when continuous simulation conceptual rainfall-runoff models evolved to the point where the need for parsimony in parameterisation was recognised, regionalisation for ungauged catchments led to explicit quantification of parameter scale-dependence. However, for physics-based models, there has been a failure to account for the scale-dependence of parameters, despite clear evidence that appropriate representation of basic physical properties within models is dependent on the scale of model temporal and spatial discretization. There has perhaps been a naïve belief that physically-based properties are by definition scale-independent. Failure to progress understanding of these issues poses an urgent set of challenges. For example atmospheric models are now routinely applied at km scale over continents, but despite recent discussion of hyper-resolution modelling, the implications for associated

hydrological discretization and parameterization are unclear. This paper discusses these issues and a framework for analysis. Methods include numerical experimentation to determine emergent properties, empirical analysis of alternative discretization scales and methodologies, and the analysis of large-scale model performance. Current examples from Western Canada are presented.

Title: Seamless prediction of water fluxes across scales

Presenter/First Author: Luis E Samaniego, Helmholtz Centre for Environmental Research UFZ Leipzig, Leipzig,

Presenter/First Author Email: luis.samaniego@ufz.de

Co-authors: Oldrich Rakovec, Helmholtz Centre for Environmental Research UFZ Leipzig, Leipzig, Germany; Rohini Kumar, Helmholtz Centre for Environmental Research UFZ Leipzig, Leipzig, Germany; Juliane Mai, Helmholtz Centre for Environmental Research UFZ Leipzig, Leipzig, Germany; David Schaefer, Helmholtz Centre for Environmental Research - UFZ, Leipzig, Germany; Matthias Cuntz, Helmholtz Centre for Environmental Research UFZ Leipzig, Leipzig, Germany; Martin Schrön, Helmholtz Centre for Environmental Research UFZ Leipzig, Leipzig, Germany; Stephan Thober, Helmholtz Centre for Environmental Research UFZ Leipzig, Leipzig, Germany; Matthias Zink, Helmholtz Centre for Environmental Research - UFZ, Leipzig, Germany; Sabine Attinger, Helmholtz Centre for Environmental Research-UFZ, Leipzig, Germany

Published Material: Some results have been presented at previous AGU and EGU meetings 2014. mHM/MPR related issues were published in Samaniego et al. 2010 WRR, Kumar et al. 2013ab WRR, as well as, in Samaniego et al. 2011 JHM. Manuscript in preparation for WRR.

Abstract Body: Developing the ability to seamlessly predict streamflow and other state variables like soil moisture at catchment, regional, continental or global scales with spatial resolutions varying from hundreds to thousands of meters is fundamental for improving our understanding of the water balance at scales relevant for decision making as well as for improving our understanding of the potential impacts of climate change on water resources. Hydrologic observations, however, are hardly available at the scale at which the predictions are needed. Streamflow, for example is a quite reliable signal but it represents the integral response over the whole basin. In situ soil moisture observations have a very small control volume and are hardly available at a regional scale. Remote sensing products such as the total water storage anomaly or soil moisture, on the other hand, are spatially explicit but observed at resolutions much larger than those required. It is therefore necessary to develop a framework that incorporates observations at their native resolutions into a hydrologic model without the need of using ad hoc up/downscaling techniques to match observations.

Here, we show the capability of the Multiscale Parameter Regionalization (MPR) technique within the mesoscale Hydrologic Model (mHM) to perform this task. MPR is an effective method to find quasi scale invariant parameter sets tested over 250 Pan-EU river basins varying from 100 - 500,000 km^2. The model is forced using the E-OBS data set available at a (0.25×0.25)° resolution from ECA&D during the period 1951-2012. The effective parameters obtained with simulations at this scale can effectively reproduce the total water storage anomalies retrieved by GRACE (NASA) at the spatial resolution (1 × 1)°, the gridded evapotranspiration estimated by LandFlux (ETH) (0.5×0.5)° as well as at tens of eddy flux stations (FLUXNET) whose footprint is about 1 hm^2. Cross-validation experiments lead to the conclusion that mHM estimated water fluxes are robust since less than 25% of river basins exhibit NSE of 0.4 or less for daily discharge. Likewise, the TWS anomalies, exhibit a large spatial correlation with those obtained from GRACE. Comparison against observed latent heat indicates that the dynamics and magnitude of the simulated values are well captured by the model at most locations.

Title: Evaluating the Scalability of a Process-Consistent Hydrologic Model

Presenter/First Author: Tyler J Smith, Clarkson University, Potsdam, NY

Presenter/First Author Email: tsmith@clarkson.edu

Co-authors: Lucy Amanda Marshall, University of New South Wales, Sydney, NSW, Australia; Brian L McGlynn, Duke University, Durham, NC; Kaitlin D Hayes, Clarkson University, Potsdam, NY

Published Material: A portion of the results were presented at the 2014 AGU Fall Meeting and are part of a manuscript under review in Water Resources Research.

Abstract Body: Hydrologic models often fail to generate simulations that are consistent with internal watershed processes, despite commonly being able to match streamflow dynamics (following calibration). This shortcoming is particularly attributed to simple, conceptual models due to a lack of physical realism. At the same time, hydrologic model simulations are confronted with complications caused by a potential shifting of dominant processes with scale. In this study, we explore the scalability, sensitivity, and transferability of the parameters of the Catchment Connectivity Model (CCM). The CCM was developed following a dominant process conceptualization based on empirical hillslope hydrologic connectivity observations at the Tenderfoot Creek Experimental Forest (TCEF; Montana, USA). The three-parameter CCM is a spatially explicit model structure that has been validated against extensive field observations of hillslope hydrologic connectivity (an internal process simulated by the model) to demonstrate its internal consistency, in addition to a traditional assessment to the external streamflow dynamics. Specifically, we explored the variation in model parameterization across multiple scales across seven nested TCEF watersheds. A diagnostic model calibration analysis was considered where the role of a priori parameter ranges was explored in relation to both external (streamflow) and internal (hydrologic connectivity) model performance. This investigation allowed us to develop a more in-depth understanding of the model structure, its scalability, its sensitivity, and its transferability from one watershed to the next.

Title: Multi-scale studies of Permafrost Thaw Impacts on Eco-Hydrology in the Southern Fringe of Permafrost, Northwestern Canada.

Presenter/First Author: William L Quinton, Wilfrid Laurier University, Waterloo, ON

Presenter/First Author Email: wquinton@wlu.ca

Co-authors: Jennifer Lynn Baltzer, Wilfrid Laurier University, Waterloo, ON, Canada; Oliver Sonnentag, University of Montreal, Montreal, QC, Canada; Aaron A Berg, University of Guelph, Guelph, ON, Canada; Laura Chasmer, Wilfrid Laurier University, Waterloo, ON, Canada; Ryan Connon, Wilfrid Laurier University, New Hamburg, ON, Canada

Abstract Body: The southern Taiga Plains ecoregion is one of the most rapidly warming regions on Earth, and is experiencing unprecedented rates

of industrial expansion and related human disturbance. The permafrost in this region is relatively warm, thin and discontinuous. As a result, permafrost thaw is widespread and often leads to the transformation of forested permafrost terrains to permafrost-free, tree-less wetlands. Such permafrost thaw-induced landcover change has the potential to disrupt the hydrological cycle at local and regional scales. However, the hydrological implications of this permafrost-thaw induced land cover transformation remain poorly understood despite its demonstrated pan-arctic occurrence. As a result, there is an urgent need for an improved understanding of, and ability to predict permafrost thaw and its hydrological consequences. This paper presents the results of a long term field study on permafrost thaw-induced land-cover change and the resulting hydrological impact; and demonstrates how this new knowledge is applied to improve predictive capacities. Field measurements were conducted between 1999 and 2014 at Scotty Creek in the peatland-dominated southern fringe of discontinuous permafrost near Fort Simpson, Northwest Territories. Field studies at Scotty Creek have focussed on 1) improving the understanding of the volume and timing of runoff for different ground thaw and moisture conditions; 2) simulating the major water flux and storage processes controlling runoff; 3) characterising permafrost impacts at larger scales through field investigation and subsequent adaptation of a regional-scale permafrost model; and 4) estimating future quantities of runoff and surface water storage under possible scenarios of climate warming and human disturbance. Progress on each of these areas of will be the described.

Title: Frequency Bias Correction (FBC) - A new alternative for addressing GCM dependence biases for hydrological applications

Presenter/First Author: Ashish Sharma, University of New South Wales, Sydney, NSW

Presenter/First Author Email: a.sharma@unsw.edu.au

Co-authors: Nguyen Ha, , , ; Rajeshwar Mehrotra, University of New South Wales, Sydney, NSW, Australia

Abstract Body: Addressing systematic persistence biases in GCM simulations is being increasingly recognised as a first step before any hydrological climate change impact assessment. This is in contrast to many bias correction procedures that focus on correcting biases in moments and are referred to as distribution-based bias correction approaches. The current options for addressing persistence biases comprise of the Nested Bias Correction (NBC) or its recursive variant, the Recursive NBC (RNBC), which correct lag 1 autocorrelation biases across specified nesting time scales. While these represent the only alternatives available to correct persistence biases (and hence are of considerable use in storage related applications in hydrology), the assumption of pre-defined time scales and a focus on the lag 1 autocorrelation limits their generality in representing persistence.

Here we present the Frequency Bias Correction (FBC) as an alternative to the NBC, that aims to correct for biases in the spectral representation of the data. Focussing on the entire spectrum instead of a handful of time-scales allows a more comprehensive treatment of any persistence related biases that may exist in the GCM simulations being processed. The FBC is was tested for MIROC5 precipitation simulations across the Australian land mass and compared to the empirical quantile mapping (EQM) and RNBC in terms of its ability to maintain distribution and persistence related attributes. Results indicate that the FBC corrects distributional and dependence attributes relevant in hydrological design and operation of water storage systems.

Title: A Model for Water Flow in Patterned Glacial Till Incorporating Coupled Multi-Scale Heterogeneity Effects

Presenter/First Author: Xicai Pan, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: xicai.pan@usask.ca

Co-authors: Melkamu Ali, University of Saskatchewan, Saskatoon, SK, Canada; Andrew M Ireson, University of Saskatchewan, Saskatoon, SK, Canada; Warren Helgason, University of Saskatchewan, Saskatoon, SK, Canada

Abstract Body: Representing subgrid-scale heterogeneity is becoming increasingly more feasible in land surface modeling and large scale hydrological modeling with the advance of computational power. However, in complex environments, such as the internally drained prairie basins, with highly variable snowpack and soil properties, our understanding of spatiotemporal storage dynamics and flow paths is still incomplete. An extensive and comprehensive field monitoring program was implemented to assess the field-scale water balance within a heterogeneous prairie pasture site. A 2-D hydrological model, including a novel representation of the patterned glacial till and associated surface properties, was developed. Instead of assuming homogeneous precipitation and soil properties over grids, the key soil parameters for two representative profiles were identified by inverse modeling using a simple 1-D hydrological model and field measurements of soil temperature, water content and water level. Then the parameters for spatial variability of those two profiles and boundary conditions were determined by near-surface soil water content surveys. The modeling results will be discussed in conjunction with the observed features.

Title: Assessment of Hydrological Behaviour of a Snowmelt-Dominated Catchment at Different Scales

Presenter/First Author: Mahyar Shafii, University of Waterloo, Waterloo, ON

Presenter/First Author Email: mshafiih@uwaterloo.ca

Co-authors: Nandita B Basu, University of Waterloo, Waterloo, ON, Canada; James R Craig, University of Waterloo, Waterloo, ON, Canada; Sherry L Schiff, University of Waterloo, Waterloo, ON, Canada; Philippe Van Cappellen, University of Waterloo, Waterloo, ON, Canada; Hans Hermann Dürr, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Snow-dominated catchments are subject to different water input dynamics than their rainfall-dominated counterparts. Therefore, such catchments might experience different runoff generating processes, which might not be appropriately reproduced by the existing conceptual rainfall-runoff models. As a result, understanding about the dominant physical controls on the response of snowmelt-dominated watersheds is crucially important in the selection of hydrologic models. The focus of this research is on the Grand River watershed (7000 km^2), the largest watershed in southern Ontario in Canada, which comprises 25 per cent of the Canadian land area draining into Lake Erie. To gain insight into the hydrological functioning of the Grand River watershed – at different spatial scales – data obtained during snowmelt season are used. The data are obtained from numerous sampling experiments in different sub-basins and at multiple points along the main river. The variations in hydrographs over time and scale are analyzed to investigate how they are combined to yield the observed hydrological response of the entire watershed. Subsequently,

a structurally flexible hydrologic model (called RAVEN) is designed to reproduce the watershed hydrological response. The model will also be used to address nested hydrologic responses (at different scales).

Title: Stochastic Interpretation of Thermal Response Test with Complex Ground Heat Exchanger Model

Presenter/First Author: Philippe Pasquier, Polytechnique Montreal, Montreal, QC

Presenter/First Author Email: philippe.pasquier@polymtl.ca

Co-authors: Denis Marcotte, , ,

Published Material: The presentation will present original material and sumarize the work presented in the following contributions: Marcotte, D. & Pasquier, P., 2008. Fast fluid and ground temperature computation for geothermal ground-loop heat exchanger systems. *Geothermics*, 37(6), pp.651–665. Pasquier, P. & Marcotte, D., 2014. Joint use of quasi-3D response model and spectral method to simulate borehole heat exchanger. *Geothermics*, 51, pp.281–299. Pasquier, P., 2015. Stochastic interpretation of thermal response test with TRT-SInterp. *Computers & Geosciences*, 75, pp.73–87.

Abstract Body: Integrating the temperature measurements made in the grout or in the vertical pipes of a ground heat exchanger during a thermal response test can be challenging for conventional interpretation methods. To fill this gap, a quasi-3D thermal response and capacity model is used to generate the transfer functions of the borehole at the location of the temperature probes. The transfer functions are then convolved in the spectral domain with an input function describing the variation of the heating power to obtain the simulated temperatures at the probes location. The unknown thermal parameters (thermal conductivity and volumetric heat capacity of the ground and grout, pipes spacing, initial ground temperature) are identified by an inversion method. It is shown that use of a spectral method combined with a response model allows integration in a stochastic framework of the measurements made at various depth in the borehole.

Title: Simulation of Borehole Thermal Energy Storage with the Haar Wavelet Method

Presenter/First Author: Alain Nguyen, Ecole Polytechnique de Montreal, Montréal, QC

Presenter/First Author Email: t.nguyen@polymtl.ca

Co-authors: Philippe Pasquier, Polytechnique Montreal, Montreal, QC, Canada

Abstract Body: In recent years, use of borehole thermal energy storage systems has become more frequent as these systems allow a significant reduction of the overall energy consumption of buildings located in cold climates. To predict the performances of a system, assess the influence of regional groundwater flow on the thermal storage or simply predict the ground temperature for a given input heat load signal, numerical simulations are usually performed. In this work, a thermal resistance and capacity model is used to simulate a borehole thermal energy storage system under the effect of heat advection driven by regional groundwater flow. The resulting model is a stiff ordinary differential equation system which can present numerical challenges for conventional implicit multistep or Runge-Kutta solvers. To speed up the solution of the problem, the Haar wavelet method is used in conjunction with a multistep segmentation approach which recalculates the step size at each iteration based on the local truncation error estimation given by the Adams-Bashforth method. The method presented in this conference is compared with commercial stiff solvers. Current results indicate that the proposed method is efficient in terms of memory usage and is always 2 to 10 times faster than state-of-the-art solvers.

Title: Numerical Simulation of Deep Bore Heat Pumps

Presenter/First Author: Venkata Ramesh Melanathuru, University of Windsor, Windsor,

Presenter/First Author Email: melanatv@uwindsor.ca

Co-authors: Tirupati Bolisetti, University of Windsor, Windsor, ON, Canada; Stan Reitsma, GeoSource Energy Inc., Caledonia, ON, Canada; David S K Ting, University of Windsor, Windsor, ON, Canada

Abstract Body: Depletion of fossil fuels in the nature poses a greater threat to our civilization. To meet the energy challenges, environmentally friendly renewable energy sources are being explored. The availability of underground energy is more abundant and comparatively easy to extract. One such technology deals with exploitation of earth’s energy referred to as geothermal energy. Deep Bore Heat Pumps, that extract energy during winter times and discharge temperatures during summer, are gaining prominence and popularity due to its simplicity and reliability. Commissioning of this system requires large investment, which usually relies on reliable, powerful guesstimating tools. Therefore, there is a strong need to develop tools to arrive at optimal sizing of deep borehole exchangers.

This paper presents the results of a three-dimensional numerical simulation model for a U-Tube type of heat exchanger. This may be a gross simplification of the fact that there is grout and earth surrounding the exchanger. But, this approximation of considering a constant temperature reduces much pre-processing and computational effort. The PVC is considered as pipe material and water is as heat exchanger fluid. The heat is transferred from the outer surface to the water because of the conductivity of the solid material of the pipe and flow of the water. A velocity inlet and pressure outlet model is assumed. By solving the energy equation and laminar flow, the velocity and pressure profiles are obtained.

A thorough parametric study is conducted by using different span lengths, diameter of the pipe, velocity of the fluid and conductivity of the material. This study helped us in establishing the empirical equations for the temperature rise, power requirements and variables of the process viz., velocity, pressure drop etc.

Title: The use of shallow geothermal energy for bridge deck deicing

Presenter/First Author: Konstantinos Velegrinos, University of Manitoba, Winnipeg,

Presenter/First Author Email: velegrin@myumanitoba.ca

Co-authors: Hartmut Michael Hollaender, University of Manitoba, Winnipeg, MB, Canada; Rob Sinclair, , ,

Abstract Body: Bridges are examples of critical infrastructures in Canada. Exposure to the extreme winter conditions of the Prairies produces rapid freezing conditions from heat loss through both the top and bottom bridge deck surface and these results in hazardous ice and snow conditions. A practical and cost-effective geothermal system to de-ice bridges in a timely manner will significantly reduce both accident and salt corrosion concerns. The subsurface soil and rock contain very large volumes of stored energy, mainly from solar radiation; in spite of this natural-stored energy, temperature declines have and will occur in geothermal systems without seasonal thermal balancing. Manitoba (MB) faces a very cold and long winter. Consequently, this high energy requirement requires a heat pump system for the rapid temperature rise required for bridge deck heating.

A 30-year climate record was obtained from Environment Canada. The data allowed defining standard air temperature curves. We calculated the expected energy consumption for heating bridges based on these curves. The simulation software FEFLOW is capable of simulating heat conduction, groundwater advection, surface radiation, spatial ground property variation, and mass transport around a set of ground heat exchangers. We used soil temperature data from the Highway 210 Test Site, near Ile des Chenes, MB to calibrate the model. The model predicted the groundwater temperature for the life cycle of 50 years. We show in this presentation that winter heating loads require at least the same energy load to be added to the aquifer in the summer.

Title: Development of a Thermo-Hydro-Chemical (THC) Model for Studying the Hydrogeochemical Behavior of Standing Column Wells

Presenter/First Author: Fanny Eppner, Ecole Polytechnique de Montreal, Saint-Hubert,

Presenter/First Author Email: fanny.eppner@polymtl.ca

Co-authors: Philippe Pasquier, Polytechnique Montreal, Montreal, QC, Canada; Paul Baudron, Polytechnique Montreal, Montreal, QC, Canada

Abstract Body: Standing column wells are ground heat exchangers that provide cooling or heating energy to buildings. In certain cases, they might allow to realize energy savings compared to other low temperature systems. Nonetheless, as they use groundwater directly as heat carrier fluid, they favor scaling and precipitation of minerals in the heat exchanger and well, therefore reduce the generated energy savings and increase the operation costs. With the aim to study the hydrogeochemical behavior of a standing column well and identify potential mitigation measures, a coupled thermo-hydro-chemical (THC) model is presented. In this work, geochemical reactions are expressed as slow chemical reactions for precipitation and dissolution while fast reactions are used to model local equilibrium reactions. The resulting model involves nine solute chemical species and three slow elementary reactions involving calcite. Reaction rate constants of these reactions are obtained through empirical relations taking into account groundwater temperature. The geochemical reactions are integrated within a heat and transport standing column well model that couple temperature, flow and chemical reactions. The transport equations are solved for three total concentrations under the constraint that a local equilibrium of the solute species is established. In order to validate the approach used, a simplified thermo-hydro-chemical model was developed and compared with reference solutions provided by PHREEQC. Both approaches show consistent results in terms of concentration of the aqueous species with a relative error lower than 10 %. Current simulation results confirm that dissolution in the rock around the well is possible and that a significant mass of calcite could precipitate in the well and within the mechanical equipment. Therefore, this study provides the first evidence that maintaining water quality and system's integrity in a standing column well could require water treatment systems.

Title: Analytical Approaches to Modelling Temperature Variations for a Vertical Ground-Coupled Heat Pump System

Presenter/First Author: David Tyler Gordon, University of Windsor, Windsor,

Presenter/First Author Email: gordonv@uwindsor.ca

Co-authors: Tirupati Bolisetti, University of Windsor, Windsor, ON, Canada; Stan Reitsma, GeoSource Energy Inc., Caledonia, ON, Canada; David S K Ting, University of Windsor, Windsor, ON, Canada

Abstract Body: When designing a vertical ground-coupled heat pump (GCHP) system it is important to optimize

the system by considering the thermal potential of the subsurface and various economic factors.

This paper reviews the analytical models used to size the ground heat exchanger (GHX)

component of the system; the models under consideration include the infinite-line source (ILS)

model, the infinite-cylindrical source (ICS) model, and the composite cylindrical

source (CCS) model. For comparison purposes, each model is applied to an example building utilizing a

single borehole system. The ILS model has been proven to be acceptable when investigating

long-term trends whereas the ICS and CMC models are more appropriate

for short-term trends. For a cycling system, attention should be placed on the

transient behavior of a GCHP during the first minutes of operation. Using data from building

loads and time of operation for the heat pump, the temperature variations of the heat transfer

fluid and the borehole wall are predicted for the system. It is discussed that when a system is

sized according to the larger of its peak heating or cooling demand, in situations where one is

larger than the other, annual ground temperature imbalances may result and degrade the performance of the system over time. The possible benefits of properly cycling a geothermal heat

pump include the reduction of annual ground temperature imbalances and economic savings.

This paper investigates the appropriateness of using the CCS model for illustrating the short-

term ground and fluid temperature responses when cycling a GCHP.

Title: Projected changes to hot air-temperature spells for Canada based on a Regional Climate Model ensemble

Presenter/First Author: Dae Il Jeong, University of Quebec at Montreal UQAM, Montreal,

Presenter/First Author Email: jeong@sca.uqam.ca

Co-authors: Laxmi Sushama, St. Francis Xavier University, Antigonish, Canada; Gulilat Tefera Diro, University of Quebec at Montreal UQAM, Montreal, QC, Canada; M. Naveed Khaliq, National Research Council, Ottawa, ON, Canada; Hugo Beltrami, St. Francis Xavier University, Ottawa, ON, Canada; Daniel Caya, Ouranos Consortium, Montreal, QC, Canada

Abstract Body: Extreme hot spells can have significant impacts on human society and ecosystems, and therefore it is important to assess how these extreme events will evolve in a changing climate. In this study, the impact of climate change on hot days, hot spells, and heat waves, over 10 climatic regions covering Canada, based on 11 Regional Climate Model (RCM) simulations from the North American Regional Climate Change Assessment Program (NARCCAP) for the June to August summer period, will be presented. These simulations were produced with six RCMs driven by four Atmosphere-Ocean General Circulation Models (AOGCM), for the A2 emission scenario, for the current 1970–1999 and future 2040–2069 periods. Two types of hot days, namely HD-1 and HD-2, defined respectively as days with only daily maximum temperature (Tmax) and both Tmax and daily minimum temperature (Tmin) exceeding their respective thresholds (i.e., period-of-record 90th percentile of Tmax and Tmin values), are considered in the study. Analogous to these hot days, two types of hot spells, namely HS-1 and HS-2, are identified as spells of consecutive HD-1 and HD-2 type hot days. In the study, heat waves are defined as periods of three or more consecutive days, with Tmax above 32°C threshold. Results suggest future increases in the number of both types of hot days and hot spell events for the 10 climatic regions considered. However, the projected changes show high spatial variability and are highly dependent on the RCM and driving AOGCM combination. Extreme hot spell events such as HS-2 type hot spells of longer duration are expected to experience relatively larger increases compared to hot spells of moderate duration, implying considerable heat related environmental and health risks. Regionally, the Great Lakes, West Coast, Northern Plains, and Maritimes regions are found to be more affected due to increases in the frequency and severity of hot spells and/or heat wave characteristics, requiring more in depth studies for these regions to facilitate appropriate adaptation measures.

Title: Sensitivity of Summer Stream Temperatures to Climate Variability in the Pacific Northwest United States

Presenter/First Author: Charles Luce, USDA Forest Service, Boise, ID

Presenter/First Author Email: cluce@fs.fed.us

Co-authors: Brian P Staab, US Forest Service, Portland, OR; Marc G Kramer, University of Florida, Ft Walton Beach, FL; Seth J. Wenger, University of Georgia, Athens, GA; Dan Isaak, USDA Forest Service, Boise, ID; Callie McConnell, , ,

Published Material: Recently published in a paper in Water Resources Research (Summer 2014). No presentation has been made at a professional society meeting.

Abstract Body: Estimating differences in thermal response among streams to a warming climate is important for prioritizing native fish conservation efforts. While there are plentiful estimates of air temperature responses to climate change, the sensitivity of streams, particularly small headwater streams, to warming temperatures is less well understood. A substantial body of literature correlates sub-annual scale temperature variations in air and stream temperatures driven by annual cycles in solar angle; however, these may be a low-precision proxy for climate change driven changes in the stream energy balance. We analyzed summer stream temperature records from forested streams in the Pacific Northwest for interannual correlations to air temperature and standardized annual streamflow departures. A significant pattern emerged where cold streams always showed lower sensitivities to air temperature variation, while warm streams could be insensitive or sensitive depending on geological or vegetation context. A pattern where cold streams are less sensitive to direct temperature increases is important for conservation planning, although substantial questions may yet remain for secondary effects related to snow, runoff, groundwater, or vegetation changes induced by climate change.

Title: River Temperature Dynamics and Corresponding Surface / Streambed Heat Fluxes

Presenter/First Author: Daniel Caissie, Fisheries and Oceans Canada, Moncton, NB

Presenter/First Author Email: Daniel.Caissie@dfo-mpo.gc.ca

Co-authors: Barret Kurylyk, University of Calgary, Calgary, AB, Canada; Nassir El-Jabi, , , ; André St-Hilaire, Institut National de la Recherche Scientifique - centre Eau, Terre et Environnement, Quebec city, QC, Canada; Kerry T B MacQuarrie, University of New Brunswick, Fredericton, NB, Canada

Published Material: Some of the findings within the presentation was published in the Journal of Hydrology (2014: 519: 1441-1452)

Abstract Body: The thermal regime of rivers plays an important role in the overall health of aquatic ecosystems. River water temperature is important for water quality parameters that are considered when conducting environmental impact assessments and developing effective fisheries management. As such, it is important to understand the thermal behaviour of rivers and related heat exchange processes. This study looks at different heat exchange processes responsible for water temperature variability on both temporal (e.g., diel, daily, seasonal) and spatial scales (small vs. large rivers). Both surface and streambed heat fluxes were quantified within the studied watercourses. Surface heat flux was quantified using data from instream microclimate stations whereas streambed heat flux was quantified using measured temperatures within the streambed. Accordingly, streambed temperatures were measured at different depths and were used as a tracer to predict the magnitude and direction of

groundwater flow using an inverse solution to the advection-conduction heat transport equation. The streambed flux analysis was carried out under different conditions, namely under natural surface water temperature conditions (i.e., as measured in the field), under steady-state conditions (e.g. under stream ice cover) and for conditions where the surface water temperatures followed a sinusoidal function. Modeling examples will be presented, including the implication of using water temperature models as a tool to better understand and protect important fisheries resources under current climate as well as under future climate conditions.

Title: Using Distributed Temperature Sensing (DTS) and LDCA to Parse Thermal Forcings in Small Creeks

Presenter/First Author: Christine E. Hatch, University of Massachusetts Amherst, Amherst, MA

Presenter/First Author Email: chatch@geo.umass.edu

Co-authors: David A Boughton, NOAA Fisheries, Santa Cruz, CA; Ethan Mora, , ,

Published Material: Method published in WRR 2014, partially presented at AGU's Fall meeting in 2012

Abstract Body: Temperature has long been used as an indicator of ecosystem health and suitability for aquatic species, particularly in sensitive areas crucial to the persistence of declining fish populations. Typically, stream temperature surveys have long duration but only at point locations, limiting the precision of efforts to predict stream temperatures or understand broader climate linkages, and single–logger data give no insight into the spatial heterogeneity of thermal conditions often exploited by biota. Distributed Temperature Sensing (DTS) provides temperature data at high spatial and temporal resolution up to 5–km in length, allowing for detailed assessment of a creek's heat budget. Rather than calculating a detailed energy balance from a single site or using a statistical approach, here we describe a hybrid method that uses Least Dependent Component Analysis (LDCA) capable of taking advantage of DTS data density in time and space. The method identifies distinct thermal components in the stream's heat budget, using only temperature data and an algorithm based on mutual information that parses signals in the temperature data into dominant components or groups of parameters that force temperature signals in similar ways. These signals can be interpreted as sets of heat-flux elements sharing coordinated (non-independent) dynamics, both simplifying the number of heat budget components as well as the number thermally forcing stream temperatures. Comparing these components to meteorological data and fluvial system structure allowed us to relate the groups back to causal heating and cooling mechanisms, which can be tested directly with targeted heat-budget studies. We applied this method to a small, arid–land creek, and found that a minimum of three distinct components were necessary to describe the thermal heterogeneity of a 1–km reach. We could also estimate a spatial response profile of each component, yielding insight into possible links between stream geomorphology and function. This method shows promise to aid with siting and defining detailed heat–budget studies, determining the dimensionality of heat budgets in natural streams, and more broadly for associating thermal components to fluvial structure and processes.

Title: Quantifying Groundwater-Surface Water Interactions with a Stream Energy Balance, Cordillera Blanca, Peru

Presenter/First Author: Lauren Dorothy Somers, McGill University, Montreal,

Presenter/First Author Email: lauren.somers@mail.mcgill.ca

Co-authors: Jeffrey M McKenzie, McGill University, Montreal, QC, Canada; Laura Lautz, Syracuse University, Syracuse, NY; Ryan Gordon, Syracuse University, Syracuse, NY; Oliver Henry Wigmore, The Ohio State University, Columbus, OH; Bryan G Mark, OSU-Byrd Polar Rsrch Ctr, Columbus, OH

Abstract Body: Communities and industries in the Cordillera Blanca mountain range, Northern Peruvian Andes, rely extensively on streams fed by both groundwater and glacier meltwater for water during the dry season. It is hypothesized that groundwater baseflow accounts for at least half of the overall stream discharge during the dry season. Heat tracing (energy balance) was used to determine groundwater advection to the stream. Data was collected along a 4 km reach of the Quilcayhuanca River, including meteorological observations, stream discharge, stream dimensions, groundwater temperature, shading and view to sky observations. Stream temperature was also recorded using thermochrons at 39 points along the stream for 4.9 days. Field data was used to determine boundary conditions for a numerical stream temperature model, HFLUX (http://hydrology.syr.edu/hflux.html). The model calculates all energy fluxes entering and leaving the stream, including solar radiation, advection of groundwater, evaporative heat flux, sensible heat flux, and streambed conduction. The model, which calculates a stream temperature profile through time, was calibrated to measured temperatures. A groundwater baseflow profile for the stream is derived from the calibrated model. It is observed that groundwater baseflow dampens diurnal temperature fluctuations and that, during most of the day, the groundwater temperature is warmer than the stream temperature. Model sensitivity analysis showed that the simulations were, in decreasing order, most sensitive to solar radiation, groundwater baseflow volume, and groundwater temperature. These results suggest that groundwater-surface water interactions in the Cordillera Blanca have a significant impact on the stream thermal regime system and that the stream energy balance may be a viable way to quantify groundwater contributions.

Title: Spatial Variability of Thermal Refuges Analysed in Relation to Landscape Hydromorphology in the Restigouche River Watershed

Presenter: Normand Bergeron, INRS, Quebec, QC

Presenter Email: normand.bergeron@ete.inrs.ca

First Author: Stephen Dugdale, University of New Brunswick, Fredericton,

First Author Email: stephen.dugdale@unb.ca

First Author Student?: No

Co-authors: André St-Hilaire, Institut National de la Recherche Scientifique - centre Eau, Terre et Environnement, Quebec city, QC, Canada

Published Material: The findings are currently in the proofing stage and will be imminently published in Remote Sensing of Environment.

Abstract Body: Water temperature is an important variable governing the distribution and behaviour of fish. Salmonids are particularly intolerant of high temperatures and survive heat waves using discrete units of cold water, known as 'thermal refuges'. Currently, patterns of thermal refuge distribution and the mechanisms governing it are poorly understood, especially at large scales. However, given that climate change poses a threat to salmon populations in Europe and North America, these cold

water units are increasingly important for salmonids in the summer. We used airborne thermal infrared thermal imaging (TIR) to characterise the spatial distribution of thermal refuges in nearly 700 km of rivers in the Restigouche River watershed. Thermal refuges were classified into different categories, with those identified as groundwater-driven proving to be the most abundant. GIS analysis was used to assemble a series of landscape metrics that were tested for links with the spatial distribution of groundwater thermal refuges. Jacobs' selectivity index was used to investigate the relationship between landscape metrics and the local-scale occurrence of thermal refuges. Results showed that the presence of thermal refuges was significantly associated with high values of channel curvature (X2 $p < 0.05$, df = 9). Regression analysis was used to assess correlations between landscape metrics and the larger-scale density of thermal refuges (no. refuges per river km). Using a quadratic model ($R^2 = 0.83$, $p < 0.05$), we observed a strong correlation between the river's entrenchment ratio (a measure of channel confinement) and the density of thermal refuges. Our results indicate that the spatial distribution of groundwater thermal refuges is strongly connected to landscape hydromorphology. This is the first study to examine the spatial distribution of thermal refuges at riverscape scales and it is hoped that such data will help conservation efforts to preserve critical thermal habitats in rivers threatened by climate change.

Title: Preserving, augmenting, and creating cold-water thermal refugia in rivers: concepts derived from research on the Miramichi River, New Brunswick

Presenter/First Author: Barret L Kurylyk, Organization Not Listed, Fredericton, NB

Presenter/First Author Email: bkurylyk@gmail.com

Co-authors: Kerry T B MacQuarrie, University of New Brunswick, Fredericton, NB, Canada; Tommi Linnansaari, University of New Brunswick, Fredericton, NB, Canada; Richard A. Cunjak, University of New Brunswick, Fredericton, NB, Canada; Allen Curry, Canadian Rivers Institute, Fredericton, Canada

Published Material: This research has been published online in the journal *Ecohydrology* under the same title as this abstract (DOI: 10.1002/eco.1566).

Abstract Body: Summer water temperatures are rising in many river systems in North America, and this warming trend is projected to intensify in the coming decades. Cold-water fish may alleviate thermal stress in summer by aggregating in discrete cold-water plumes that provide thermal refuge from high ambient river temperatures. Reliance on cold-water thermal refugia is expected to increase in a warming climate, and many river reaches already lack suitable thermal refugia as a result of an absence of thermal diversity. A comprehensive fish management strategy could proactively address this imminent threat to cold-water fish populations across North America by preserving existing thermal refugia, augmenting thermal anomalies to improve performance as refugia, and creating new thermal refugia in uniformly warm river reaches.

We provide practical recommendations on how these measures can be accomplished based on insight derived from recent research focused on the Miramichi River, New Brunswick. Opportunities include limiting land use change, construction aggregate extraction (e.g. sand and gravel pits), and groundwater pumping/consumption. Existing thermal anomalies can be enhanced by controlling advective thermal mixing between cold-water tributaries and the river mainstem flow, installing riparian shading, and adding temporary structures for protection from avian predators. New refugia can be created by temporarily pumping groundwater to discrete points within the river during periods of thermal stress. These concepts are discussed in the context of a comprehensive thermal refugia management strategy.

Title: Multi-layer stratification of groundwater temperatures in Ordovician and Silurian aquifers at the Victor Diamond Mine, as evidence of groundwater recharge under past cold climate conditions and limited deep groundwater circulation in James Bay Lowlands, near Attawapiskat, Ontario

Presenter/First Author: Simon Gautrey, AMEC, Hamilton,

Presenter/First Author Email: simon.gautrey@amecfw.com

Co-authors: Patrick Rummel, , , ; Brian Steinback, , ,

Abstract Body: The Victor Diamond Mine is located in the James Bay Lowlands, approximately 90 km west of Attawapiskat. The mine site is underlain by up to 270 m of flat lying sedimentary bedrock capped by up to 60 m of marine sediments from the post glacial Tyrell Sea. Groundwater temperatures collected from monitoring locations around the mine reveal three horizons of stable groundwater temperature, in addition to a shallow horizon of seasonal variation. These horizons are: an upper horizon of approximately 150 m of predominantly limestone bedrock with temperatures between 4.0 to 4.5 °C; a middle horizon of predominantly limestone from approximately 150 to 220 m depth with temperatures between 2.5 to 3.3 °C, and a lower horizon from 220 to 270 m depth of mudstone with temperatures greater than 5.0 °C. While the temperature of the upper horizon matches the average annual groundwater temperature in the overburden suggesting the temperatures are advection controlled, and the temperature of the lower horizon can be explained by the geothermal gradient, the temperature of the middle horizon is anomalously low. Based on groundwater chemistry data, previous investigators at the site had hypothesized that there was relic Tyrell Sea Water trapped in some aquifers. The temperature data presented herein supports this hypothesis. The presence of a wide area of low temperature groundwater at the site, approximately 4,400 years after the retreat of the Tyrell Sea and 7,900 years after the retreat of the glaciers suggests that there is limited groundwater circulation in the deeper limestone aquifers of the James Bay Lowlands. Furthermore, given the Tyrell Sea was present in the area for 3,500 years, the data implies either more active groundwater circulation during the Tyrell Sea period, or different hydrogeologic conditions possibly driven by a glacial advance over sea water.

Title: Soil and vegetation development affect the evolution of hydrological pathways in engineered hillslopes

Presenter/First Author: Willemijn M Appels, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: willemijn.appels@usask.ca

Co-authors: Andrew M Ireson, University of Saskatchewan, Saskatoon, SK, Canada; Jeffrey McDonnell, University of Saskatchewan, Saskatoon, SK, Canada; Lee S. Barbour, University of Saskatchewan, Saskatoon, SK, Canada

Published Material: Parts of this work have been presented at the GSA annual meeting in Vancouver, October 2014.

Abstract Body: The structure and hydraulic properties of soils and bedrock within a hillslope combined with the timing and rates of water availability control the partitioning of precipitation into vertical and lateral flowpaths. In natural hillslope sites, heterogeneity in both soil texture and structure are the result of long-term landscape evolution processes and consequently can be assumed to be static relative to the timescale of rainfall-runoff processes. However; engineered hillslopes, constructed commonly as reclamation covers overlying mine waste, have been observed to undergo rapid changes in hydraulic properties over relatively short timescales (i.e. 3-5 years) as a result of weathering and vegetation growth. Rainfall-runoff responses on such hillslopes would therefore not only be expected to reflect seasonal dynamics, but also the evolution of the system from a relatively homogeneous initial condition to a system with increasing heterogeneity of soil texture and structure.

We present results of a combined field and modeling study of three prototype soil covers on a saline-sodic shale overburden dump north of Fort McMurray, Canada. Since their construction in 1999, soil properties, hydrological response to atmospheric and vegetative demands, and vegetation properties have been extensively monitored. The three covers have undergone substantial evolution due to freeze-thaw and wet-dry cycles processes and aggrading vegetation, increasing rooting depth and density.

In this work, we quantify hydrological processes in the reclamation covers, focusing on inter- and intra-annual patterns. To this purpose we analyzed the long-term hydrometric data with field sampling of the distribution of salts and the stable isotopes of water within soil water and subsurface flow in the base of the cover. We use a 2D Hydrus model to explore the co-evolution of soil and vegetation and quantify its effect on flow partitioning and salt movement into the soil.

Title: Hydrological Functioning of a Constructed Watershed

Presenter/First Author: Scott J Ketcheson, University of Waterloo, Waterloo, ON

Presenter/First Author Email: sjketche@uwaterloo.ca

Co-authors: Jonathan S Price, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Reclamation in the oil sands areas requires the reconstruction of entire landforms and drainage systems. Much reclamation research has focused on assessing the performance of individual hillslopes; however, there is a need for an integrated, catchment-scale approach to fully develop an understanding of the hydrological functioning of constructed watersheds. This research aims to couple the controls on water distribution, storage and release within individual landforms (reclaimed slopes, tailings sand upland aquifer and fen peatland) to their hydrologic role (i.e., storage or conveyor) within the context of the larger scale landscape in a constructed system.

The oldest slope (reclaimed in 2007) exhibited a surface infiltration rate three times larger than slopes reclaimed more recently (2012). Consequently, soil water storage was reduced on the 2012 slopes and infiltration-excess surface runoff generation conveyed water rapidly downslope during intense precipitation events. In the fen peatland, high water table levels were sustained throughout the summers of 2013 and 2014, with persistent ponded water in localized depressions in the surface of the placed peat. Large upward hydraulic gradients measured in the fen suggest strong connectivity with the tailings sand upland aquifer; however very low surface infiltration rates on the capping upland reclamation soil constrained recharge to the sand aquifer, which remains below designed water contents in much of the upland.

Title: Controls on Plot-Scale Evapotranspiration from a Constructed Fen in a Post-Mined Oil Sands Landscape, Fort McMurray, Alberta

Presenter/First Author: Sarah Scarlett, University of Waterloo, Waterloo, ON

Presenter/First Author Email: sarahjscarlett@gmail.com

Co-authors: Richard M Petrone, University of Waterloo, Waterloo, ON, Canada; Jonathan S Price, University of Waterloo, Waterloo, ON, Canada

Abstract Body: In the oil sands development region of the Western Boreal Plains (WBP) mining companies now recognize the importance of peatland ecosystems, as they cover >60% of the regional pre-mined landscape. To date, reclamation efforts have been focused on uplands and open water marsh wetlands. However, these wetland systems are not abundant in the sub-humid climate of the WBP due to high evaporative demand, where evapotranspiration (*ET*) is the dominant hydrologic flux from wetlands in this region. Suncor's pilot constructed fen was completed in 2013, engineered with the intent to support natural fen vegetation and hydrologic processes. The purpose of this study is to evaluate the influences of vegetation and treatment types on evapotranspiration demands from the constructed fen. Multiple study sites (31) were monitored across the fen during the 2014 field season, located in vegetation plots (control/moss/vascular) with varying treatments (mulched/unmulched). Plot-scale actual *ET* was quantified with weighing lysimeters and chamber measurements. These measurements were used to adjust equilibrium *ET*, calculated using Priestly-Taylor for control and moss plots and Penman-Monteith for seedling plots, where values of stomatal resistance and leaf area index were available. A roaming meteorological station was used to quantify available energy over individual plot types. *ET* rates were, on average, lower in moss plots than control and vascular. Mulch further reduced *ET*, with lowest rates in mulched moss plots. These trends were likely caused by different thermal regimes and lower available energy in mulched plots, where ground temperatures were ~3°C lower. Mulch further provided a favorable microclimate for moss establishment by elevating near-surface relative humidity. Currently, these reclamation practices have not yet been well tested in this region and have relied on knowledge from other study areas where climate is dissimilar. The results of this study will provide insight into effective reclamation practices for reducing evaporative stress and ensuring successful establishment of functioning peatland ecosystems in the WBP.

Title: Examining the Water Use Efficiency of a Constructed Fen-Upland Watershed in Alberta, Canada.

Presenter/First Author: George Sutherland, University of Waterloo, Waterloo, ON

Presenter/First Author Email: george.sutherland@uwaterloo.ca

Co-authors: Richard M Petrone, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Oil sands development in the western boreal plains (WBP), northern Alberta, involves widespread surface mining, which disturbs natural ecosystems. More than 50% of the land cover impacted by oil sands leases are wetlands--the majority of which are fen peatlands. Recently, oil sands companies have focused on testing the concept of constructing peatlands into their post-extraction closure landscape. This research uses eddy covariance and climate monitoring systems to examine the fluxes of energy, H2O, and CO2 between a constructed fen-upland watershed and the atmosphere. The objective of this is to characterize the hydro-meteorologic functioning and initial trajectory of the constructed watershed relative to natural upland-fen systems over a two year (2013-2014) monitoring period following construction. Results from 2013 indicate that while evapotranspiration (ET) from the constructed fen was greater than ET from the upland, both fell below climate normals and ET measured from natural fen peatlands in the same region. In addition, both the constructed fen and upland were sources of CO2 in 2013; however, the constructed fen shifted to a small sink of CO2 in 2014, while increasing its ET by 50% relative to 2013. Precipitation and soil moisture were limiting factors in the constructed upland, which remained a source of CO2 in 2014 and experienced ET rates comparable to 2013. With vegetation growth, both the constructed fen and upland experienced an increase in their water use efficiency (WUE) over the two year study period.

Title: Multi-Year Water Balance Assessment of a Constructed Wetland, Fort McMurray, Alberta

Presenter/First Author: Erin Nicholls, McMaster University, Hamilton,

Presenter/First Author Email: nicholem@mcmaster.ca

Co-authors: Sean Kevin Carey, McMaster University, Hamilton, ON, Canada; Gordon B Drewitt, , , ; Elyn Humphreys, Carleton University, Ottawa, ON, Canada; M. Graham Clark, Carleton University, Ottawa, ON, Canada; Carl A Mendoza, University of Alberta, Edmonton, AB, Canada

Abstract Body: Surface mining for oil sands strips away the boreal landscape, leaving behind open pits, tailings and overburden piles. While previous reclamation efforts have focused on upland forests, rebuilding wetland systems is less well understood. The success of constructed wetlands is dependent on the supply and storage of water to promote wetland vegetation, peat accumulation and limit elevated salinity. In 2012, Syncrude Canada Ltd. completed construction of the Sandhill Fen Watershed (SFW), a 52-ha upland-wetland system designed to evaluate wetland reclamation strategies. SFW includes upland hummocks, vegetated swales, a water storage pond, fen wetland and an underdrain system. The objective of this study is to develop a water balance for the SFW. A semi-distributed water balance approach was utilized to quantify fluxes and stores within different landscape units. Fresh water was pumped into the system from a nearby lake, and outflow was measured at a weir and sump that collected surface and subsurface drainage. ET was measured using three eddy covariance towers at upland and lowland sites. Precipitation was quantified using tipping buckets, snow surveys, and continuous depth and SWE measurements. 29 near surface wells measured water table fluctuations in along with deep piezometers measuring deeper flow pathways. Results reported range from January 2013 through October 2014 and present the calculation of water balance components in the upland and lowland areas. In 2013, lateral inflow and outflow dominated hydrological fluxes and precipitation was higher than the climatic normal. In 2014, pumps remained mostly off, with vertical fluxes controlling the water balance. Lateral redistribution of water from uplands to wetlands was observed in 2014. Higher ET rates were observed in 2013 than 2014 at upland and lowland locations, with higher ET from the lowland tower in both years. Water table in 2013 fluctuated greatly, while in 2014, water table slowly declined throughout the summer and responded to large rain events in the fall. With 2013 highly managed, and 2014 climatically normal with little artificial controls, comparisons between these years provide insight on how management practices influence the hydrologic dynamics and the overall water balance of the SFW.

Title: Carbon and water vapour fluxes for the first two years of a constructed wetland.

Presenter/First Author: M. Graham Clark, Carleton University, Ottawa, ON

Presenter/First Author Email: matthewgclark@cmail.carleton.ca

Co-authors: Elyn Humphreys, Carleton University, Ottawa, ON, Canada; Sean Kevin Carey, McMaster University, Hamilton, ON, Canada

Abstract Body: The Sandhill Fen Watershed project is a pilot study by Syncrude Canada Ltd. involving the construction of a 50 ha mixed upland (forested) and lowland (wetland) watershed. The project is the first large scale attempt in constructing a boreal peatland and as such will help assess certification for mine closure. The physical construction was completed in 2012 with the initial re-vegetative planting occurring in the same year. In 2013 pumps were used to simulate ground water through-flow and in 2014 the pumps were disengaged to allow the system to naturally respond. Throughout this period the vegetation, both planted and colonized, developed a substantial cover over soil and peat substrates. This study contrasts the first two years of atmospheric energy, water, and carbon fluxes to the atmosphere during the wetland ecosystem's initial development. In 2013 there was a net loss of carbon from the lowland regions, but by 2014 the carbon balance was almost neutral. Evapotranspiration from the ecosystem also increased over the same period. As the lowlands mature, energy and carbon fluxes appear to be shifting towards what is observed in naturally formed boreal peatlands. Furthermore, over the two years, and despite high concentrations of sulphur, preliminary evidence suggests that methanogenic communities appear to be establishing in the wetland.

Title: Evaluating the Effectiveness of an Inversion Technique for Well-Pad Restoration to a Peatland Ecosystem: Ecohydrological Conditions and Carbon Exchange

Presenter/First Author: Maria Strack, University of Calgary, Calgary, AB

Presenter/First Author Email: mstrack@ucalgary.ca

Co-authors: Matthew Coulas, , , ; Bin Xu, Northern Alberta Institute of Technology, Peace River, AB, Canada; Gabrielle Préfontaine-Dastous, , , ; Line Rochefort, , ,

Published Material: Vegetation data from 2013 was presented as a poster at a small scientific meeting for industry and academic partners.

Abstract Body: A large portion of the oil sands deposit in boreal Alberta is accessible only by in situ extraction techniques that involve the construction of well pads distributed across the boreal landscape. Given that at least 30% of the region is covered by peatland, many of these well-pads are constructed within these wetland ecosystems. We tested a well-pad inversion technique involving either complete removal of the mineral soil pad and inversion of the previously buried peat or inversion of some of the pad and peat (resulting in mineral soil burial). On top of the resulting peat surface, the moss layer transfer technique was used to reintroduce plants to the site with donor material sourced from areas dominated by 1) *Sphagnum* moss, 2) brown mosses or 3) Polytrichum moss. These treatments were compared to areas without plant reintroduction both with and without straw mulch. During the second full growing season following plant reintroduction, total vegetation cover was over 60% across the pad, being lowest in the section without plant introduction or mulch. Bryophyte cover was lower and graminoid cover higher than the neighbouring undisturbed peatland. There was little effect of the source of vegetation material on the resultant plant cover. Water table was on average deeper than the neighbouring peatland, although both wetter and drier areas were present with no clear effect of inversion type. The ecohydrological conditions combined to result in greater productivity on the restored well-pad than in the surrounding peatland. Although initial ecohydrological conditions remain dissimilar to the undisturbed peatland, the rapid revegetation by wetland plants including bryophytes, favourable water table position, and uptake of carbon dioxide during the growing season suggest that inversion is a promising technique for restoration of well-pads to peatland ecosystems.

Title: Integrating weather and climate predictions for seamless hydrologic ensemble forecasting: A case study in Yalong River basin

Presenter/First Author: Aizhong Ye, Beijing Normal University, Beijng,

Presenter/First Author Email: azye@bnu.edu.cn

Co-authors: Qingyun Duan, Beijing Normal University, Beijing, China; Xiaoxue Deng, Beijing Normal University, Beijing, China; Feng Ma, BNU Beijing Normal University, Beijing, China; Zheng Zhou, Beijing Normal University, Beijing, China

Abstract Body: The accuracy of precipitation forecasts by numerical weather and climate models has been improved in recent years. However, these forecasts still cannot be used directly for hydrological forecasting and must be post-processed to extract useful predictive information. In this paper, we study how different designs of canonical events can help post-processing of Global Ensemble Forecast System (GEFS) precipitation forecast products and improving hydrological forecasting in Yalong River basin, China. First, we selected different types of canonical events for precipitation and compared post-processed precipitation with observed precipitation. Second, we used the post-processed precipitation to drive a distributed hydrological model to obtain hydrological ensemble forecasts and compared those forecasts with observed streamflow. We found that design of canonical events can help extract more useful information, especially using up to date observed precipitation to set up canonical events. We also revised the “Schaake shuffle” to improve the accuracy of precipitation forecasts from combined events. Last, we integrated GEFS and Climate Forecast System version 2 (CFSv2) precipitation forecasts and used them to generate seamless hydrological forecasts across different time scales. The integrated streamflow forecasts have longer lead times and higher accuracy than ESP streamflow forecasts and the forecast based on original CFSv2 precipitation forecasts.

Title: The Dynamics of East African Climate and the Suitability of crop Mapping over the Mountainous Areas in a changing climate

Presenter/First Author: George Otieno, University of Nairobi, Nairobi,

Presenter/First Author Email: gotieno2000@gmail.com

Abstract Body: The East African region is bordered by mountains that are crucial in modulating the climate of the region. The current evidence of climate change and climate variability poses risks to the sustainable development of the society.

The study examined trends in projected rainfall and air temperature and suitability of growing major staple food under a changing climate around the mountainous areas of Kenya, Uganda, Tanzania and Ethiopia.

The data used were observed rainfall, temperature, the second version of African Rainfall Climatology (ARC2) for the period 1981-2010 and future projection from 2011-2040, model estimates of future climate scenarios under Representative Concentration Pathway (RCP 4.5) was obtained from Coupled Model Inter-comparison Project Phase 5(CMIP5). The Mann-Kendal test was used for trend analysis and the FAO ECO-crop model was used for suitability mapping of various agricultural zones for production of maize and beans at the lowlands and down slope of the mountainous areas.

At least ten stations indicated a temperature rise of 0.3 per decade. High seasonal rainfall variability was experienced during March-May and October-December seasons. The values of Mann-Kendal were in the range of 0.8 - 2.0. The projection showed that temperature will continue to rise by about 0.5 per decade.

There was marginal suitability for production of beans and maize over most parts of the four countries. Most of the western and central part of Kenya showed high potential for production of the two crops. This trend was also reported in central Part of Uganda and coastal area of Tanzania.

The future suitability mapping for crops production showed quite similar patterns as the current situation. The highland and rift valley regions would no longer be suitable for growing the crops. The increased human activities around these regions like deforestation probably could account for the decline in suitability of growing these crops.

The threats from climate change are likely to impact negatively on the agricultural activities around the mountainous areas. The farming community living around the slopes of the mountainous areas should diversify the farming activities and best practices to cope with current climate variability and adapt to future climate changes.

Title: Forecasting of Rainfall under rainfed agriculture of Pakistan

Presenter/First Author: Mukhtar Ahmed, Organization Not Listed, Rawalpindi,

Presenter/First Author Email: ahmadmukhtar@uaar.edu.pk

Co-authors: Fayyaz ul Hassan, Comsats Institute of Science and Technology, Islamabad, Pakistan

Abstract Body: Farmers in dry areas are vulnerable to climatic fluctuations and they need adjustment in the agricultural management to the amount and timing of rainfall to optimise yield and economic returns for a given season at a specific location. Skilful long-range forecasts of rainfall can increase the preparedness of farm managers above a level that is solely based on past experiences. The two prominent modes of interannual variability that impact the Indian subcontinent are the El-Niño Southern Oscillation (ENSO) and the Indian Ocean Dipole (IOD). Forecasting of intermittent rainfall in dryland areas of Pakistan like Pothwar poses

number of major challenges. One of the challenges relates to modelling zero, skewed, non-stationary, and non-linear data. To address this, a probabilistic statistical model to forecast monsoon and wheat growing period rainfall was applied to three dryland areas of Pothwar. The model uses logistic regression through Generalised Additive Models (GAMs) to determine the probability of rainfall, occurring in the systems. This study explores climatic predictors (Indian and Pacific Ocean SSTs indicating states of the ENSO and the IOD) those influence rainfall variability over the Indian subcontinent for their usefulness in forecasting seasonal rainfall (monsoon rainfall and three rainfall intervals during the wheat growing season). The output revealed that in the study region the occurrence and variability of rainfall was driven by SSTs, therefore forecasts can be made with good skill to bridge the gaps between potential and average wheat yield by management decisons like adjusting sowing time and use of appropriate genotypes. Furthermore the model validation for rainfall forecasting was evaluated by forecasting skill scores like R^2, NSE (Nash–Sutcliffe model efficiency coefficient), RMSE (Root Mean Square Error), S% (Skill Score S), LEPS (Leniar error in probability space), BSS (Brier Skill Score) and ROC (Receiver Operating Characteristics, p-value) to confirm the effeciency of GAM and to make comparison between different validation skills to do cross validation of forecast rainfall. Similarly, application of forecast systems across the whole value chain in agricultural production offers considerable benefits in improving overall operational management of agricultural production.

Title: Wavelet-based cross-correlation analysis of Pacific Ocean climate data and streamflow for long-term streamflow forecasting

Presenter/First Author: Andres M Ticlavilca, Utah State University, Montgomery Village, MD

Presenter/First Author Email: andres.t@aggiemail.usu.edu

Co-authors: Inga Maslova, American University, Washington, DC; Mac McKee, Utah Water Research Laboratory, Logan, UT

Abstract Body: Wavelet-based cross-correlation analysis is performed in both time and frequency domains to study lead-lag relationships between Pacific Ocean climate data and streamflow in Utah, US. The Pacific Ocean climate data are Southern Oscillation Index, Pacific sea surface temperature and sea surface temperature anomaly. The data are decomposed into meaningful components formulated in terms of wavelet multiresolution analysis. The results from the wavelet-based cross-correlation analysis are used to select the data to build a forecasting model based on a Bayesian machine learning approach. This new methodology can incorporate key information from the trends of the Pacific Ocean climate time series to produce improved long-term streamflow predictions up to 12 months ahead.

Title: Analysis Of The 2012 Flooding Events Downstream Of Shiroro Reservoir, A Case Of Gurmana Niger State, Nigeria

Presenter/First Author: Bahago Abubakar Rukayyah, Federal University of Technology, Minna,

Presenter/First Author Email: rukendabis@yahoo.com

Co-authors: Halilu Shaba Ahmad, National Space Research & Development Agency, Abuja, Nigeria; Aishetu Abdulkadir, , ,

Abstract Body: This study carried out geospatial analysis of the 2012 Flood event, downstream of Shiroro Reservoir at Gurmana in Niger State, Nigeria as an input to contingency planning and emergency management. Satellite imageries, topographic map of Niger State, administrative map of Nigeria, SRTM DEM, GPS coordinates, and flood photographs were integrated to map the flooding event, analyze the spatial extent and disaster risk areas. The results indicated that out of 67.896km² about 0.33385km² of land were flooded. Farmlands and transportation routes were severely affected with about fifty (50) members of the households in the study area were displaced. The vulnerability analysis indicated that the areas between 0-100m are highly vulnerable and between 101-200m are less vulnerable. This shows that if no measures are taken to prevent the population of buildings on the floodplains, the next flood could be a major disaster to Gurmana. On this note, I strongly recommend that the people of Gurmana should be relocated. The field observation indicates that the occurrence of flood in the study area was due to the heavy rain, which coincided with river inundation and land use land cover leading to backwash to the village since the flow into the mains were impeded. Hence a comprehensive geospatial analysis and mapping for emergency management, disaster management and flood contingency planning in the region is inevitable.

Title: Record ice cover on Lake Superior in 2014: Observations and implications

Presenter/First Author: Jay A Austin, University of Minnesota Duluth, Duluth, MN

Presenter/First Author Email: jaustin@d.umn.edu

Co-authors: Daniel Titze, , ,

Abstract Body: Record-breaking cold in the Laurentian Great Lakes region during the winter of 2013-2014 resulted in abnormally long and intense ice cover on Lake Superior. The ice climate on Superior fell well outside the recent range of observed variability. Mooring observations from three locations in the western, central and eastern portions of the lake provide insight into the behavior of the lake during heavy ice cover. Surface heat fluxes were dramatically dampened during the season, and the character of the circulation in the upper water column changed dramatically. Observations of ice drift velocities were made using an ADCP, showing that ice drift direction was consistent with local winds, and ice drift speeds were a consistently about 3% of wind speeds across a wide range of wind speeds. This close coupling suggests that the force balance on the ice is a simple balance between wind and water drag. Ice keels of 6m thickness occurred on a regular basis throughout the season, and ice keels of up to 12m depth were observed. The impact of the high ice cover was felt through the remainder of the year, with the onset of stratification delayed in the lake until early to mid-August, resulting in a short, cool summer season.

Title: An Observational Study of the Influence of Ice Formation on Heat and Water Loss from the Upper Great Lakes.

Presenter/First Author: Peter Blanken, University of Colorado, Boulder, Boulder, CO

Presenter/First Author Email: blanken@colorado.edu

Co-authors: Christopher Spence, Environment Canada Saskatoon, Saskatoon, SK, Canada; John D Lenters, LimnoTech, Ann Arbor, MI; Andrew Gronewold, NOAA Ann Arbor, Ann Arbor, MI

Abstract Body: Ice cover on the Great Lakes is highly variable in both space and time, and poorly understood feedbacks between the lakes and atmosphere hinder our ability to predict fluctuations in water levels due to wintertime ice conditions. The economic costs of ice can be large, with an estimated shipping loss alone of $705 million in 2013-14. When ice is present, its cover is usually discontinuous with areas of exposed water in direct contact with the atmosphere. Using time-lapse photography and remote sensing, we detailed the development of ice formation on northern Lake Michigan, and related this to simultaneous direct measurements of the turbulent fluxes of sensible and latent heat using the eddy covariance approach. Footprint analysis of the area contributing to the turbulent fluxes together with the fraction of ice cover in the sampling area allowed us to examine the dynamic changes in sensible heat and evaporative water loss that occur as ice developed. Significant decreases in the sensible and latent heat fluxes occurred when an ice cover of 30% was achieved. Annually, compared to adjacent ice-sparse northern Lake Huron, ice resulted in a 43% reduction in the evaporative water loss, and a 57% reduction in the sensible heat loss.

Title: Elucidating the Primary Mechanisms Responsible for the Rapid Warming of the Laurentian Great Lakes

Presenter/First Author: Michael Notaro, University of Wisconsin-Madison, Madison, WI

Presenter/First Author Email: mnotaro@wisc.edu

Co-authors: Yafang Zhong, University of Wisconsin Madison, Madison, WI; Stephen J Vavrus, Univ Wisconsin, Madison, WI

Published Material: We have not written a publication on these results yet. We presented the results at the 2014 AGU Fall Meeting. We were invited to submit an abstract for an invited talk by John Lenters.

Abstract Body: During the last three decades, the Laurentian Great Lakes have exhibited rapid warming, particularly the deep portions of Lakes Superior and Michigan. The fact that the lakes are warming more rapidly than air over nearby coastal regions is counterintuitive from the simple perspective of heat capacity. The summertime lake warming is characterized by a distinct step function jump between 1997 and 1998. The currently accepted paradigm for this rapid lake warming is the ice albedo feedback, triggered by a rapid decline in lake ice cover since the late 1970s. Here, we challenge this paradigm through the application of a high-resolution regional climate model, focusing specifically on the 1997-1998 transition as the primary cause for the long-term lake temperature trend. Through a series of carefully designed manipulation experiments, we decompose the relative contribution of antecedent wintertime lake conditions (e.g. lake temperatures, ice cover) versus synchronous, springtime-to-summertime large-scale meteorological forcings (e.g. air temperature, solar radiation) towards the abrupt lake warming from 1997 to 1998. Both the long-term trend (1979-pres.) and 1997-1998 transition are characterized by positive trends in 500-hPa heights, air temperatures, and solar radiation and negative trends in cloud cover during spring-summer across the basin. Over the deep lake areas, the amplified summertime warming of the lakes, compared to air, is largely attributed to antecedent warming of the wintertime lake temperatures and their subsequent support for earlier lake stratification. In contrast, the warming of shallow lake areas is primarily in response to large-scale meteorological drivers during spring-summer, namely greater solar radiation and air temperatures. Changes in winter-spring ice cover between 1997 and 1998 produce minimal impacts on the timing of lake stratification or subsequent summer lake temperatures, thereby challenging the existing ice albedo paradigm.

Title: The Great Lakes Evaporation Network (GLEN): More than just evaporation

Presenter/First Author: John D Lenters, LimnoTech, Ann Arbor, MI

Presenter/First Author Email: jlenters@limno.com

Co-authors: Peter Blanken, University of Colorado, Boulder, Boulder, CO; Christopher Spence, Environment Canada Saskatoon, Saskatoon, SK, Canada; Andrew Gronewold, NOAA Ann Arbor, Ann Arbor, MI; Branko Kerkez, University of Michigan Ann Arbor, Ann Arbor, MI; Norma Froelich, Northern Michigan University, Marquette, MI; Wendy Leger, , ,

Abstract Body: The North American Great Lakes constitute the largest freshwater surface in the world. Beginning in the late 1990s – a period that commenced with a strong El Niño event – the Great Lakes experienced a regime shift in winter ice cover and summer water temperatures that resulted in higher summer evaporation rates, followed shortly thereafter by a dramatic decline in water levels. Recent research suggests that evaporation rates over the lakes have, for the most part, remained high since then, due primarily to warmer summer water temperatures and an earlier start to the evaporation season. On the other hand, cold, high-ice winters such as 2013-14 cause occasional deviations from this trend, highlighting the large interannual variability in the Great Lakes system and the continued need for long-term observations. A growing ensemble of in situ measurements – including offshore eddy flux towers, buoy-based sensors, and vessel-based platforms – are being deployed through an ongoing, bi-national collaboration to reduce uncertainties in the Great Lakes water balance, provide a more robust basis for short- and long-term projections, and fill a significant gap in over-lake flux measurements and related meteorological data. Here, we provide an overview of this initiative, known as the Great Lakes Evaporation Network (GLEN). Although the network was initiated in response to the need for improved estimates of Great Lakes evaporation, it is intended to be of utility for a wide range of applied and basic research needs – not just evaporation and water levels. As such, we provide an overview of the latest data collection efforts, the current and planned array of instrumentation and platforms, and the network of heat, moisture, carbon flux, and meteorological observations that are likely to be of interest to research scientists, operational forecasters, commercial shipping, recreational boaters, and other stakeholders in the Great Lakes community.

Title: Recent advances in Environment Canada's modelling efforts in the Great Lakes

Presenter/First Author: Frank Seglenieks, Environment Canada, ,

Presenter/First Author Email: frank.seglenieks@ec.gc.ca

Co-authors: Vincent Fortin, Environment Canada Dorval, Dorval, QC, Canada; Dorothy A Durnford, Meteorlogical Service of Canada, Dorval, QC, Canada; Bruce Davison, Environment Canada, Saskatoon, SK, Canada; Erika Klyszejko, Environment Canada, Ottawa, ON, Canada; Murray MacKay, Environment Canada Toronto, Toronto, ON, Canada; Etienne Gaborit, Environment Canada Dorval, Dorval, QC, Canada; Milena Dimitrijevic, Environment Canada Dorval, Dorval, QC, Canada; Frederic Dupont, , , ; Stéphane Bélair, Environment Canada, Dorval, QC, Canada; Gregory C Smith, Environment Canada, Quebec, QC, Canada

Published Material: As this presentation will share results from many different researchers it is possible that some it may have been previously reported in scientific meetings or the media.

Abstract Body: The Laurentian Great Lakes are an important region of Canada both in terms of its natural resources and economic activity. Environment Canada has made this region a priority in its modelling efforts. In particular, Environment Canada has developed a coupled lake-atmosphere-hydrological modelling system consisting of the Canadian Regional Deterministic Prediction System (RDPS), which is based on the Global Environmental Multiscale model (GEM), the MESH (Modélisation Environnementale Surface et Hydrologie) surface and river routing model, and a hydrodynamic model based on the three-dimensional global ocean model Nucleus for European Modelling of the Ocean (NEMO) coupled to the Community Ice Code (CICE) see ice model.

Other modelling efforts in the region include: runoff comparisons with other agencies, short-term lake level forecasts, and examining effects of future climate forecasts on lake levels, streamflow, evaporation, soil moisture and snow water equivalent. This presentation will highlight the recent efforts by Environment Canada researchers to model the different aspects of the hydrological cycle within the Great Lakes.

Title: Streamflow Prediction in the Great Lakes Basin Using Two Watershed Discretization Schemes

Presenter/First Author: Amin Haghnegahdar, University of Waterloo, Waterloo, ON

Presenter/First Author Email: ahaghneg@uwaterloo.ca

Co-authors: Bryan Tolson, University of Waterloo, Waterloo, ON, Canada; Eric D Soulis, University of Waterloo, Waterloo, ON, Canada; Etienne Gaborit, Environment Canada Dorval, Dorval, QC, Canada; Vincent Fortin, Environment Canada Dorval, Dorval, QC, Canada

Abstract Body: The North American Great Lakes are fundamental to the society, economy, and environment in the United States and Canada. Consequently, a proper management of the Great Lakes water system is crucial for both countries. Large-scale distributed physically-based models are one of the key tools used to inform policy makers for integrated and sustainable water and environmental resources management. Representation of the heterogeneity in nature remains one of the main challenges for these models and is accomplished primarily via watershed discretization. In this work two watershed discretization schemes are compared for the application of a semi-distributed Land Surface-Hydrological modelling system, MESH (Modélisation Environmentale–Surface et Hydrologie), in the Great Lakes Basin. One scheme is simpler neglecting the within pixel heterogeneity. The second scheme is more complex representing within pixel heterogeneity using spatial land cover info. These schemes are compared in terms of their skill to predict streamflow as well as their calibration cost. Results from this work enables MESH modellers to evaluate the gain in model performance by adding more info and computational time, and select the better one that suits their interest at the end.

Title: Closing the Gap Between the Geologic and Historical Records in the Laurentian Great Lakes by Providing the Most Detailed Account of Paleo Lake Level, Ranging from Decades to Five Millennia.

Presenter/First Author: John W Johnston, University of Waterloo, Waterloo, ON

Presenter/First Author Email: jwjohnston@uwaterloo.ca

Co-authors: Kenneth E Lepper, North Dakota Univ, Fargo, ND; Erin Argyilan, Indiana University Northwest, Gary, IN; Douglas A Wilcox, , , ; Steve J Baedke, James Madison University, Harrisonburg, VA; Todd A Thompson, , ,

Published Material: A portion was recently published in a scientific journal: Johnston. J.W., Thompson, T.A., and Wilcox, D.A. (2014) Paleohydrographic reconstructions from strandplains of beach ridges in the Laurentian Great Lakes, in Martini, I. P., and Wanless, H. R., eds., Sedimentary Coastal Zones from High to Low Latitudes: Similarities and Differences: Geological Society, London, Special Publications, 388, 213-228. http://dx.doi.org/10.1144/SP388.22

Abstract Body: The current temporal and spatial context of water-level change, drivers of change, and possible future scenarios of the Laurentian Great Lakes is controversial. Paleohydrographs are being constructed from measured subsurface elevations of paleo-swash zones and modelled ages in strandplains of beach ridges that are preserved in embayments along the margins of the lakes. More than 800 elevations and 200 ages have been collected from 15 strandplains to construct site-specific strandplain paleohydrographs. Paleo shoreline elevations from whole strandplains or sets of correlative paleo-beaches within strandplains are then used to establish an outlet paleohydrograph for each lake. Adjusting strandplain paleohydrograph elevations to account for glacial isostatic adjustment (GIA) and refining age models help define the outlet paleohydrograph. This iterative approach helps identify common basin-wide water-level patterns and changes in outlet location or conveyance. Systematic patterns of elevation and geomorphic/sedimentologic properties in individual, groups and sets of beach ridges in strandplains suggest that long-term patterns of water-level change and sediment supply occurred on decadal, centennial, and millennial scales. Current data from strandplains of Lake Huron are being compared to data from Lake Michigan (Baedke & Thompson 2000) to produce an outlet paleohydrograph representative of this large hydraulically connected lake. Comparison with the outlet paleohydrograph of Lake Superior (Johnston et al. 2012) will help to decipher a more accurate understanding of GIA, water-level fluctuations, and outlet conveyance. These refinements are expected to complement the instrumental lake-level record back through time. The extended record can then be used to augment knowledge of natural (climate-driven) fluctuations and, thereby, to contribute to the effective management of the largest fresh, surface-water system in the world.

Title: Regional Analysis of Baseflow Contribution to the Grand River, Ontario, Canada

Presenter/First Author: Tricia Anne Stadnyk, University of Manitoba, Winnipeg, MB

Presenter/First Author Email: tricia.stadnyk@umanitoba.ca

Co-authors: John J Gibson, University of Victoria, Victoria, BC, Canada; Fred J Longstaffe, University of Western Ontario, London, ON, Canada

Published Material: Journal of Hydrologic Engineering; published in fall 2014

Abstract Body: With uncertainty surrounding long-term projection of in-stream flow needs, baseflow estimation is an increasingly important component of hydrology and hydrologic modelling. With several methods available to chose from, it is important to understand the advantages and disadvantages of traditional and newer methods of baseflow recession analysis. Operationally, recursive digital filtering (RDF) techniques are commonly applied; however, questions have been raised about the reliability and parameterization of these methods. A comparison of three baseflow separation methods is performed, including two popular RDFs (HYSEP and BFLOW) and one hydrologic model (WATFLOOD). The methods are applied to two baseflow dominant sub-basins of the Grand River Basin in southern Ontario, Canada. The Eramosa River and Whiteman's Creek sub-basins are similar in size (236 and 383 km^2, respectively) and have similar annual runoff distributions, yet significantly different physiography governing runoff generation. Sub-basin physiographic characteristics result in significant differences in annual baseflow distributions, and stable water isotopes (SWIs) are applied for verification of baseflow contribution. Results are shown to support the application of SWIs for regional hydrograph separation and highlight the need for more efficient, yet physically-based baseflow separation in regions with complex physiography.

Title: Human impacts on the carbon cycle of large river basins in boreal rivers of eastern Canada

Presenter/First Author: Jean-Francois Helie, GEOTOP-UQAM, Montreal, QC

Presenter/First Author Email: helie.jean-francois@uqam.ca

Co-authors: Claude Hillaire-Marcel, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Eric Rosa, Université du Québec en Abitibi-Témiscamingue, Amos, QC, Canada

Abstract Body: Carbon sources and cycling in boreal environments are currently the focus of a growing number of investigations in Eastern Canada, mainly beacause of the importance of hydropower and its potential in this region. Here, we investigate inorganic and organic carbon cycling in large eastern canadian river basins. Some of these rivers are impounded (La Grande 3400 m^3/s, Eastmain, St. Lawrence 12 100 m^3/s, Ottawa 1950 m^3/s and Nelson 2370 m^3/s) and some a pristine (Great Whales 680 m^3/s and Koksoak) river systems. These major rivers were sampled monthly at their outlet for at least one year. The St. Lawrence River has been under investigation since June of 1997 on a bi-weekly basis. Also, synoptic surveys were undertaken in August 2008 on the La Grande and Great Whales Rivers. At each visit, physico-chemical parameters were measured and samples were collected for the analysis of i) major ions concentrations; ii) $\delta^{13}C$ of dissolved inorganic and organic carbon as well as particulate organic carbon (respectively DIC, DOC and POC); iii) $\delta^{18}O$ and $\delta^{2}H$ of the water molecule; and iv) radio-isotopes (Uranium series and Strontium). In all the sampled river systems, POC concentrations were at least an order of magnitude smaller than the dissolved forms. As a result, the dissolved forms will be the focus of this investigation. Rivers draining carbonates (St.Lawrence and Nelson Rivers) present higher DIC concentrations and higher ⍰^{13}C in DIC, in response to the dissolution of soil carbonates. DOC/DIC ratios above 2.4 are observed in rivers draining silicates; their lower ⍰^{13}C-DIC content directly reflects the organic matter oxidation in soils. However, the DIC isotopic composition of impounded rivers draining silicates reflects both the organic oxidation origin of DIC and CO_2 degassing along the reservoir. The striking feature of this boreal data set is the homogeneity of the isotopic composition of DOC (-27.4±0.2‰ vs V-PDB). Moreover, C:N ratios and ^{14}C activity (A^{14}C) of bulk dissolved organic matter (MOD) measured in the La Grande River reveal that this most of the DOC is relatively fresh and young (A^{14}C higher than 100% MC).

Title: Controls of longitudinal variation in $\delta^{13}C$-DIC in rivers: A global meta-analysis

Presenter/First Author: Katherine Anne Roach, University of Quebec at Trois-Rivieres, Trois-Rivieres, QC

Presenter/First Author Email: roackat@gmail.com

Co-authors: Marco A Rodríguez, Université du Québec à Trois-Rivières, Trois-Rivieres, QC, Canada; Yves Paradis, Ministère des Forêts, de la Faune et des Parcs, Quebec, Canada, QC, Canada; Gilbert Cabana, Organization Not Listed, Trois-Rivières, Canada

Published Material: These findings are in review in the journal Ecosystems.

Abstract Body: Gas exchange between the water and the atmosphere strongly influences the $\delta^{13}C$ signature of the inorganic carbon pool in large rivers. Because the $\delta^{13}C$ signature of DIC at isotopic equilibrium with the atmosphere ($\delta^{13}C\text{-}DIC_{equilibrium}$) is dependent on pH and temperature, we were interested in determining if these physicochemical variables could be used to generate an isoscape, or a map of the stable isotope variation in DIC, in rivers. We conducted a literature survey to examine the relationship between $\delta^{13}C$-DIC and $\delta^{13}C\text{-}DIC_{equilibrium}$ in rivers throughout the world. We then used generalized additive mixed models to investigate if deviations from $\delta^{13}C\text{-}DIC_{equilibrium}$ ($\delta^{13}C\text{-}DIC_{disequilibrium}$) and $\delta^{13}C$-DIC in lotic ecosystems were related to ecological variables including the partial pressure of dissolved CO_2, elevation, and Strahler order. To evaluate if carbonate weathering or groundwater inflow was responsible for longitudinal variation in $\delta^{13}C$-DIC, we compared within-river trends in weathering products and groundwater inflow with within-river trends in $\delta^{13}C$-DIC in the main stem of 18 of the rivers. For more than 99% of the samples, DIC was more depleted in ^{13}C than $\delta^{13}C\text{-}DIC_{equilibrium}$. The GAMMs revealed that, whereas morphometric variables (elevation, Strahler order) explained a large fraction of the variation in $\delta^{13}C\text{-}DIC_{disequilibrium}$, morphometric and geochemical variables (DIC, pH, pCO_2) explained a large fraction of the variation in $\delta^{13}C$-DIC. In all rivers with limited groundwater inputs, headwaters were isotopically heavier than downstream reaches, suggesting greater inputs of DIC from groundwater than from terrestrial ecosystems. Rivers with groundwater inflow in both upper and lower reaches had higher rates of change in $\delta^{13}C$-DIC than rivers where groundwater inflow was limited to lower reaches, indicating that rivers with groundwater inputs in headwaters will be more suitable for use of $\delta^{13}C$ in analyses of the spatial ecology of consumers.

Title: Carbon isotopic ratios reveal complex strategies in the use of the hydrological network by fish in a large river ecosystem

Presenter/First Author: Luc Farly, Université du Québec à Trois-Rivières, Trois-Rivieres, QC

Presenter/First Author Email: Luc.Farly@uqtr.ca

Co-authors: Simon Boisvert, Université du Québec à Trois-Rivières, Trois-Rivieres, QC, Canada; Marco A Rodríguez, Université du Québec à Trois-Rivières, Trois-Rivieres, QC, Canada; Philippe Brodeur, Gouvernement du Québec, Trois-rivières, QC, Canada; Gilbert Cabana, Organization Not Listed, Trois-Rivières, Canada

Abstract Body: By reducing the connectivity within large river systems, dams perturb the completion of the life cycle of many mobile organisms that depend on upstream tributaries not only to reproduce but also to feed on alternate food sources. The isotopic signatures of sessile organisms, such as invertebrates, can be used to map the isotopic baselines or "isoscapes" of river systems, against which fish isotopic ratios can be compared for evidence of sendentarity or movement. Here we exploit the clear distinctiviness in carbon isotopic ratios of inorganic and organic fractions from a large tributary of the St-Lawrence River Canada compared to the river main stem to track throughout the year the movements and feeding in nine species of potentially highly mobile fish. Carbon isotope data of fish muscle tissues allowed us to identify three general migration patterns and sources of productivity in this large river system. Our study offers a better understanding of fish movements in large rivers, providing a tool to predict with more confidence the possible impacts of dam building projects on fish assemblages.

Title: *Transport of oil sands process-affected water from tailings sands to a constructed fen peatland*

Presenter/First Author: Eric D Kessel, University of Waterloo, Waterloo, ON

Presenter/First Author Email: e2kessel@uwaterloo.ca

Co-authors: Jonathan S Price, University of Waterloo, Waterloo, ON, Canada; Scott J Ketcheson, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Reclamation of the Athabasca oil sands region requires the reconstruction of fen peatlands in which mine waste materials (e.g.,petroleum coke and tailings sand) and salvaged reclamation materials (including peat) are commonly used. Tailings materials used to construct the upland areas that provides water to a constructed fen on the Suncor Energy lease have elevated concentrations of sodium (Na) and Naphthenic acids (NAs) being transported into the fen via a permeable layer beneath the peat. Peat (2 m thick) is expected to disperse and adsorp Na and NAs moving upwards through the peat profile. Water chemistry samples taken in 2013 and 2014 indicate the presence of Na and NAs at the base of the peat profile, and little in the rooting zone. For example, in 2013 Na concentrations averaged 314 mg/L in the upland (tailings sand) and 121 mg/L, 78.5 mg/L, and 87.3 mg/L in the fen peat at 150, 90, and 50 cm depths, respectively. In 2014, Na concentrations averaged 154.6 mg / L in the upland and 109 mg/L, 70.6 mg/L, and 82.1 mg/L in the fen at comparable depths, which indicates that Na present in the system was diluted. However, in 2013 NAs concentrations averaged 24.1 mg/L in the upland and 12.5 mg/L, 1.19 mg/L, and below detection in the fen at 150, 90, and 50 cm depths, respectively, generally increasing in 2014 to 26.8 mg/L in the upland and 11.1 mg/L, 5.47 mg/L, and 1.23 mg/L in the fen at comparable depths. The different behavior of Na versus NAs may be a result of NAs moving through “windows” faster than the mean rate; further assessment is required to understand this.The success of future reclaimed fen peatlands depend on designs accounting for the management of water quality. Further monitoring is required to characterize the rate of solute movement.

Title: Assessment the pools and potential redistribution of sodium in a constructed fen peatland system

Presenter/First Author: Rubi Simhayov, University of Waterloo, Waterloo, ON

Presenter/First Author Email: rbsimhayov@uwaterloo.ca

Co-authors: Jonathan S Price, University of Waterloo, Waterloo, ON, Canada

Abstract Body: A constructed fen peatland on a post-mined oil sands landscape in northern Alberta incorporates materials from the mining site into the constructed system. Peat is used for the fen, tailings sand is used for the upland and petroleum coke is used for a high permeability connecting basal layer. The use of these byproducts of oil production requires an understanding of the transport and attenuation mechanisms of potential solutes they may contain such as sodium (Na), since they may impact the plants and microbial community of the fen. To meet this goal we need a prior understanding of the type of solutes, their concentration and movement. We believe sodium (Na) to have the highest potential toxicity to plants. Material digestion results indicate that following construction peat contained the highest concentration of Na (445 mg/kg) compared with coke (215 mg/kg) and sand (80 mg/kg). However, results of a batch experiment showed that peat has the lowest range of available Na of the building materials examined. Using the results a mass balance of Na was done and the calculations indicate that a large pool of available Na exists in the created upland. This pool, which through groundwater flow is directed to the peatland, exceeds the adsorption capacity of the peat. If the outflow of Na in surface runoff from the fen is limited, as is expected, Na is likely to accumulate in the fen over the short- and medium-term, with implications for vegetation succession.

Title: A Comparison of Soil Nitrogen Availability Between a Post Mined Reclaimed Wetland and Two Natural Wetlands in Fort McMurray, Alberta.

Presenter/First Author: Chelsea Thorne, McMaster University, Hamilton, ON

Presenter/First Author Email: thornece@mcmaster.ca

Co-authors: Sean Kevin Carey, McMaster University, Hamilton, ON, Canada; Elyn Humphreys, Carleton University, Ottawa, ON, Canada; Merrin L Macrae, University of Waterloo, Waterloo, ON, Canada; Richard M Petrone, University of Waterloo, Waterloo, ON, Canada

Abstract Body: In situ measurement of soil nitrogen dynamics is a potential method for evaluating the health of constructed wetlands following oil sands mining. The objective of this study is to measure and compare the soil nitrogen availability of a reclaimed fen (Sandhill fen) with a nutrient-rich reference fen (Poplar fen) and a nutrient-poor reference fen (Pauciflora fen) in the Athabasca oil sands region of Northern Alberta. TIN, NO_3^-, and NH_4^+ supply rates were determined along hillslope-wetland transects using Western Ag Innovations Plant Root Simulator (PRS) probes at all three sites in 2014. Net N mineralization was determined simultaneously using the buried polyethylene bag approach. Overall, TIN supply rates were greatest at the poor fen and least at the constructed Sandhill fen. In contrast, net mineralization was greatest at the rich fen but again least at the Sandhill fen. Relatively low N supply rates and net mineralization at the Sandhill fen were likely due to lower soil organic matter content and limiting soil moisture in these newly constructed substrates. Spatial differences along the hillslopes also varied among sites. The Sandhill fen had higher TIN supply rates upslope but no differences in net N mineralization rates. The rich fen also had higher TIN supply rates upslope but greatest net mineralization rates downslope. Furthermore, the nutrient rich site exhibited a strong negative correlation between NO_3^- supply and net N mineralization, which contrast the measurement approaches. These results highlight the importance of N storage and transport processes and offer insight into the N processes of a constructed fen.

Title: Understanding Flow Pathways, Major Chemical Transformations and Water Sources Using Hydrochemical and Hydrometric Data in a Constructed Fen, Fort McMurray Alberta

Presenter/First Author: Kelly Biagi, McMaster University, Hamilton, ON

Presenter/First Author Email: biagikm@mcmaster.ca

Co-authors: Sean Kevin Carey, McMaster University, Hamilton, ON, Canada; Erin Nicholls, McMaster University, Hamilton, Canada; Carl A Mendoza, University of Alberta, Edmonton, AB, Canada

Abstract Body: Bitumen extraction in the Athabasca oil-sands from open-pit mining creates significant landscape disturbance of wetland and forest ecosystems that must be returned to pre-equivalent capability, as required by Albert legislation. To date, reclamation activity has focused on upland ecosystems with more limited efforts on wetland and peatland ecosystems. Syncrude Canada Ltd. has constructed a 52 hectare upland-wetland system, the Sandhill Fen Watershed (SFW), to advance understanding on wetland reclamation strategies. The objective of this research is to identify and understand the sources, flow pathways and major chemical transformations of water as it moves throughout SFW. Surface and pore water samples from >20 well locations within SFW were analyzed for major chemical ions and oxygen and hydrogen stable isotopes. In addition, high frequency measurements of specific conductivity were recorded at 10 well locations to map salinity variability and how the SFW responsds to environmental changes. Stable isotopes have identified the source waters in SFW based on the dinstict signatures of input waters and the local meteoric water line. Major ion data has categorized the hydrochemical facies existing in the surface and subsurface waters of SFW and thus classifying areas with similar water composition. In addition, sodium adsorption ratios were evaluated to highlight areas where there is cation exchange between calcium and sodium, which is critical information for the success of vegetation. Major ion concentrations vary throughout SFW with values ranging from 100-500 mg/L and 50-650 mg/L for Ca and Na, respectively. Specific conductivity is also highly variable between the uplands and lowlands with values ranging from 1500-4000 µS/cm and 1000-2500 µS/cm. Collectively, the data provides insight to water sources, flow pathways and chemical changes within SFW, and provides insight into future evolution of the watershed.

Title: Microfossil Biomonitors of Reclamation Success

Presenter: Caitlin Garner, Brock Univ, St Catharines, ON

Presenter Email: cg09uy@badger.ac.brocku.ca

First Author: Francine M G McCarthy, Brock Univ, St Catharines, ON

First Author Email: fmccarthy@brocku.ca

First Author Student?: No

Co-authors: Lisa Neville, , ,

Published Material: GAC 2014 Fredericton abstract, but more data now available.

Abstract Body: Microfossils record various types of anthropogenic impact, from siltation and eutrophication associated with indigenous people to the increase in toxic chemicals associated with urbanization and industrialization. In addition to documenting anthropogenic impact, microfossils can be used to assess the success of mitigation and reclamation studies. The fossil remains of organic-walled algae (e.g., dinoflagellate cysts and desmids) record much more hospitable conditions in a Sustainable Lake South (Pond 15 in the Suncor Experimental Wetlands) than in the adjacent Sustainable Lake North (Pond 14). Similarly, the testate amoeba (thecamoebian) fauna in Pond 15 is more diverse, whereas Pond 14 contains almost exclusively hardy centropyxid taxa. This is attributed to the amendment of Pond 15 by nutrients, notably phosphorus, which appears to have speeded up the reclamation process. Microfossils are thus useful biomonitors of reclamation success, and based on the more diverse algal and protozoan communities in the pond that received phosphorous over a several year period, this appears to be a useful reclamation strategy.

Title: Introduction to Soil Bioengineering Applications for Mining Reclamation of Re-Constructed Waterways within Alberta Oil Sands Overburden Mine Dumps

Presenter/First Author: Pierre Raymond, Terra Erosion Control Ltd., Nelson, BC

Presenter/First Author Email: info@terraerosion.com

Abstract Body: In 2003 a waterway swale was retrofitted into an Alberta oil sands overburden dump. The swale has an average gradient of 4 degrees and is approximately 600 m long and 30 m wide from ridge to ridge with a depth ranging from 2 to 4 m. It is composed of two lateral swales connecting onto the main swale and has a catchment basin of approximately 32 ha. The substrate consists of muskeg placed over clay capping and oil sands tailings.

In spring 2004 an erosion control prescription using a soil bioengineering approach was implemented. It consisted of the following: brush sills installed across the swale, smaller diameter cuttings installed in the middle of each sill to improve water dispersion and the planting of live stakes. Contour fascines were also installed across the swale, in two locations above the brush sills, as a trial. After 5 years the findings of this trial site were reviewed and the soil bioengineering design was adjusted and applied to the implementation of two additional swales in 2010.

Lessons Learned

Brush sills result in channel erosion. When combined with accumulated organic debris this results in falling water or a hydraulic jump and the creation of splash erosion. The use of contour fascines, without brush sills, appears to be diffusing water instead of creating channels and splash erosion. Wetland species were established as a result of seeds germinating from within the seed bank of the applied muskeg and a wetland was created. This approach allowed for the establishment of riparian herbaceous, shrub and tree species, recreating habitat on disturbed land.

Based on these findings, trial sites using large diameter (30 cm) contour fascines were established in the spring of 2010 over two newly constructed swales within an overburden mine dump. These trial sites were monitored until the fall of 2014 and assessed as excellent. This approach is now being considered for use as a template for mine closure on reconstructed waterways of mine dumps.

Title: Quantifying the Link Between Hydrological Connectivity and Taxa Requirements in the Development of a Sustainable Environmental Flows Strategy for the Grand Lake Meadows Wetland, New Brunswick, Canad

Presenter/First Author: Wendy A Monk, Canadian Rivers Institute, University of New Brunswick, Fredericton, NB

Presenter/First Author Email: wmonk@unb.ca

Co-authors: Zoe G O'Malley, Canadian Rivers Institute, University of New Brunswick, Fredericton, NB, Canada; Jessica M Orlofske, , , ; Donald J Baird, Enivironment Canada @ Canadian Rivers Institute, University of New Brunswick, Fredericton, NB, Canada; Allen Curry, Canadian Rivers Institute, Fredericton, Canada

Abstract Body: Understanding the physical and biological mechanisms that contribute to flow-ecology relationships is a critical goal in the development of environmental flows frameworks. As one of the largest freshwater wetlands in Atlantic Canada, the Grand Lake Meadows (GLM) wetland (~116,000 ha) is a significant ecological and cultural habitat between Grand Lake and the mainstem Saint John River (SJR). However, the flow of the SJR is highly regulated with over 200 flow control structures along both the tributaries and mainstem leading to varying temporal and spatial lateral connectivity. The nearest flow impediment on the mainstem upstream of the GLM is Mactaquac Dam (MD), which is also one of the largest flow-regulating structures in the SJR system. Changes to the structure or operation of MD have the potential to modify both aquatic and terrestrial habitats upstream and downstream and significantly affect the hydrological connectivity with the GLM. Here we present a preliminary data analysis exploring the relationship between the ecological community and the hydrological connectivity between the mainstem and wetland habitat using statistical-, GIS- and literature review-based information. In addition, we combine water level data and GIS information to illustrate a case study focusing on dragonfly species-at-risk, which require both the riverine and wetland habitat to complete their life cycle. These data provide the base for the preliminary environmental flows framework for the wetland highlighting the importance of a critical and quantified evaluation of the habitat suitability and connectivity requirements for the aquatic community.

Title: Groundwater Exploration in the Pru District of Ghana using1D and 2D Electrical Resistivity Methods

Presenter/First Author: Jonas Narh Sikah, Kwame Nkrumah University of Science and Technology, Kumasi,

Presenter/First Author Email: jonassikah@gmail.com

Co-authors: Akwasi A. Aning, Kwame Nkrumah University of Science and Technology, Kumasi - Ghana, Kumasi, Ghana; Sylvester K. Danuor, Kwame Nkrumah University of Science and Technology, Kumasi - Ghana, Kumasi, Ghana; Evans Manu, Council for Scientific and Industrial Research(CSIR), Accra, Ghana; Collins Okrah, Council for Scientific and Industrial Research(CSIR), Accra, Ghana

Published Material: The paper was presented at African Geoscience Students Conference 2014 at Kwame Nkrumah University of Science and Technology, Kumasi - Ghana. The paper has not yet been published, I am now looking for a geoscience journal to send for review.

Abstract Body: Integrated geophysical techniques involving 2D electrical resistivity tomography (ERT) and vertical electrical sounding (VES) were used to delineate groundwater potential zones for borehole siting in the Pru District of the Brong-Ahafo Region of Ghana. The ABEM Terrameter LS was employed in the survey. A total of fifteen (15) 400m-ERT profiles and thirty-one (31) VES points were investigated using the Schlumberger protocol. The Res1DINV and Res2DINV inversion software were used for the data analysis. The results of the VES generally revealed either three or four subsurface geological layers at the selected points. The second and third layers were found to possess relatively low-to-moderate resistivity values indicative of potential aquifer zones. The resistivity of the fourth layer indicated the presence of slightly-fractured to fresh bedrock. The fractured zones at the selected points are expected to be intercepted from within 20 to 80 m depth to yield water during borehole drilling.

Title: Changing Climate and Altering Hydrological Regime - A Case from Karnali River Basin of Nepal Himalaya

Presenter/First Author: Jeeban Panthi, Small Earth Nepal, Kathmandu,

Presenter/First Author Email: jeeban@smallearth.org.np

Co-authors: Kabiraj Khatiwada, Tribhuvan University, Kathmandu, Nepal; Madan Lall Shrestha, Nepal Academy of Science and Technology, Kathmandu, Nepal

Abstract Body: Global climate change has local implications. Focusing on datasets from the Karnali river basin in western Nepal of Himalayan region, this research provides an overview of hydro-climatic changes that have been observed during 1981-2012. The spatial and temporal trends of temperature and precipitation from 32 meteorological stations distributed in the basin were analyzed. River discharge and precipitation observation are studied to understand the rainfall-runoff relationship. The non-parametric Mann-Kendall test and Sen's methods were used to study trend in climate data. Results show that the average precipitation in the basin is decreasing by 4.36 mm/year. However, the precipitation trend in monsoon season over mountain region is increasing significantly. Increasing trends were observed for both minimum and maximum temperature. The peak discharge (August) is found to be a month later than the peak precipitation (July) over the basin. Annual precipitation amount is decreasing but the river discharge is found to be significantly increasing.

Title: Plant Enhanced Bioremediation Of BTEX Contaminated Groundwater Using *Canna Generalis*

Presenter/First Author: Shreejita Basu, Indian Institute of Technology Delhi, New Delhi,

Presenter/First Author Email: shreejita.basu@gmail.com

Co-authors: Brijesh K Yadav, Indian Institute of Technology Roorkee, Roorkee, India; Shashi Mathur, , ,

Abstract Body: Occurrence of groundwater contamination by BTEX (Benzene, Toluene, Ethyl benzene and Xylene) arises from leaking underground storage tanks and accidental spills.These compounds can be a long term source of pollution to down gradient receptors.The most suited environmentally benign option to remove these contaminants from soil-water systems is bioremediation. These contaminants get biodegraded by indigeneous microorganisms but the process of natural bioremediation is quite slow.Constructed wetlands which have been used widely for secondary treatment of wastewater containing organic pollutants could enhance the rate of bioremediation of BTEX. This study utilizes the plant *Canna Generalis* grown hydroponically in pot-scale gravel beds to investigate its potential for enhanced bioremediation of groundwater contaminated with toluene.Preliminary batch experiments were used for quantifying the biodegradation rate of toluene in contaminated groundwater. Toluene uptake was quantified experimentally and numerically under controlled conditions using wetlands with and without shoot biomass, along with unplanted gravel bed. The residual toluene concentration in the wetlands was measured for one week using gas chromatography.Daily evaporation and evapotranspiration was also measured in the wetlands.The difference in the mass balance calculations was accounted for contaminant loss due to plant uptake, biodegradation and evapotranspiration processes. The total time required for biodegradation of toluene was found to be lowest in the wetland with shoot biomass followed by wetland without shoot biomass and unplanted gravel bed. The cumulative uptake of toluene in the shoots was observed to rise rapidly before it reached a peak value. Continuity equation integrated with active plant uptake kinetics was used for simulating the residual concentration of toluene in the wetlands. The simulated results were compared quite well with the observed data for the entire period of the experiment. Sensitivity analysis suggested that the residual toluene concentration was more sensitive to biodegradation rate constant (K_1) as compared to diffusion rate constant (D_r) for both the wetland cases. These results can be used to frame in-situ plant-assisted bioremediation techniques for BTEX contaminated sites.

Title: The Geochemical Responses Of Small Tundra Lake Catchments To Landscape Perturbation, Upland Region North-East of Inuvik, Northwest Territories

Presenter/First Author: Erika C Hille, University of Victoria, Victoria, BC

Presenter/First Author Email: ehille@uvic.ca

Co-authors: Daniel L Peters, Environment Canada, Victoria, BC, Canada; Fred Wrona, Environment Canada @ Water & Climate Impacts Research Centre, University of Victoria, Victoria, BC, Canada; Steven V Kokelj, Northwest Territories Geoscience Office, Yellowknife, NT, Canada

Published Material: The results presented in this poster were used in my MSc thesis. Preliminary results from this study were also presented at the ArcticNet ASM (2010, 2013) and the IPY Arctic Change Conference (2012).

Abstract Body: The overall goal of this study was to examine the geochemical linkages between the contributing catchment and lakes affected by shoreline retrogressive thaw slumping (SRTS) in Northwestern Canada. Detailed geochemical data was obtained from a pair of representative small tundra lake catchments (Control vs Affected by SRTS), supplemented with less detailed data obtained from 10 regional small tundra lake catchments. The concentration of major ions and nutrients in the study lakes exhibited strong seasonal variability. The concentration of major ions and nutrients increased over the winter months due to the processes associated with ice formation, then decreased at the onset of spring snow and ice melt in response to melt water inputs and dilution. Notably, the concentration of nutrients increased at the beginning of spring melt, which was attributed to the mobilization of surficial organic materials by runoff, but then decreased as the spring months progressed and runoff to the lake became more diluted. With the exception of rainfall events, the concentration of major ions and nutrients in the lakes increased over the open water period due to the addition of relatively ion-rich runoff and concentration via evaporation. In the control lakes, the concentration of most major ions and nutrients decreased during heavy rainfall events in response to the addition of relatively dilute landscape runoff. Notably, the concentration of major ions in SRTS-impacted lakes increased during summer rainfall events. In addition to landscape-level hydrological processes, the concentration of major ions in the study lakes was driven by SRTS. The concentration of major ions was significantly higher in the SRTS-affected study lakes than in the unaffected study lakes due to the addition of relatively ion-rich runoff from SRTS-affected terrain during the spring and summer months. Interestingly, SRTS had no significant effect on the concentration of nutrients in the study lakes.

Title: Analysis of Extreme Climate Events in the Volta River Basin

Presenter/First Author: Fati Aziz, Department of� Disaster Prevention and Mitigation, Takoradi,

Presenter/First Author Email: fatiaziz17@gmail.com

Co-authors: Emmanuel Obuobie, CSIR Water Research Institute, Accra, Ghana

Abstract Body: Countries which share the Volta River Basin in West Africa recorded significant impacts arising from extreme events especially in the late 20th century. This study analyzed changes in temperature and precipitation extremes over the Volta River Basin using the RClimdex software. The data used included observed daily records of precipitation and maximum and minimum temperatures for the period 1981-2010 derived from meteorological stations located within the basin. Indices relevant for the region were selected out of the 27 key indices for Climate Change detection settled on by the Expert Team on Climate Change Detection and Indices (ETCCDI) and used for our analysis. Results obtained from such simple analysis provide a basic and first step to understanding how climatic extremes have been changing in the Volta Basin region. It also serves as a basis for further detailed analysis to help in the development and adoption of management practices for the sustainable development of water resources in the Volta Basin under changing conditions.

Title: Examination of Field Scale Hydrological Processes Under Three Different Tillage Methods in Southern Ontario: Conventional Till (CT); Modified Till (MT); and No Till (NT)

Presenter/First Author: Ian Martin, Newcastle University, Newcastle Upon Tyne,

Presenter/First Author Email: ian.a.moore.martin@gmail.com

Abstract Body: In the wake of the severe algal blooms of 2011 and 2013 in the Great Lakes, international governing bodies such as the United Nations, are advocating for increased studies on nutrient dynamics within agricultural systems. Understanding farm contributions to nutrient loads entering the Great Lakes involves quantifying nutrient export from different tillage practices common in the Great Lakes basin, which include no-till (NT), conventional till (CT) and modified tillage (MT). Understanding differences in nutrient export from different tillage practices may well be related to structural differences in the upper portion of the vadose zone which impact infiltration, soil moisture and overall effectiveness of artificially draining cultivated fields by tiles and exporting nutrients to surface water bodies. Added to the importance of understanding how different tillage practices impact hydrology and the efficiency of exporting of nutrients to surface water bodies is how present increased year-to-year climatic variability and future climate/hydrological change will impact these systems. This study examines the hydrological balances within three ~.6 ha tiled plots each with different (NT, CT, MT) tillage practices but common soil type, nutrient application, cultivated crop, and precipitation patterns.

Title: Advancements in Tracer Dilution Gauging: Quantifying Uncertainties in Streamflow Data

Presenter/First Author: Mark Elliott Richardson, University of British Columbia, Vancouver, BC

Presenter/First Author Email: matsi31@gmail.com

Co-authors: Robert Dan Moore, University of British Columbia, Vancouver, BC, Canada; Andre Zimmerman, Northwest Hydraulic Consultants, North Vancouver, BC, Canada

Abstract Body: In the last decade, there has been increasing attention within both the operational and research communities to quantify the uncertainties in streamflow data. Dilution gauging via stream tracers (dominantly salt or Rhodamine dye) can be a powerful tool for measuring stream discharge or exploring solute dynamics, especially in steep, rough streams that cannot be gauged using the area-velocity method. However, many questions involved in the technique remain unresolved despite decades of usage in research and industry: (1) for salt dilution gauging via injection of dry salt, what is the most accurate and robust approach to calibrating the relation between salt concentration and electrical conductivity, (2) to what extent does the calibration factor vary with background water chemistry, (3) for gauging with Rhodamine WT, what is the effect of sorption to suspended sediment, (4) can mixing lengths be predicted from geomorphic properties of the stream channel, and (5) how sensitive is the integral of the salt breakthrough curve to location along or across the channel? These questions were addressed through a combination of field work conducted at mountain streams in southwest British Columbia and controlled laboratory studies. Based on the results, recommendations are made for best practices to ensure accuracy and robustness of streamflow measurements.

Title: Understanding the Spatial anisotropy of Daily Rainfall using Radar Information

Presenter/First Author: Yeboah Gyasi-Agyei, Central Queensland University, Rockhampton, QLD

Presenter/First Author Email: y.gyasi-agyei@cqu.edu.au

Abstract Body: Spatial variability of rainfall has been recognised as an important factor controlling the hydrologic response of catchments. However, gauged daily rainfall data are often available at scattered locations over the catchments. The current research is looking into how to capitalise on the spatial structure of radar rainfall data for improving Kriging interpolation of the limited gauge data over catchments at 1 km^2 grid scale. 114 gauged stations within a 128km x 128km region of Brisbane (Mt Stapylton), Australia, radar field were used for the case study. Correlograms, the backbone of Kriging interpolation methods, were developed using a Fast Fourier Transform method on the Gaussianised radar and gauged data. It is observed that the correlograms vary from day to day and display significant anisotropy. For the radar data, locally varying anisotropy (LVA) was examined by developing the correlogram centred on each pixel and for different radial distances. Leave one out cross validation was carried out using the empirical correlogram tables as well as different fitting strategies of a two-dimensional exponential distribution for both the gauged and the radar data at the gauged locations. Results indicate that the correlograms based on the radar data outperforms the gauged ones as judged by statistics including mean-square-error, mean-bias, mean-absolute-bias and mean-standard-deviation. While the radar data display significant LVA, it was observed that LVA did not significantly improve the estimates compared with the global anisotropy. Ongoing research is generating large ensembles over the 128km x 128km region to be used for evaluation of the different correlograms where LVA is expected to outperform the global one.

Title: Hydraulic behavior of a fractured massif

Presenter/First Author: Adriana Pina, Organization Not Listed, Bogota,

Presenter/First Author Email: appinaf@unal.edu.co

Co-authors: Leonardo David Donado-Garzon, Universidad Nacional de Colombia-Bogota, Bogota Dc, Colombia

Abstract Body: A set of hydraulic test were performed along "La Linea Tunnel" in Los Andes Mountain (Colombia), in order to establish the changes in the interaction among groundwater, surface water and civil work. This research is focused on the analysis of the hydraulic tests performed in 20 boreholes between 9 and 10 m length with dip among 10° and 50° were drilled in the massif. The latter is composed by two main geological groups of rocks. The first one is igneous and the second one is metamorphic. Whole massif is highly fractured and was traversed by means of a tunnel of 8200 m length with a variable depth between 100 and 800 m from surface. Nine fault zones are traversed; most of them are related with some creek in surface whose flows have diminished since the tunnel was built.

Fractured-rocks have spatially and temporally variability in the hydraulic parameters. This is generally attributed to fracture intensity and connectivity. In consequence, boreholes were located closed to fracture zones. 16 hydraulic tests were performed to characterize hydrogeological parameters. Well-tests were analyzed via diagnostic plots of both, drawdown and its derivate versus time using AQTSOLVE.

Most of the tests show combined effects. For early times a double porosity effect is shown followed by a constant drawdown which derivate declines to zero. This response appears to be due to dewatering of the fracture.

However, diagnostic plot for two tests indicate a vertical fracture of infinite conductivity. This is consistent with their location, where the highest part of the mountain crossed by the tunnel is found. The tests show that of fractures define the hydraulic behavior of the massif. Additionally, this test let us know the dimension of the flow. In this case, the flow is quasi-2D (almost radial).

In contrast, other tests (where top of the mountain is near) achieve steady state in late time. It means that the massif is dewatered but those tests do not allow to estimate the flow dimension.

Title: Paleoflood History of an Oxbow Lake in the Désert River Catchment Area, Southwestern Québec, Canada

Presenter/First Author: Frank Oliva, University of Ottawa, Ottawa, ON

Presenter/First Author Email: foliva@uottawa.ca

Co-authors: Andre E Viau, University of Ottawa, Ottawa, ON, Canada; Jean Bjornson, , ,

Abstract Body: Most paleoflood reconstructions come from the arid dry climate of southwestern USA and in Europe with few studies being conducted in temperate climates of North America. In this study we show that oxbow lakes can be used to reconstruct past flood events in temperate regions. Sediment cores extracted from an oxbow lake along the Désert River in southwestern Québec, Canada were analyzed for magnetic susceptibility, loss-on-ignition and grain-size. Results show a strong relationship between past flood events and known climate variability on multi-decadal to centennial timescales over the past 1650 years. Higher frequencies of floods were observed during the Little Ice Age (LIA; 1450-1850 AD) and the Dark Ages Cold Period (DACP; 300-800 AD) known to have been more humid than the Medieval Warm Period (MWP; 900-1200 AD). This study provides evidence to support the use of oxbow lakes in temperate regions as a proxy of past hydroclimatic changes on regional scales, thus leading to a better understanding for future floods under a changing climate.

Title: Climatic Controls of Low Water Levels on the Mackenzie River Mainstem, Summer and Autumn, 2014.

Presenter: Daniel L Peters, Environment Canada, Victoria, BC

Presenter Email: daniel.peters@ec.gc.ca

First Author: David E Atkinson, University of Victoria, Victoria, BC

First Author Email: datkinso@uvic.ca

First Author Student?: No

Abstract Body: The Mackenzie River serves an important transportation role for communities along its valley and in the western Canadian Arctic. Annual transportation by barge represents the only way to get large and heavy items to many northern coastal communities. In the case of one of the major tug and barge operators in Northwest Territories, freight is trucked to Hay River and then barged from Great Slave Lake to the Beaufort Sea. In some years water levels along the river are low, which can present navigational problems. Operators often insert their own routing marks and water level gauges along the river using charts and experience accumulated over many years. In most cases, however, because the river bed morphometry can change relatively rapidly, charts do not necessarily keep pace, which leaves operators relying on their own skill and experience. Water levels on the river are controlled by a combination of: direct runoff from snowmelt and rainfall events within its watershed, stored runoff accumulated in the large lakes, and water released from regulated watersheds (ie Peace River headwaters) that feed the Mackenzie. When viewed as a function of seasonal atmospheric forcing, weather events or non-events, such as lack of precipitation, can occur in different areas within the Mackenzie's large collection area and exert an impact on navigable water levels, and it is likely that all three elements of water level control must be in phase for a large water level anomaly to result. The 2014 season was of particular note; operators on the Mackenzie River mainstem indicated that summer water levels were some of the lowest they had observed in many years. This in turn resulted in serious delivery difficulties for communities and shippers in the Beaufort Sea region, including lost perishable supplies when a shipment had to be dropped at the shore 100 km away from the town it was destined for, and increased numbers of trips required, forced by lower cargo capacities resulting from reduced potential barge draft. This paper will present a preliminary overview of climatic and hydrological drivers for the observed 2014 low water levels along the Mackenzie River using the framework of the control mechanisms identified above. Focus will center on the Mackenzie River mainstem from Great Slave Lake to the Delta.

Title: Dynamic Fractional Wettability During Infiltration of Water, Ethanol, and Aqueous-ethanol Solutions in Post Wildfire Soils.

Presenter/First Author: Sarah MB Beatty, McMaster University, Hamilton, ON

Presenter/First Author Email: beattysm@mcmaster.ca

Co-authors: James E Smith, McMaster University, Hamilton, ON, Canada

Published Material: Some data and findings were reported in a Journal of Hydrology paper, in 2014, accepted. Beatty, SM and Smith, JE (2014). Infiltration of water and ethanol solutions in water repellent post wildfire soils. Journal of Hydrology, 514, 233-248.

Abstract Body: Soil hydrophobicity or soil water repellency is an emerging area of interest across a wide scope of research disciplines that includes hydrology, soil physics, wildfire, agriculture, geochemistry and geomorphology. Often treated as a near-surface phenomenon, reduced wettability soils can generate substantial impacts on soil hydraulic properties and infiltration behaviours, and have larger scale implications on groundwater fluxes and overland flow. There is growing consensus that many soils exhibit complex wettabilities, with soil matrices being comprised of particle fractions that exhibit a range of contact angles which can change over time. To help develop mechanistic insight in such systems, this work presents a combination of *in situ* field (3D) and laboratory (1D) experimental data collected in naturally repellent post wildfire soils using tension infiltrometers (4.4cm and 8cm, respectively) and different infiltrating fluids. Forty nine infiltration tests were conducted in the field, and 20 column experiments were conducted in the lab using water, ethanol, and Molarity of Ethanol Drop (MED)-derived aqueous-ethanol solutions. By experimentally eliminating positive pore-water pressures through tension infiltration, observations of infiltration initiated by capillary pull were more readily observable. Early- and late-time infiltration rates were analysed in-combination and showed clear relationships in within-material variability, differences in infiltration fluids, and site specific differences in infiltration. These relationships generated more information than traditional analysis approaches. Analytical approaches based on idealized wettable-system principles yielded suspect results in the form of negative Ksat and Sorptivity values. This also introduced uncertainty into positive values of Ksat and Sorptivity. Results of this kind challenge our ability to rely on traditional approaches for analyzing infiltration data and drawing meaningful conclusions in non-wetting / fractionally wettable / dynamic systems. There is great opportunity to develop new approaches for developing mechanistic insight into these systems, particularly over

times scales of infiltration and groundwater recharge.

Title: Debye decomposition of complex electrical conductivity spectra of contaminated sediments

Presenter/First Author: Andrea Ustra, USP University of Sao Paulo, Sao Paulo, SP

Presenter/First Author Email: andreaustra@iag.usp.br

Co-authors: Carlos Alberto Mendonça, IAG Institute of Astronomy, Geophysics and Atmospheric Sciences, Sao Paulo, Brazil; Dimitrios Ntarlagiannis, Rutgers University, Newark, NJ; Lee D Slater, Rutgers Univ, Newark, NJ

Abstract Body: The relevance of geophysical investigation to hydrogeology problems have been extensively reported in the literature. Electrical methods have shown to be successful in characterizing and monitoring groundwater flow and contamination plumes in the subsurface. The spectral induced polarization (SIP) geophysical method has been considered a promising tool in environmental and hydrogeophysical studies. Induced polarization (IP) is a phenomenon associated with energy storage in a medium, stimulated by an induced electrical current. The SIP method records the complex, frequency dependent, expression of the IP phenomenon. SIP data are frequently interpreted with the use of phenomenological models that describe relaxation processes, such as the Debye relaxation model. One common procedure, known as Debye Decomposition (DD), is to fit SIP data using several distinct Debye relaxation models. The objective of our work is to interpret the relaxation time distribution obtained with DD for SIP data from an experiment with sand-clay mixtures contaminated by toluene. We apply an alternative formulation for DD, where a different set of parameters are recast, with a close relationship to the continuous formulation for the complex conductivity method. The procedure determines frequency-independent parameters that modulate SIP spectra and the range spanned by the conductivity spectra between low and high frequency limits. Using these two parameters, the complex conductivity can be normalized and decomposed into smaller contributions. Each contribution can then be associated with specific relaxation processes that are characterized in terms of distinct parameters, such as electrochemical or interfacial, derived from inverted parameters obtained. Our discrete version of the continuous DD yields a distribution of relaxation times with associated gate probabilities and two frequency-independent parameters that allow for interpretation in terms of petrophysical parameters from mechanistic models. The relaxation time distribution obtained for the toluene contaminated samples identified two main polarization processes related to different polarization mechanisms (electrochemical and Maxwell-Wagner) that were not clearly distinguishable in complex conductivity spectra.

Title: Downscaling Daily Precipitation with the Climate Forecast System Reanalysis across Canada

Presenter/First Author: Dikra Khedhaouiria, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Québec, QC

Presenter/First Author Email: dikra.khedhaouiria@ete.inrs.ca

Co-authors: Alain Mailhot, Institut National de la Recherche Scientifique, Québec, QC, Canada; Anne-Catherine Favre Pugin, GINP-ENSE3, Grenoble, France; Guillaume Talbot, Institut National de la Recherche Scientifique, Québec, QC, Canada

Abstract Body: One of the most important challenge in assessing historical precipitation across Canada is related to the low station density, especially up north the 50°N of latitude. The reanalysis datasets are now an attractive alternative that reconstructs the past state of the atmosphere using Numerical Weather Prediction methods assimilating past observations, to generate spatially and temporally continuous meteorological fields. The objective of this study is to access to what extent the Climate Forecast System Reanalysis (CFSR) reproduces precipitations for potential application in hydrology.

CFSR, produced by the National Centers for Environmental Prediction (NCEP), covers the period from 1979 to 2010 and includes daily precipitation series at 38 km resolution. Two important issues are addressed: 1) to what extent the CFSR reproduces the observed precipitation at stations for different time scales? 2) Do physically and statistically-based post-treatments of CFSR precipitations permit to match recorded ones? The first issue is examined through bias, correlation and variability estimates when CFSR and station series are compared at different time scales. The second issue is addressed with Stochastic Model Output Statistical (SMOS) approach which proceeds in two steps: first precipitation occurrence is determined and, if precipitation occurs, then precipitation intensity is estimated.

Results showed satisfactory performances according to bias and correlation on series in eastern and western parts of the country, especially during winter and fall for correlation and summer for bias. Precipitations in the Rockies were not accurately represented by CFSR (e.g. rain-shadow effect). Preliminaries SMOS results are promising and suggested this method could be used to downscale grid-cell CFSR precipitation to specific sites. The next steps are to relate spatially and seasonally SMOS parameters to be able to assess statistics on precipitation in regions where no stations are available.

First Author: Michel Baraer, Ecole de Technologie Superieur, Montreal, QC

First Author Email: michel.baraer@etsmtl.ca

First Author Student?: No

Co-authors: Alexandre Guittard, Ecole de Technologie Superieur, Montreal, QC, Canada; Jeffrey M McKenzie, McGill University, Montreal, QC, Canada; Bryan G Mark, OSU-Byrd Polar Rsrch Ctr, Columbus, OH

Abstract Body: Predicting the impact of the glaciers retreat on water quality for the downstream populations is an objective that requires a good understanding of the contamination and transport mechanisms of pollutant. Where contaminants are heavy metals, identifying the origins of the contamination and differentiating between the anthropogenic and natural contamination origins in particular is a required step. In Northern Peru, the Rio Santa dry season discharge is projected to decline with the ongoing Cordillera Blanca glaciers retreat making the identification of the heavy metal contamination sources a priority. The scale of the watershed, more than 13,000 km^2 combined with the high density of mines of different size makes the anthropogenic contamination non-point of source like. In those conditions, differentiating between the natural and anthropogenic contamination origins requires identifying their distinct hydrochemical signatures.

In order to identify hydrochemical contaminant origin dependant signatures in the Rio Santa watershed, 5 areas of known contamination origins were sampled during the summer 2014. Samples of surface water and groundwater, suspended and riverbed sediments have been collected at each site. Each sample was analyzed for trace metals using an ICP-MS or an ICP EOS, depending on the concentration of metals. Preliminary results show that natural contamination is characterized by low levels of arsenic and calcium and high level of sulfates and fluorine compared with mine drainage. The possibility to use those characteristics to trace contamination origins is investigated and options are being proposed.

Title: Mapping the depth of a small lake using ground-penetrating radar

Presenter/First Author: Roberta F Sears, University of Toronto, Toronto, ON

Presenter/First Author Email: roberta.sears@mail.utoronto.ca

Co-authors: Grant Ferris, University of Toronto, Toronto, ON, Canada; Carl-Georg Bank, University of Toronto, Toronto, ON, Canada

Abstract Body: A geophysical study was designed to determine if ground-penetrating radar is a feasible means of mapping small bodies of water where sonar cannot be deployed. We collected ground-penetrating radar data by canoe on a small (250 x 100 m) lake near Deep River, approximately 250 km NW of Ottawa in Ontario. This lake is situated between a glacial-fluvial sand aquifer and a wetland just South of the Ottawa River and formed because of the construction of the Trans-Canada Highway. The radargrams were collected with a 400 MHz antenna and exhibit sharp reflections off the bottom of the lake, as well as a lower interface (between the mud and till). GPS was used to record the Easting and Northing coordinates at both the starting and ending locations for all twenty survey lines. Picking the two-way-time arrivals, converting these to depth, and placing them into the UTM coordinate system allowed us to create a bathymetric contour map of the lake bottom which we can compare to measurements done with a plumb line. The results show water depths of up to 3 m and generally a steeper drop on the East side of the lake. Our survey exemplifies the feasibility and applicability of using GPR on small bodies of water.

Title: Arctic Tundra Lakes in a Region Impacted by Permafrost Disturbance – Application of Isotope Signatures for Enhanced Hydrological Understanding

Presenter/First Author: Daniel L Peters, Environment Canada, Victoria, BC

Presenter/First Author Email: daniel.peters@ec.gc.ca

Co-authors: Kevin W Turner, Brock University, St Catharines, ON, Canada; Erika C Hille, University of Victoria, Victoria, BC, Canada; Fred Wrona, Environment Canada @ Water & Climate Impacts Research Centre, University of Victoria, Victoria, BC, Canada; Steven V Kokelj, Northwest Territories Geoscience Office, Yellowknife, NT, Canada

Abstract Body: A projected "hot spot" of climate warming and development is the Mackenzie River Delta region, Northwest Territories, Canada. The upland tundra areas within the Mackenzie Gas Project development area north of Inuvik contain thousands of small lakes with poorly defined ephemeral drainage that are underlain by permafrost and ice-rich sediments for which the basic water balance controls are not fully understood. Natural retrogressive thaw slumps are common along lakeshores and the rapid drainage of ice-rich permafrost-dammed lakes has been occurring. Oil/gas exploration activities and infrastructure construction may result in terrain disturbance and localized degradation of permafrost, while climate change may increase the magnitude and frequency of thermokarst processes. These disturbed lakes are believed to act as historical analogues for the future effects of climate change on the hydrology, geochemistry, and aquatic ecology of tundra lake catchments in the continuous permafrost zone of northwestern Canada. Environment Canada initiated an integrated research program in 2005 with the overall goal of improving our understanding of lake hydroecological impacts associated with shoreline slumping. Limited catchment studies have examined water-balance parameters (precipitation, evaporation, and surface flows) for tundra lakes in the development area. Comparisons of naturally-occurring water isotopes (^{18}O and ^{2}H) are useful indicators of water balance variations among lakes in remote permafrost regions where hydroclimatic information is very limited. In particular, information on evaporation-to-inflow ratios and residence times would provide useful information for estimating appropriate water withdrawals from lakes within the proposed development area and provide a temporal perspective on geochemical impacts due to slumping. Another key objective is identifying whether permafrost slumping impacts the hydrology of tundra lakes via catchment area enlargement and/or enhanced snow accumulation. Here, we present preliminary isotope hydrology findings from i) 7 years of seasonal surveys in a pair of representative lake catchments and ii) annual synoptic surveys in up to 60 lakes, including those with and without shoreline slumping, located along the proposed Mackenzie Valley Gas Pipeline.

Title: Hydro-Climatic Variability and Runoff Response in Glacial River Basin: A Case from Langtang River Basin of Nepal Himalaya

Presenter/First Author: Nicky Shree Shrestha, Kathmandu University, Dhulikhel,

Presenter/First Author Email: nicky@nicky.com.np

Co-authors: Piyush Dahal, The Small Earth Nepal, Kathmandu, Nepal; Rijan B Kayastha, Kathmandu University, Dhulikhel, Kavre, Nepal

Abstract Body: The Himalayas display great climatic variability. The variability in climatic parameters has greatly affected the water resource availability due to the occurrence of frequent and uneven extreme events. Climate change is expected to contribute to increased variability of river runoff due to changes in the other climatic variables as well as the melting of snow glaciers. Therefore, it is essential to understand the underpinnings of hydro-climatic variability in order to assess the effects of climate changes and effectively meet future water supply challenges. This paper therefore provides the analysis of observed variability and change in temperature, precipitation, snow cover and its response to streamflow of Langtang River Basin of Nepal. Langtang River basin which lies in Langtang Valley of Rasuwa district is glacier-fed and provides sustained flow during dry seasons to fulfill the water requirements for downstream.

The observed hydro-meteorological data for the period 1988 to 2009 obtained from Department of Hydrology and Meteorology, Government of Nepal was used for this study. Trend analysis of temperature data using non parametric Mann-Kendall test revealed that there is increasing trend of temperature and was more pronounced in winter season (December, January, February) and both are statistically significant at the 95% confidence level. Also observation shows that the total number of days per year below $0^{o}C$ has been decreasing. Similarly, total annual precipitation showed increasing trend but have large interannual variation. Pre monsoon, post monsoon and winter precipitation also showed significant increasing trend whereas the monsoon precipitation was observed to have significant decreasing trend. Monsoon precipitation in the region amounts 84.78% of total annual precipitation. Snow cover area (2002-2014) examined using the data acquired from MODIS snow data showed decreasing trend of snow cover area in Langtang river basin. The annual stream flow showed decreasing trend. The streamflow at monsoon and post monsoon seasons were found to be decreasing and winter and pre monsoon streanflow showed increasing trend. The streamflow was observed to start increasing in June and reach peak in July and August. In the post-monsoon period and winter, snowmelt contribution to the total discharge is large.

Title: Hydrological forecasting events in the context of global warming using Fokker-Plank-Kolmogorov's equation

Presenter/First Author: André Guy Tranquille Temgoua, University of Douala, Douala,

Presenter/First Author Email: andretemgoua@gmail.com

Co-authors: Richard Martel, INRS-Eau Terre Environnement, Quebec, QC, Canada; Zanin Kavazovic, , , ; Daniela Blessent, Universidad de Medellín, Medellín, Colombia; Uta Gabriel, , , ; Nomessi Kokutse, University of Lome, Lome, Togo

Abstract Body: In the last decade, stochastic and deterministic approaches were widely used in hydrological analyses to predict events with reliable results. However, scientists are still looking for the best solution and the most efficient forecasting method to evaluate a future hydrologic event that could help to prevent damage of infrastructures.

This paper is proposing a method based on application of Fokker-Plank-Kolmogorov's equation in hydrological modeling in the context of climate change. The method provides a new insight in ongoing hydrological processes to forecast and define action priorities. The model is based on stochastic analysis and consists in determining and optimizing numerical approximates of sensitive parameters in hydrological processes. The application of FPK was used to establish the water level of a dam in different scenarios with the goal of preventing the floods.

In this paper, the strategy is to focus on the optimization of sensitive parameters in hydrological processes. Hence, at each stage of an identified hydrological process, a probabilistic density function (PDF) is determined enabling the optimization of decision-making in stochastic modeling. The objective was to simulate hydrological scenarios that could take place in the case of a long storm on a studied watershed. The novel approach significantly reduced uncertainties in hydrological modeling and forecasting. It was also possible to manage white noise processes and their intensities with acceptable accuracy. The approach yielded more accurate forecast and was used to manage the adjustment of the water level of a dam subject to instability and efficiency. Results of simulations were in good agreement with recorded data. The approach enabled different scenarios of storms and analyzes their impact on a dam and the surroundings of the studied area. The methodology and benefits are presented in this paper.

Title: A Study on Debris(floating waste) Flow Simulation in Hantangang dam Using the EFDC Model.

Presenter/First Author: Suk-Hwan Jang, Organization Not Listed, Gyeonggi-do,

Presenter/First Author Email: drjang@daejin.ac.kr

Co-authors: Ji Hwan Oh, , , ; Su Hee Han, , ,

Abstract Body: Dam and reservoir are very important facilities to prevent flood and also using water resources. Hantangang dam designed only for the purpose of flood control whose bottom outlets are specially designed at the original river bed level and can pass through inflow sediments almost naturally during flood periods are often planned for the new flood control.(Tetsuya Sumi, 2008).

Hantangangdam in Hantan river, length is 690.0 meter, height is 83.5 meter and flood control capacity is 2.7 hundred million tons. Generally, Flood Control dam is large of water level changes. And floodplain is exposed in the dry season because it does not store water. Therefore, Maintenance method is different other multipurpose dam. Also, Width and depth of Mainstream in Hantanriver is very irregular and meandering characteristrics. It was difficult to determine the distribution of floating waste.

In this study, GIS analysis was conducted for basin topography for actual basin to estimate predict space and flow analysis were simulated through the EFDC model considering water level, flood condition of frequency. Find the inflow route and delay zone of floating waste in hantan river. After that, I try to present the effective debris collection method. Analysis were reviewed along 6 cases–Small sized flood(2yr, 5yr frequency), medium sized flood(25yr, 50yr frequency), large sized flood(100yr, 200yr frequency).

The result of small sized flood, debris is incapacitated under the influence of river curvature, it was simulated to be partially accumulated in a specific area. In particular, floating waste is expanding the width of the flow rate while at the confluences can not go downstream. The result of medium sized flood, floodwave is overflow the mainstream that flood in ploodplains with wide area. The result of large sized flood, dam site area is analyzed Under the influence of the above largest dam drainage, and water depth is deeper flow both mainstream and tributaries of the most delayed in the region to be a large amount of debris distribution. Also wide floodplain to flooding scope is rapidly increasing and thus the area that can be distributed floating garbage were analyzed to rise significantly.

Title: Comparing catchment mean transit times and landscape characteristics for mesoscale catchments in northeastern Ontario

Presenter/First Author: Krystopher J Chutko, Nipissing University, North Bay,

Presenter/First Author Email: krystopc@nipissingu.ca

Co-authors: April Lynda James, Nipissing University, North Bay, ON, Canada; Chris McConnell, Ontario Ministry of Environment and Climate Change, Dorset, ON, Canada; Huaxia Yao, Nipissing University, North Bay, ON, Canada

Abstract Body: Improved accessibility to stable water isotope (SWI) analyses has highlighted SWI-based evaluation of streamflow partitioning and mean transit times (MTT) as powerful ways to generate new information on water cycling for large scale catchments. Located in northeastern Ontario, Lake Nipissing is part of an important headwater tributary to the Great Lakes. In 2012, we initiated a stable water isotope (SWI) study of the Sturgeon River-Lake Nipissing-French River (SNF) basin, to examine how landscape characteristics influence streamflow generation at scales where both natural landscape variation (e.g. surface reservoirs, clay belt soils, forested headwaters) and anthropogenic influence (power generation, urbanization, agriculture) are anticipated to influence water quantity and quality. Catchments range in size from 35 to 6,875 km^2, with a median size of 146 km^2 and mean catchment slopes from 1 to 8%. Landcover includes considerable agricultural (0-18%) and/or urban (0-47%) area. Lakes and wetlands together cover 10-25% of catchment area, with large individual lakes (e.g. Lake Temagami) acting as important reservoir storage for hydropower generation. In this poster, we present a comparative analysis of MTT estimates generated using periodic regression analysis of 1-2 years of biweekly to monthly streamflow and precipitation observations. MTT estimates are longest for the smallest catchments (<1000 km^2) but have high variability (472 – 722 days); the largest catchments (2400-6800 km^2) exhibit much more uniform but shorter MTT (386-430 days). There are negative correlations between MTT and mean catchment slope (R^2=0.71, p<0.01), and MTT and total % area of lakes and wetlands (R^2=0.33, p<0.05). Comparison of MTT estimates across two major forks of the Sturgeon River with substantial differences in flow manipulation show similar MTT estimates (~390 days) suggesting that similarities in % lake/wetland and mean catchment slope may be more influential in these instances.

Title: High frequency monitoring of lake and weather conditions in Lake Nipissing, Ontario: Exploring the 2014 hydrographical dataset

Presenter/First Author: Krystopher J Chutko, Nipissing University, North Bay,

Presenter/First Author Email: krystopc@nipissingu.ca

Co-authors: Dan Walters, Nipissing University, North Bay, ON, Canada; April Lynda James, Nipissing University, North Bay, ON, Canada; Mark Wachowiak, Nipissing University, North Bay, ON, Canada; Chris McConnell, Ontario Ministry of Environment and Climate Change, Dorset, ON, Canada; Huaxia Yao, Nipissing University, North Bay, ON, Canada; Andrew Paterson, Ontario Ministry of Environment and Climate Change, Dorset, ON, Canada; James Rusak, Queen's University, Kingston, ON, Canada

Abstract Body: In 2014, high frequency monitoring of water and weather conditions was undertaken in three bays (Cache, Callander and West Bay) on Lake Nipissing, a large (822 km^2), relatively shallow lake located in northeastern Ontario. Lake Nipissing is part of an important headwater tributary to the Great Lakes. Eight of the 12 major river inflows to Lake Nipissing have been evaluated as either impaired or marginal in water quality, and historical data shows total phosphorus (TP) levels exceeding provincial water quality objectives and evidence of eutrophic conditions in bays with upstream agricultural activity (Callander and Cache). Lake Nipissing's walleye population has been reported as highly stressed with ecosystem change listed as one potential cause of the unexplained decline in adult walleye abundance. High frequency monitoring of lake and weather conditions was initiated in a 2013 pilot project in Callander Bay and extended to the three bays in 2014. In each bay, a data buoy was deployed, instrumented with thermistors and light sensors at 1 m intervals through the water column. At two locations, an EXO2 water quality sonde recorded continuous measurements of pH, conductivity, turbidity, chlorophyll, and total algae at a 1 m depth and *in situ* meteorological data. Data were collected on a 10 minute interval. Regular profile surveys (conductivity, temperature, DO) were performed at each buoy using a YSI multi-parameter probe. In this poster, we present the 2014 dataset collected from the three bays, with specific examination of seasonal and event-based trends and influence of meteorological conditions on thermal structure. We explore the development and use of custom data visualization and analysis tools as well as those available through the Global Lake Ecological Observatory Network (GLEON) for generation of lake hydrographical metrics (e.g. Schmidt stability, epilimnion depth, anoxic lake volume and sediment area, thermocline, mixed layer depth, Lake Number).

Title: Application of SWAT model to quantify blue and green water resources in Alberta

Presenter/First Author: Monireh Faramarzi, University of Alberta, Edmonton,

Presenter/First Author Email: monireh.faramarzi@ualberta.ca

Co-authors: Karim Abbaspour, EAWAG Swiss Federal Institute of Aquatic Science and Technology, Duebendorf, Switzerland; Greg Goss, , ,

Published Material: This is a three years research project, funded by Alberta Innovates Energy and Environment Solutions on 2014. It is started since March 2014 and the results have been recently submitted for publication in an ISI Journal. The status of the manuscript is "under review". General objectives of the project have been reported in local and regional media. We have also discussed our results with the scientists and local experts trough personal meetings.

Abstract Body: Dynamic nature of water resources, both spatially and temporally, present a significant challenge to sustaining economic developments, ensuring food security, and implementing other development plans in Alberta and elsewhere in the world. A sound knowledge of internal renewable water resources availability and reliability is needed to lay a strong basis for a long-term planning and management. In this study we used the program Soil and Water Assessment Tool (SWAT), in combination with the Sequential Uncertainty Fitting program (SUFI-2), to calibrate and validate a hydrologic model of Alberta. Monthly data from 135 hydrometric stations and wheat yield was used to calibrate the model. This dual-objective calibration increased reliability in the prediction of soil water balance components. The study period was 1993-2007 for calibration and 1983-1993 for validation. The heterogeneous hydro-

climatic conditions and the diverse management practices in combination with the scarcity of data in the remote areas and mountainous regions made hydrological modeling challenging. A data discrimination procedure was developed to represent most of the natural and anthropogenic processes in the watersheds. The calibrated model was further used to quantify water resources including blue water flow (river discharge plus deep aquifer recharge), green water flow (evapotranspiration), green water storage (soil moisture), and aquifer recharge at the subbasin spatial and monthly temporal scale. Uncertainty analyses were also performed to predict the errors related to the input data, model structure, and management measures. The results of this study will be integrated with other dynamic predictive models (e.g., climate change, water demand, economic evaluation) to enable analysis of alternative management options in the future.

Title: Modeling the Partitioning of Precipitation over the Almadinah Watershed, Saudi Arabia: An Integrated Approach

Presenter/First Author: Talal Alharbi, King Saud University, Riyadh,

Presenter/First Author Email: tgalharbi@yahoo.com

Co-authors: Mohamed Sultan, Western Michigan Univ, Kalamazoo, MI; Mohamed Ahmed, Western Michigan University, Kalamazoo, MI

Abstract Body: Assessment and development of freshwater resources remain the main and the only key to sustain the Kingdom of Saudi Arabia growing population and increasing water consumption. An integrated (remote sensing, GIS, and modeling) approach was applied to spatially delineate the recharge areas of, and model the precipitation of precipitation over, the Almadinah watershed, the largest (area: ~108,000 km2) watershed in the Kingdome of Saudi Arabia, during the past three decades. The Soil Water Assessment Tool (SWAT) was used to estimate the partitioning of precipitation into runoff, recharge, and evaporation. SWAT model inputs were generated as follows: (1) daily rainfall data extracted from the Tropical Rainfall Measuring Mission (TRMM) data which is calibrated against rain gauges measurements; (2) soil data were extracted from the geologic maps generated by Saudi Geological Survey; (3) land use maps extracted from the U.S. Geological Survey (USGS) 1-km global Land Use and Land Cover database; (4) topography data were generated from a mosaic of Shuttle Radar Topography Mission (SRTM; 90 m spatial resolution) data; and (5) other climatic parameters including solar radiation, wind speed, air temperature, and relative humidity were obtained from the Climate Forecast System Reanalysis (CFSR) database. SWAT model was calibrated against the discharge data extracted from the archival runoff datasets. The average annual modeling results over the Almadinah watershed through the period from 1980 to 2010 revealed: (1) rainfall was estimated at 58 mm; (2) stream flow were estimated at 19.1 mm (33% of the rainfall); (3) the potential recharge was estimated at 7.2 mm (12.5% of the rainfall); and (4) initial losses is estimated at 31.3 mm (54% of the rainfall). Our results invite the deployment of technical projects such as dam construction and wells installation for groundwater extraction within the Almadinah watershed.

Title: Hydrological Modeling of the Niger River (West Africa) for Flow Prediction in Ungauged Basins.

Presenter/First Author: Jamilatou Chaibou Begou, AGRHYMET Regional Center, Niamey,

Presenter/First Author Email: jamilabegou@yahoo.fr

Co-authors: Seifeddine Jomaa, , Magdeburg, Germany; Sihem Benabdallah, , , ; Pibgnina Bazie, , , ; Michael Rode, Helmholtz Centre for Environmental Research UFZ, Magdeburg, Germany

Abstract Body: In West Africa, many drainage basins are ungauged or poorly gauged, and in some cases existing measurement networks are declining. Prediction of discharge and other hydrological characteristics of ungauged basins is therefore an important priority for water resources planning and management and for ecological studies. The ultimate goal of our study is flow estimation in ungauged catchments of the Niger basin through hydrological modeling of the Bani River using SWAT and its parameters transfer to the upper Niger. The calibration task presented in this article, is the foundation for regionalization of model parameters, which will be addressed in the companion paper. In the present article the modelling framework: model description, study area and data, calibration strategy and results are presented. The Bani is located in the upper part of the Niger River and drains an area of about 101, 000 km^2 at the outlet of Douna. The climate is tropical, humid to semi-arid from the South to the North with an average annual rainfall of 1050 mm. Global datasets used are from USGS hydrosheds DEM, USGS LCI GlobCov2009 and the FAO Digital Soil Map of the World. Daily measured rainfall from nine rain gauges and maximum and minimum temperature from five weather stations covering the period 1981-1997 were used for model setup. Sensitivity analysis, calibration and validation were performed within SWATCUP using GLUE procedure at the catchment's outlet (Douna) and at two additional internal stations (Pankourou and Bougouni). Model parameters were calibrated at daily time step on ten years (1983-1992) then validated on 5 years (1993-1997). A warm-up period of two years (1981-1982) was considered. Calibration and validation results are good at the catchment's outlet (Nash and R^2 equal to 0.76 and 0.79 for calibration, 0.84 and 0.87 for validation). Model performance was slightly lower for the additional gauging stations (Nash equal to 0.73 and 0.58) but again always higher for the validation period (0.77 and 0.65). These statistics suggest that the model performance can be judged as satisfactory, especially considering limited data condition and a high climatic gradient characterizing the Bani catchment.

Title: Radiogenic and Stable Strontium Isotope Variation in Rivers Draining the Canadian Precambrian Shield

Presenter/First Author: Ross Stevenson, Universite du Quebec a Montreal, Montreal, QC

Presenter/First Author Email: stevenson.ross@uqam.ca

Co-authors: Christopher R Pearce, , , ; Eric Rosa, Université du Québec en Abitibi-Témiscamingue, Amos, QC, Canada; Claude Hillaire-Marcel, University of Quebec at Montreal UQAM, Montreal, QC, Canada

Abstract Body: We present new radiogenic (87Sr/86Sr) and stable (δ88Sr/86Sr) strontium isotope data from four rivers of the Canadian Precambrian Shield. Radiogenic Sr isotope ratios reflect the contributions of different crustal sources, while the stable strontium isotope ratios can be used to calculate weathering rates. All four rivers flow into Hudson Bay or Hudson Strait. Three rivers drain the Precambrian Shield of Northern Quebec (The Koksoak, Great Whale and La Grande Rivers). The fourth one, the Nelson River, drains the Precambrian Shield of Northern Manitoba and Phanerozoic sedimentary deposits, through supplies from Lake Winnipeg and the North and South Saskatchewan Rivers. The Nelson, La Grande and Koksoak have one or more hydroelectric dams, while the Great Whale River remains free of hydroelectric development. Radiogenic strontium isotopes provide constraints on the geology of the terrain underlying the drainage basin whereas stable strontium isotopes fractionate in response to precipitation and dissolution reactions. Combining these radiogenic and stable isotope systems leads to a better understanding of the weathering of the Canadian Shield. Preliminary data reveals that the difference in the

geology of the drainage basin of the Nelson River is evident from lower 87Sr/86Sr ratios (0.713) compared to the other three rivers (0.728-0.735). Seasonal variations in the 87Sr/86Sr ratios are evident in some of the rivers and absent in others. Preliminary stable strontium isotope data (δ88Sr/86Sr) exhibits variations between 0.25 and 0.35 per mil, values that are consistent with those measured in rivers from elsewhere in the world.

Title: Progress in modeling high latitude land surface hydrological processes

Presenter/First Author: Dennis P Lettenmaier, University of California Los Angeles, Los Angeles, CA

Presenter/First Author Email: dlettenm@ucla.edu

Abstract Body: High latitude environments pose special challenges to land surface models. In addition to the need to represent land-atmosphere energy and moisture fluxes in a consistent manner, phase change is a dominant process, prevalent both in the need to represent snow and snow free hydrological processes, but also frozen soils which may be permanent aside from seasonal surface thawing (permafrost) or seasonally ephemeral. Land surface models represent these processes with varying degrees of fidelity, although many modeling groups have given them increased attention over the last decade or so. I review some of the key issues, and progress in modeling from the perspective of community modeling efforts, including the US DOE-funded Regional Arctic System Model (RASM), field experiments past and planned, and high resolution process models, and the extent to which they have affected the evolution of macroscale land surface schemes in coupled land-atmosphere models.

Title: Changing Climate and Streamflow in the Western Canadian Arctic

Presenter/First Author: Philip Marsh, Wilfrid Laurier University, Waterloo, ON

Presenter/First Author Email: p.marsh@outlook.com

Co-authors: Stefano Endrizzi, , Horgen, Switzerland; Daqing Yang, Organization Not Listed, Washington, DC; Tyler de Jong, , ,

Published Material: Previous work has described changes in streamflow for one watershed. This paper will expand this work to six watersheds crossing the treeline and diagnose the observed changes.

Abstract Body: The climate, landcover and permafrost are changing across the Western Canadian Arctic, with resulting changes in streamflow. Observed changes include warming air temperatures, decreasing precipitation, earlier onset of spring snowmelt, warming and deepening active layer, and north of the treeline expansion of shrubs. For one watershed north of the treeline, decreases in total, and peak, spring melt streamflow and delayed timing of melt runoff have been described. This paper will consider changes in spring melt streamflow for 6 watersheds along a 200 km transect crossing the arctic treeline in the vicinity of Inuvik, NWT, Canada, and will diagnose the integrated impact of changes in climate, landcover and permafrost, on the spring melt hydrology of these watersheds.

Title: Polar amplification and elevation-dependence in trends of Northern Hemisphere snow cover extent, 1971-2014

Presenter/First Author: Stephen J Dery, University of Northern British Columbia, Prince George, BC

Presenter/First Author Email: sdery@unbc.ca

Co-authors: Marco A. Hernández-Henríquez, University of Northern British Columbia, Prince George, BC, Canada; Christopher Derksen, Environment Canada Toronto, Toronto, ON, Canada

Abstract Body: Recent years have exhibited large declines in snow cover extent (SCE) in the Northern Hemisphere (NH), marked by earlier snowmelt in the springtime. In northern latitudes, the snow-albedo feedback (SAF) is most pronounced in the spring and may be contributing to these decreasing trends in SCE. Rising surface air temperatures and changes in precipitation patterns could also vary the declining trends in SCE depending on latitude and elevation. Previous trend analyses of NH SCE are extended here to cover the period 1 October 1971 to 30 September 2014 using observed data from the National Oceanic and Atmospheric Administration snow chart climate data record. Trends in snow coverage (significant when $p < 0.05$) with latitude and elevation are investigated using the Mann-Kendall test. Over the 43-year period, strong polar amplification of negative trends in snow cover are observed. The majority of statistically-significant negative trends are found in the mid- to high-latitudes, reaching a maximum reduction at 75.5°N. There is also elevation dependence of SCE over time as statistically-significant negative trends occur at most elevations, with a minimum reached at 3950 m a.s.l. These strong negative trends exhibited in the mid- to high-latitudes and mid- to high-elevations provide evidence of polar amplification and elevation dependence of trends in snow cover in a warming climate, suggesting a leading role of the SAF on the recent retreat of NH snow cover.

Title: Examining the influences of changes in snowpack structure on the declining Bathurst caribou herd in the Northwest Territories.

Presenter/First Author: Michael English, Wilfrid Laurier University, Waterloo, ON

Presenter/First Author Email: menglish@wlu.ca

Co-authors: Jan Adamczewski, , , ; Sarantia Katsaras, , , ; Jennifer Hickman, , , ; Roy Judas, , , ; Libo Wang, Environment Canada, Downsview, ON, Canada; Peter Toose, Environment Canada Toronto, Toronto, ON, Canada; Colin Robertson, , , ; Chris Derksen, , , ; Benoit Monpetit, , ,

Abstract Body: Over the past 15 years the Bathurst Caribou herd in the Northwest Territories has undergone a dramatic 96% decrease in population. The objective of this research is to determine if snowpack conditions in the winter foraging grounds of the Bathurst herd have changed over long periods of time in response to a warming climate and, in response to this, if the frequency of ice lens formation in the snowpack has changed over the past 20 years. Changes in snowpack characteristics such as dpeth, and increases in ice lenses may provide physiological challenges to caribou as for 6-7 months of the year their primary food source –lichen- lays at the base of the annual snowpack. To explore this idea remote sensing tools are employed. The Globsnow database is utilized to quantify changes in snowpack water equivalent (SWE) and assess the probability of ice lens formation especially during the fall and spring of sequential years between the late 1990's to present time. The snowpack water equivalent data is derived from a combination of SSM/I satellite data (passive microwave emissions at 37 GHz and 19 GHz) and local weather station data. Over the past several years the Environment and Natural Resources

Ministry (Wildlife Division) of the Government of the Northwest Territories has monitored the movement of approximately 20 caribou of the Bathurst herd outfitted with satellite collars. Assuming the movement of these individuals is representative of the pattern of movement of the non-collared herd it is possible to relate caribou spatial movement with respect to snowpack conditions on a daily basis. To assess whether snowpack conditions impact the distribution of the collared caribou specific pixels within the fall to early spring foraging habitat have been selected for long term evaluation and compared to caribou occurrence. Areas previously burned by forest fires are included in the data evaluation.

Title: The Impacts of Thermal Perturbation and Permafrost Disturbances on Runoff Pathways and Stream Water Quality, Cape Bounty, Melville Island, Nunavut

Presenter/First Author: Daniel Lamhonwah, Queen's University, Kingston,

Presenter/First Author Email: daniel.lamhonwah@queensu.ca

Co-authors: Melissa J Lafreniere, Queen's University, Kingston, ON, Canada; Scott F Lamoureux, Queen's University, Kingston, ON, Canada; Brent B Wolfe, Wilfrid Laurier University, Waterloo, ON, Canada

Published Material: Some results from this study will be presented at the Arctic Change 2014 conference (December 8 to 13) in poster form. We hope to present our full research as an oral presentation at the Joint Assembly where we can discuss results in greater detail.

Abstract Body: The Intergovernmental Panel on Climate Change (IPCC 2013) has projected that continued warming of the Arctic will substantially impact hydrological processes. However, there is limited research examining how runoff dynamics will respond to deepening active layers and permafrost disturbances, specifically active layer detachments (ALDs). Our research addresses this knowledge gap through research carried out at the Cape Bounty Arctic Watershed Observatory (CBAWO) in the Canadian Arctic, where significant localized ALDs occurred in 2007. We used major ion concentrations and stable isotope values (D, 18O and d-excess) as hydrological tracers to determine the relative contribution of different water sources (snowmelt, rainfall, soil water) to hillslope runoff in an undisturbed catchment (Goose) during summer 2012, a season characterized by high air surface temperatures, deep active layer thaw and above normal rainfall. We also investigated the same tracers at this undisturbed catchment and at a recently disturbed catchment (Ptarmigan) at CBAWO from 2006 to 2014 to identify possible longer terms changes in water sources and/or pathway that may have occurred in response to disturbance or interannual variability in climate.

Results indicate that deep active layer thaw increases the storage capacity of for summer rainfall and displaces stored soil water, which affects stream water chemistry as solute-rich waters are moved to the stream. Soil water with the highest solute concentrations are found progressively deeper in the soil profile and at the maximum active layer depth. Hence, the deeper the active layer thaw proceeds, the more likely this water can be moved to the surface following displacement by rainfall. ALDs create new channels for surface flow where meteoric water interacts with exposed solute-rich ground ice. This routing of water through new exposed permafrost soil directly impacts the variability and composition of ion concentrations in stream water. Hydrochemical variability (i.e. greater variations in ion concentrations) appears to increase over time from the onset of the disturbance. Consistent δD and δ18O in stream waters suggest that differences in water pathways, not water sources, may be the dominant control in stream water ion concentration between undisturbed and disturbed catchments.

Title: Hungry ponds in a thawing world: Variations in subarctic pond runoff quality and quantity depend on peatland moisture and frost conditions

Presenter/First Author: Matthew Q Morison, University of Waterloo, Waterloo,

Presenter/First Author Email: mmorison@uwaterloo.ca

Co-authors: Merrin L Macrae, University of Waterloo, Waterloo, ON, Canada; Richard M Petrone, University of Waterloo, Waterloo, ON, Canada; LeeAnn Fishback, , ,

Abstract Body: In subarctic permafrost environments, ecological productivity is often nutrient-limited, both in terrestrial and aquatic vegetation. The subarctic is experiencing significant climatic change, including rapid warming and changing precipitation patterns, which may result in changes in nutrient dynamics within terrestrial and aquatic systems and hydrologic transport between them. A change in nutrient dynamics may result in changes to vegetation growth, pond ecology, and food web stability in the North. The objective of this research was to characterize changes in runoff quantity and quality between peatlands and ponds over the snow-free summer seasons. Twenty-two ponds and five transects of piezometer nests along moisture gradients were instrumented to measure changes in hydrologic storage, frost table position, and water quality over two snow-free seasons (May to October) in Churchill, Manitoba, within the Hudson Bay Lowlands. Differences in antecedent moisture conditions across landscape units, combined with frost table position (inhibiting infiltration and storage) produced non-linear, threshold responses in runoff generation. Greater inputs were required to exceed storage ('fill and spill') when a lower frost table permitted deeper infiltration. Seasonal variations in groundwater chemistry were reflective of different layers of peat and mineral soil accessed at different times throughout the season, governed by frost table and water table positions. Varying thaw rates across landscape units (controlled by moisture and vegetation) resulted in changing groundwater pathways throughout the season. Changing hydrologic pathways combined with precipitation events throughout the season resulted in temporally variable nutrient concentrations in runoff and ponds. This work has implications for how nutrient dynamics and exchange between terrestrial and aquatic systems in cold regions may evolve under a changing climate.

Abstract Body: Flows from river basins in the lower Liard River valley in northwestern Canada have been rising in the last two decades as a result of climate warming. Changes in precipitation account for only about 30% of this increase. In the wetland-dominated basins that characterise the southern margin of permafrost, permafrost thaw and disappearance, and resulting land-cover change, is occurring at an unprecedented rate. Permafrost thaw has the potential to fundamentally alter the processes giving rise to streamflow in this region by altering the type and relative proportions of biophysical terrains. Field studies were conducted at the Scotty Creek Research Basin, a 152 km^2 watershed, located about 50 km south of Fort Simpson, NT. Scotty Creek is typical of other basins in the region and is underlain by discontinuous permafrost. There are three major land-cover types in the basin, each exhibiting a distinct hydrological function. Channel fens convey water to the basin outlet, while permafrost plateaus are runoff generators. Flat bogs have been shown to be primarily storage features, however ephemeral channels have been observed to cut through permafrost plateaus and allow for hydrologic interaction between bogs. These channels create series of bog cascades that drain adjacent peat plateaus and ultimately flow into the channel fen. It is shown that the transmission of water through bogs and into the fen is a mechanism that changes the effective contributing area based on antecedent moisture conditions. The dynamic contributing areas are shown to be controlled by storage thresholds. Field data indicates that transmission of water through bogs is dependent on storage levels. Sharp crested v-notch weirs and flume boxes were installed in the channels to create a continuous stage-discharge relationship to gauge runoff entering the channel fen through the bog cascades. In this study we attempt to quantify the amount of runoff produced from bog cascades and determine how the contributing area varies in time and space. The hydrological model Raven will be used to simulate this system and explore how the contributing area changes in response to storms of varying magnitudes.

Title: Root Network Impact on Soil Thermal Conductivity and Active Layer Thaw

Presenter/First Author: Stacey Van Opstal, Wilfrid Laurier University, Acton,

Presenter/First Author Email: vanx6246@mylaurier.ca

Co-authors: William L Quinton, Wilfrid Laurier University, Waterloo, ON, Canada

Abstract Body: A large portion of Canada's land surface is underlain by permafrost ranging from continuous to isolated and sporadic. Future increases in regional air temperatures are expected to lead to widespread degradation of permafrost, particularly in the zone of discontinuous permafrost where ground temperatures are close to the freezing point. This study examines the impact of black spruce root networks on the thermal conductivity of northern peatland soils and their resultant impact on active layer thaw. Measurements were taken in the Scotty Creek research basin, a wetland dominated area in the zone of discontinuous permafrost located near Fort Simpson, Northwest Territories. Thermal conductivities for black spruce roots and peat soils of various moisture contents were determined and used to model the relative importance the thermal conduction from each material has on the thawing of the active layer. As soil thawing progresses, the frost table and the thawed saturated zone above it descend through the wetted soil profile while the saturated horizontal hydraulic conductivity of peat decreases with depth. The influence of vegetation on soil moisture is an important aspect to consider when understanding permafrost thaw due to the relationship of thermal conductivity of soils and moisture content. Root systems of plants are known to extend vertically into the soil profile for considerable depths and can tap water and nutrients from both deep and shallow layers, black spruce roots reach only approximately 30 cm below ground. The movement of moisture by plant roots is an important component of below ground hydrological processes and is therefore also important in understanding heat movement within soils through 1) the effect of soil moisture on heat conduction, and 2) coupled heat and mass transfer processes. In the context of a peat plateau complex understanding the process of hydraulic redistribution is important because the root networks are an important mechanism of soil moisture movement and as a result the relation between the soil thermal conductivity and moisture content.

Title: Groundwater Development In Semi-Arid South India: Trends and Status

Presenter/First Author: Rajendra Prasad Sishodia, ICRISAT, Patancheru,

Presenter/First Author Email: rpsishodia@gmail.com

Co-authors: Sanjay Shukla, University of Florida, Ft Walton Beach, FL

Published Material: The manuscript is currently under final stage of preparation and it would be submitted for publication in February.

Abstract Body: Growing number of studies have indicated declining groundwater levels in the semi-arid southern region of India, however the statistical significance of the change in the level has not been analyzed. This study attempts to determine whether the semi-arid southern India is experiencing significant decline by analyzing the long term (1990-2012) groundwater levels data for three districts (administrative division in a state) with diverse land uses. Based on the length of the record, data from monitoring wells were divided into three time periods: 1990-2012 (group A), 1990-2005 (group B) and 1997-2012 (group C). Nonparametric trend tests showed that 21% of the wells in group A, 36% wells in group B and 25% of the wells in group C had a statistically significant ($p < 0.05$) declining trend in the mean annual groundwater levels. Trend tests for rainfall and rainfall adjusted groundwater levels (locally weighted regression residuals) showed that rainfall variability could not fully explain the declining trends. Increase in numbers of irrigation wells (shallow and deep), as well as the irrigated area, were the main factors causing the decline in groundwater levels. The number of closed drilled wells increased from 61,236 in 1994 to 297,601 in 2007, an increase of almost 400%. The growth in number of tube wells has caused abandonment of many traditional open (dug) wells and reduced the productivity (area irrigated per well) of drilled wells. Continued increase in groundwater-based irrigated areas is likely to increase the groundwater level declines and well drying occurrences in the future. Supply and demand management of groundwater along with a transition to resource efficient techniques such as drip irrigation could reverse this decline and increase the water availability in the region. Low specific yield and low storage capacity of these shallow weathered fractured aquifers would continue to play an increasingly important role in planning, design and management of groundwater resources of the region.

Title: Effective management of brackish irrigation water for a network of farms along a river by considering soil-water-plant feedback mechanisms: a conceptual framework development

Presenter/First Author: Syed Hamid Hussain Shah, Organization Not Listed, Faisalabad,

Presenter/First Author Email: shahgee1347@hotmail.com

Abstract Body: In semi-arid regions, irrigation water to compensate the deficit of precipitation is compulsory for crop production. The demand for quantity of water used for agricultural production is greater than the required water for domestic utilization and production factories. With increase in population, the demand for good quality water increases. The cost to purify the brackish water also increases to fulfill the demand of agriculture. Therefore, the use of marginal water quality is increasing day by day. In order to reduce the effects of salinity on crop yield, irrigation water must contain additional water for leaching. This additional water becomes part of the surface and subsurface water resources and increases the leaching requirements due to increase in salinity level for next water user.

A conceptual framework developed by Ben Gal et al., (2013) has been applied and validated for optimal management of scarce and brackish irrigation water. The conceptual model is applied to the irrigation of *Zea mays L. c*v. Jubilee on Millville Silt Loam. In this model, it is shown that how water application should be distributed between upstream and downstream plots or farms. We show the scenarios where water is traded from upstream to downstream farms keeping in view that upstream farm holds the water rights.

The conceptual ANSWER model of irrigation containing conjunctive use of fresh and waste water predicts crop yields and water consumption and tracks the water flow and level of salinity along a river dependent on irrigation management decisions. The model considers a coupled agro-physical model, in which plant response to soil and climate parameters in addition to feedback is predicted. Furthermore, the model evaluates the impact of water shortage, salinity, and unproductive application on yield for exact crop, soil and climate conditions. We find that as salinity level and inefficiency increase, the upstream user must use less water and downstream user as a result uses better quantity and quality water to optimize the system yield.

Published Material: A worked called "ESTIMATION OF SUBMARINE GROUNDWATER DISCHARGES USING RADON AND RADIUM ISOTOPES IN THE MAR MENOR LAGOON (SPAIN) AND THE PORT-MIOU CALANQUE (FRANCE)" was presented at Rapp. Comm. int. Mer Médit. in 2013. A paper has been sent to Journal of Hydrology and is under review.

Abstract Body: In highly anthropized watersheds, surface water tributaries may carry unexpectedly high quantities of radon (^{222}Rn) to surface water masses. Assessing the impact of these additional sources of radionuclides on the spatial repartition of radionuclides is a hard task for submarine groundwater discharge (SGD) investigations. A methodology was tested to the Campo de Cartagena aquifer - Mar Menor lagoon hydrosystem in SE Spain. In this area, intensive irrigation and subsequent recharge caused a severe water table rise, from which groundwater started to discharge to the main surface water stream. In addition, the uncontrolled release of brines from private groundwater desalination potentially induced artificial surface water discharges through the main stream or directly to the Mar Menor lagoon. In order to decipher the influence of the different water sources on the spatial repartition of radionuclides and to strengthen the quantification of submarine groundwater discharge fluxes, we combined a ^{222}Rn survey with the hydrodynamic modeling of the Mar Menor lagoon. Once demonstrated that reverse osmosis desalination does not affect significantly ^{222}Rn activities, it was shown that brine discharge exerted a main control on the total radionuclide discharge of the surface stream. Hydrodynamic modeling then demonstrated that high values measured along the discharge coastline were, unexpectedly, not indicators of localized SGD fluxes. Indeed, the observed high values were rather explained by the propagation of the river plume (central area), by artificial releases to the lagoon (northern area) and by agricultural groundwater drainage (southern area). These findings helped quantifying the impact of artificial releases and by then, strengthened the SGD quantification.

Title: Spatially distributed recharge modelling with commonly available data - Application to the Centre-du-Québec region of southern Quebec (Canada)

Presenter/First Author: Diogo Barnetche, GEOTOP-UQAM, Montreal,

Presenter/First Author Email: barnetche.diogo@uqam.ca

Co-authors: Marie Larocque, Univ du Quebec - Montreal, Dorval, QC, Canada; Guillaume Meyzonnat, GEOTOP-UQAM, Montréal, QC, Canada; Sylvain Gagné, Universite Du Quebec A Montrea, Montréal, Canada

Abstract Body: The estimation of mean groundwater recharge over a watershed is a relatively simple task when using a global water balance. However, such a simple recharge estimate often hides local variations of recharge that depend on geological, topographical or land use heterogeneity within the watershed. There is clearly a need to develop and use recharge models aimed at calculating spatially distributed recharge rates for regional scale hydrogeological studies. The objective of this work

was to develop an approach to quantify spatially distributed recharge rates based on commonly available data. The *HydroBilan* model was developed to estimates surface infiltration by calculating a spatial water balance with a 500 m x 500 m grid resolution. The model uses the temporally variable runoff estimate from the Runoff Curve Number (RCN) method adapted for southern Quebec, as well as the daily vertical inflows generated by the Centre d'expertise hydrique du Québec and the daily air temperature. Slope, land use and soil type data are extracted from a database typical of those generally available. A limited number of parameters, including soil freezing, moisture conditions and percentage of water that effectively infiltrates daily into the soil, require calibration. The model was calibrated with a 21-year time series on a 1550 km² sub-watershed to minimize the error between calculated runoff, evapotranspiration and seasonal evolution of the infiltration. The calibration was performed to reproduce the total runoff/recharge ratios simulated with the MOHYSE hydrological model as well as those from base flow separation data. The calibrated parameters were then used on the Nicolet and the lower Saint-François watersheds in the Centre-du-Québec region of southern Quebec (Canada; 18 300 cells over 4500 km²). The model estimates an average recharge of 152 mm/year for the study area and a preferential recharge zone over the Appalachian Mountains and a low recharge zone over the sedimentary plains. The *HydroBilan* model reaches its full potential in the Appalachian Piedmont where it allows the identification of sparsely distributed recharge areas. Potential recharge, evapotranspiration and runoff respectively represent 14%, 42% and 44% of the total water budget.

Title: Application of the Pressure-State-Response Framework for Measuring Groundwater Sustainability. Case Study: Campo de Cartagena (SE Spain)

Presenter/First Author: Javier Senent-Aparicio, Organization Not Listed, Murcia,

Presenter/First Author Email: jsenent@ucam.edu

Co-authors: Jose-Luis Garcia-Aróstegui, Insituto Geológico y Minero de España, Madrid, Spain; Julio Pérez-Sánchez, , , ; Alicia María Bielsa-Artero, , , ; Juan Carlos Domingo Pinillos, , ,

Abstract Body: In arid and semi-arid areas in which irrigated agriculture prevails, a sustainable management is difficult to achieve. The Campo de Cartagena area in the Murcia region (SE Spain) is an emblematic case of the hydrological and environmental changes caused by the intensive use of groundwater for agriculture in Mediterranean areas. It is a 1440 km² coastal plain where the climate is semiarid with an average temperature of 18˚C and an average rainfall of about 300 mm per year. The economy of the area relies on the agro-industrial sector with crops covering 1/3 of the total surface. Due to the low precipitation rate and a lack of permanent surface water, intensive irrigated agriculture has been historically and mainly supported by groundwater extraction from the aquifer system.

Since the introduction of the concept of sustainable development in the Brundtland report in the late last century, many scientists have recently turned to work on the objective measurement of sustainability through indexes. Applying these indices to the water resources management, it could be assessed the current state of them and they serve as an aid to decision-making by the competent authorities. Several issues impact the groundwater sustainability of an aquifer, such as hydrogeological, socioeconomical and environmental aspects. However, they are often treated separately, and not as an integrated process. The aim of this study is to integrate these issues and develop an index in order to assess the groundwater sustainability in a pressure-state-response framework. The proposed methodology could be extrapolated to many semi-arid basins with hydrological, environmental, social and political conditions similar to the case study.

Title: Simulating the Effects of Groundwater Dynamics on Aquifer Vulnerability

Presenter/First Author: Guillaume Meyzonnat, GEOTOP-UQAM, Montréal, QC

Presenter/First Author Email: guillaume.meyzonnat@gmail.com

Co-authors: Marie Larocque, Univ du Quebec - Montreal, Dorval, QC, Canada

Abstract Body: Groundwater vulnerability mapping is extensively used as an analytical tool for groundwater resource protection and land use management. Vulnerability mapping can however bring some limitation, as the most widely used methods (i.e. DRASTIC, GOD, SINTACS, etc.) are based on semi-objective weighted parameters. The majority of these methods do not take into account groundwater flow and solute transport. The objective of this study was to use numerical modeling to quantitatively identify the hydrogeological parameters which significantly influence contaminant transport and therefore aquifer vulnerability. A synthetic 3D model using MODFLOW and MT3D was built to represent the main characteristics (e.g. watershed scale, hydraulic gradient, recharge rate) of the Becancour watershed (2 900 km²) located in southern Québec (Canada). Diffuses sources of contamination were simulated as contaminant influx with the recharge and computed concentrations in groundwater were interpreted as a proxy of vulnerability. The numerical experiments show that maximum contaminant concentrations in groundwater are more largely influenced by hydrogeological parameters than by the size and density of the contaminant sources. At the regional scale, the simulated concentrations in groundwater are mostly sensitive to recharge rates and to the dilution potential with regional flow. At the local scale, river drainage coefficients and hydraulic gradients are the most influential parameters. As expected, these results suggest that the most vulnerable areas can be found where recharge rates are high and where the contaminant dilution potential is low. In the simulated model, the majority of contaminant input is exported out of the aquifer through the rivers. The modelling also suggests that deep bedrock aquifers could become vulnerable to anthropogenic pollution (e.g. nitrates) in the long-term, as nitrates originating from the beginning of intensive agriculture in the 70-80's may not yet have reached aquifers deeper than 75 m.

Title: The Impacts of Change in Rainfall and Groundwater Withdrawal on Groundwater Resources of Raya Valley, Northern Ethiopia.

Presenter/First Author: Merhawi GebreEgziabher GebreMichael, Addis Ababa University, Addis Ababa,

Presenter/First Author Email: meregebre@gmail.com

Abstract Body: Climate change and anthropogenic factors have direct impact on the availability of subsurface water. Groundwater potential is governed by its quality and the quantity. The groundwater quantity is interconnected with the hydrological cycle and its components. Change in climate condition will have impact on the hydrological cycle leading variability on the groundwater resource by affecting the groundwater recharge. In contrary, human impact like excessive pumping exacerbate the depletion of the groundwater potential. In this study, we give more emphasis to change in rainfall and human induced groundwater discharge, on the available groundwater resource.

We have conducted hydrological and hydrogeological study to see the impacts of change in precipitation and groundwater withdrawal using groundwater flow modeling in Raya Valley, Northern Ethiopia. Raya valley, is characterized by humid to semiarid climate condition, where surface water is limited. The hydrogeological studies had proven the groundwater is accessible along two major aquifers, these are fractured volcanic and alluvial aquifers. Geomorphological setup shows, the volcanic aquifer is situated in the humid highland area and the alluvial aquifer is found in the lowland, where the climate condition is semiarid. The major sources of water are groundwater and seasonal flooding water.

A comprehensive conceptual modeling of the basin has been carried out using hydrochemistry, isotope hydrology, and hydrogeological studies. Then we conducted the flow modeling using Modflow Pro. The model was calibrated with the actual hydrogeological condition. The model result depicted that change in rainfall have a general declining trend in water level, this is as a result of reducing groundwater recharge. Under this scenario, lowering lake level and drying up of swampy areas is observed. The simulation of increasing groundwater pumping from the aquifers have been done to predict future water use and its impact. The model results shows that, a dramatic groundwater fall up to 20 meters as a result pumping ten times the current groundwater withdrawal. Therefore, the groundwater potential of the basin can be affected under high pumping conditions and the adjacent wetlands will dry up, as a result of pumping the groundwater dependent ecosystem will be in danger.

Title: A Unified Approach for Process-based Hydrologic Modeling

Presenter/First Author: Martyn P Clark, NCAR, Boulder, CO

Presenter/First Author Email: mclark@ucar.edu

Published Material: Some material presented at AGU; papers under review in WRR.

Abstract Body: This work advances a unified approach to process-based hydrologic modeling to enable controlled and systematic evaluation of multiple model representations (hypotheses) of hydrologic processes and scaling behavior. Our approach, which we term the Structure for Unifying Multiple Modeling Alternatives (SUMMA), formulates a general set of governing model equations and spatial approximations, providing the flexibility to experiment with different spatial representations, different flux parameterizations, different model parameter values, and different time stepping schemes. In this paper we introduce the general approach used in SUMMA, detailing the spatial organization and model simplifications, and how different representations of multiple physical processes can be combined within a single modeling framework. We discuss how SUMMA can be used to systematically pursue the method of multiple working hypotheses in hydrology. In particular, we discuss how SUMMA can help tackle major hydrologic modeling challenges, including defining the appropriate complexity of a model, selecting among competing flux parameterizations, representing spatial variability across a hierarchy of scales, identifying potential improvements in computational efficiency and numerical accuracy as part of the numerical solver, and improving understanding of the various sources of model uncertainty.

Abstract Body: Air temperatures at high latitudes have increased at rates that exceed globally averaged trends, and this warming has produced rapid permafrost degradation in many areas. In discontinuous permafrost regions of the Taiga Plains of northwestern Canada, past climate warming has created a complex landscape mosaic of thawed bogs/fens and remnant peat plateaus underlain by thin permafrost. The thawing of peat plateaus can alter the landscape hydrologic connectivity by creating pathways to efficiently convey water from bogs to nearby rivers and lakes. Extensive monitoring of the thermal regime of a peat plateau-bog complex in the Scotty Creek watershed (61.3˚ N, 121.3˚W), Northwest Territories has identified rapid permafrost degradation in the past decade. In addition, satellite images indicate major landscape evolution due to permafrost thaw since 1970, and these changes have resulted in increased discharge at the watershed outlet. These long term comprehensive data facilitate the numerical modeling of idealized permafrost environments based on observed data. The objective of this project is to elucidate processes that contribute to multi-dimensional permafrost thaw and associated hydrological changes in discontinuous permafrost regions.

The thaw evolution in this peat plateau-bog complex is simulated using SUTRA, a numerical groundwater flow and heat transport model that has been modified to include freeze-thaw processes. To accommodate complex surface processes, measured climate data from 1900-2010 are used to drive a separate soil-vegetation-atmosphere-transfer model. Near-surface temperatures produced by the vertical transfer model for the peat plateau and bog are applied as the upper thermal boundary conditions for the multi-dimensional subsurface heat transport simulations. The simulated thaw development of this peat plateau will be compared to satellite imagery to assess the ability of this sequential modeling approach to reproduce observed permafrost degradation.

Title: Implications of Galling Herbivory on Ground Thaw Through Shrub-Soil Heat Transfers Within Canada's Northern Boreal Forest

Presenter/First Author: Allison McManus, Wilfrid Laurier University, Waterloo, ON

Presenter/First Author Email: mcma9840@mylaurier.ca

Co-authors: Jennifer Lynn Baltzer, Wilfrid Laurier University, Waterloo, ON, Canada; William L Quinton, Wilfrid Laurier University, Waterloo, ON, Canada

Published Material: Poster presentation of preliminary findings at the 2nd Annual General Meeting of the Changing Cold Regions Network, October 19-22, 2014. Research is not currently under review or recently accepted by a scientific journal.

Abstract Body: The significant climate warming faced by Canada's northern boreal forest has the potential to affect forest dynamics by altering the dispersion and abundance of resident natural enemies. Warmer air temperatures can impact the distribution and overwinter survival rate of these arthropods. Thus, the impacts of arthropod pests on

their host plants require better understanding. Gall-inducing mites are a resident natural enemy in high latitude forests and have been shown to drive dramatic reductions in photosynthetic carbon uptake and transpiration rates of infested plants with the potential to alter shrub-energy balance. In this study we examine the impacts the gall-inducing eriophyoid mite, *Vasates oldfieldi*, has on *Betula* shrub energy inputs to the underlying ground surface. Two hypotheses will be tested: 1) a positive feedback to permafrost thaw through a reduction in evaporative cooling on the leaf surface increasing the canopy temperature of the *Betula* shrubs. The increase in the incident longwave radiation to the ground surface leads to an increase in the active layer thickness. 2) a negative feedback on permafrost thaw through a compensatory response in the shrub leading to an increase in leaf area index (LAI) to offset the loss of photosynthetic function. This reduces the amount of incident solar radiation at the ground surface resulting in a shallower active layer. To test these hypotheses, we measured soil moisture and surface temperature, leaf temperature, active layer thickness, shortwave radiation, transpiration and LAI. Our initial findings have shown an increase in active layer thickness and soil temperature under ungalled shrubs compared to galled shrubs of similar size for both the 2013 and 2014 field seasons. The results from this experiment are of great significance as the potential for a positive feedback of warming at a very local scale can potentially influence ground thaw in the northern boreal forest.

Title: Robustness in the spring surface energy balance in a mountain basin

Presenter/First Author: Chris Marsh, Global Institute for Water Security (GIWS), University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: chris.marsh@usask.ca

Abstract Body: Complex dynamical systems, such as hydrological systems, exhibit system-wide behaviours that are due to the interaction of numerous processes and may result in system robustness. Such robustness is characterized by persistent behaviours despite system perturbations. In process-based hydrological models, inter-process interactions are typically included to increase physical realism, often at the cost of increased complexity. Model robustness is characterized by a persistence of model behaviours to perturbations in initial/boundary conditions, system parameters, and underlying model assumptions. This model robustness may reproduce system robustness and allow up-scaled and possibly falsified model representations of the system to be successful. Model robustness is distinguished from model stability by considering not just the persistence of behaviours but by also considering the interplay between model dynamics, model structure, and model assumptions that leads to this persistence. Quantifying the details of why, and under what conditions, system and model robustness occurs is critically important to deciding how to design robust hydrological models of sufficient complexity that can perform well when faced with uncertainty in parameters and forcing data.
In this work, we explore model robustness through the use of point-scale, physically based, energy-budget snowmelt models of varying degrees of physical realism and model complexity. We consider snowmelt model robustness as a possible surrogate for snowmelt system robustness over complex mountain topography. These models are driven by data from a mountain research watershed to examine the effects of surface characteristics, perturbations to meteorological forcing, and level of process representation on robustness. The results have implications for the estimation of uncertainty in the representation of complex mountain terrain and snow processes in up-scaled hydrological models and land surface schemes.

Title: Sensitivity of Snow-Vegetation Interactions and Streamflow Regimes to Climate Change in Mountain Basins

Presenter/First Author: Kabir Rasouli, University of Saskatchewan, Canmore, AB

Presenter/First Author Email: kabir.rasouli@usask.ca

Co-authors: John W Pomeroy, University of Saskatchewan, Canmore, AB, Canada; Danny G Marks, USDA-ARS Boise, Boise, ID; J. Richard Janowicz, , , ; Sean Kevin Carey, McMaster University, Hamilton, ON, Canada

Abstract Body: Understanding the interactions amongst snow processes, vegetation and runoff in mountains is crucial for climate change impact studies. In this research, a sensitivity analysis is carried out based on regional climate model scenarios, field measurements, and factors that control vegetation growth. The objectives are to investigate the interaction of concomitant vegetation and snow changes and to simulate transient changes in hydrological processes under climate change. Land cover changes alter the evapotranspiration, sublimation, snow redistribution, infiltration and runoff mechanisms which are responsible for the variability of subsurface storage, soil moisture, active layer thickness, and vegetation growth. The Cold Regions Hydrological Modelling platform (CRHM) is applied for modelling these mechanisms based on transient changes in vegetation. The model is tested in two well instrumented mountain headwater basins: Wolf Creek Research Basin, WCRB, with a very cold climate and discontinuous permafrost in the Canadian subarctic and Reynold Mountain East catchment, RME, in the Reynolds Creek Experimental Watershed with a moderate climate in Idaho, USA. The results showed that the hydrological impacts of warming decreased snowmelt runoff substantially in both basins. In WCRB warming increased the active layer depth, leading to conditions suitable for the growth of shrub tundra and conversion of some shrub tundra to forest and short vegetation to shrubs. In contrast, the hydrological response to warming in RME led to smaller snow drifts, which led to conversion of forests that were dependent on meltwater from snowdrifts to sagebrush and grass. The increase in forest area and expansion of shrubs in WCRB further decreased runoff generation at lower and middle elevations and moderated decreased runoff at higher elevations; the suppression of snow redistribution by wind shortened the melt season. The loss of forests from RME accelerated melt rates of the remaining snowpack and reduced evapotranspiration losses, slightly dampening the reduction in streamflow from the reduced snowmelt due to warming.

Title: Effects of Roads and Linear Forest Disturbances on the Snow Mass and Energy Balance

Presenter/First Author: Keith N Musselman, University of Saskatchewan, Canmore, AB

Presenter/First Author Email: keith.musselman@usask.ca

Co-authors: John W Pomeroy, University of Saskatchewan, Canmore, AB, Canada

Abstract Body: Linear disturbances for infrastructure such as roads, power transmission and pipelines are commonplace and rapidly expanding across the seasonally snow-covered needle-leaf forest zone in North America. Compared to other disturbance practices (e.g., clearings for timber harvest), the relatively narrow extent and permanence of linear

disturbances uniquely modifies surface-atmosphere exchanges, largely due to changes to longwave and shortwave radiation and greatly reduced snow interception capacity due to the reduction in needleleaf canopy. The sign and magnitude of these modifications are determined by how hydrometeorological processes such as snow interception, wind redistribution, radiation transfer and turbulent transfer of heat and water vapour are controlled by climate, forest structure, and slope-aspect. Results are presented from a modelling study of snow mass and energy balance dynamics in and around conceptual linear forest clearings. A solar ray trace model developed and tested against extensive measurements made at the Marmot Creek Research Basin is coupled to a snow energy and mass balance calculation scheme and applied to a range of latitude, slope-aspect, and disturbance and forest characteristics. The results are shown to resolve shading effects necessary to simulate the fine-scale variability in the snow surface energy balance that characterize these environments. A comparison of simulation results from a sensitivity experiment showed that the orientation of the disturbances (i.e., N-S vs. E-W), the latitude, and the width-to-tree-height ratio were three dominant factors determining the net impact of the linear disturbances on the timing and duration of snowmelt. The disparity in energy and mass balance over short distances highlights the importance of understanding the variability of hydrological inputs over forested regions that are fragmented by linear disturbances.

Title: Measuring and Modelling a Major Winter Precipitation Event in the Canadian Rockies

Presenter/First Author: Michael Schirmer, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: michael.schirmer@usask.ca

Co-authors: Xing Fang, University of Saskatchewan, Saskatoon, SK, Canada; John W Pomeroy, University of Saskatchewan, Canmore, AB, Canada

Abstract Body: Mountains present extraordinary challenges to both snow measurement and modelling. The seasonal snowpack in the Canadian Rockies is strongly influenced by accumulation and redistribution during and after snowstorms. Often just a few large storm events determine the main characteristics of the seasonal mountain snowpack. Quantifying the temporal and spatial distribution of mountain snowpacks due to individual storms is therefore of great interest for water supply prediction from mountains. In order to assess the variability and uncertainty in accumulation and ablation associated with a major snow storm, precipitation, snow accumulation and snow depth measurements were made in the Canadian Rockies during and after a major storm event in November 2014. The storm was characterised by strong winds and rapidly decreasing air temperatures as a cold front advanced from the north. Measurements suggest that snowfall of up to 90 mm SWE over two days was caused by uplifting of a warm, relatively moist, air mass as the cold front advanced. Blowing snow, and potentially preferential deposition, contributed to the highly variable post-storm snow accumulation. To assess the relative contributions to variable snow accumulation, snowfall gauge undercatch corrections were applied to sites with different wind exposures but identical precipitation gauge types and compared to results from automatic and manual snow accumulation and snow depth measurements in sheltered and open sites. A blowing snow model was then run to estimate blowing snow redistribution. The results suggest that there is great uncertainty in estimating snowfall in this environments because gauge-undercatch corrections established at flat test sites do not produce credible values in complex terrain and because snowfall gauges bridge with large snowfall amounts. The relative impacts of measurement errors, preferential deposition and blowing snow redistribution are discussed.

Title: The Influence of Site Conditions and Surface Vegetation on Snow Accumulation and Ablation in the Elk Valley, British Columbia, Canada

Presenter/First Author: David Aaron Bezeau, McMaster University, Hamilton,

Presenter/First Author Email: bezeauda@mcmaster.ca

Co-authors: Sean Kevin Carey, McMaster University, Hamilton, ON, Canada

Abstract Body: Surface mining of coal in the Elk Valley, British Columbia involves the blasting of overburden rock to access the underlying coal formations. Waste rock is placed in adjacent valleys, which influences the timing and magnitude of hydrological fluxes within the watershed. As part of a multi-year R&D program examining the influence of surface mining on watershed hydrology in the Elk Valley, British Columbia, this study investigates how: 1) site conditions and surface vegetation atop waste rock influences snow accumulation and ablation, and 2) the ability of a physically based model to simulate these processes. During the 2014 melt season, meteorological observations, turbulent fluxes determined via eddy covariance, and snow conditions were measured at three sites: 1) a bare waste-rock surface, 2) a waste-rock surface covered with agronomic grass species, and 3) a mixed pine stand on waste-rock. Elevation was the dominant control of snow accumulation, with the upper elevation site recording a maximum snow water equivalent of 670 mm, that compared to the lower elevation site with a maximum snow water equivalent of 170 mm. Ablation was driven largely by incoming short-wave radiation, which at the bare waste-rock and grass covered waste rock sites was greater than at the forested site. Melt occurred at the forest site several weeks in advance of the bare and grass covered sites. Turbulent flux contributions to snow ablation were limited at the forested site relative to the bare waste-rock and grass covered waste rock sites. The physically based Cold Regions Hydrological Model (CRHM) was able to simulate the influence of surface vegetation on the accumulation and melt dynamics. Model results were sensitive to parameters quantifying vegetation cover and blowing snow. Results of this study assist our understanding of how surface vegetation on waste rock and site conditions can influence the timing and magnitude of melt and infiltration, and subsequent freshet response.

Title: An Overview of the Risks to Water Resources from Unconventional Shale Gas Development and Hydraulic Fracturing

Presenter: Thomas Darrah, Ohio State University Main Campus, Columbus, OH

Presenter Email: darrah.24@osu.edu

First Author: Avner Vengosh, Duke University, Durham, NC

First Author Email: vengosh@duke.edu

First Author Student?: No

Co-authors: Nathaniel R Warner, Dartmouth College, Hanover, NH; Jennifer Harkness, Duke University, Durham, NC; Robert B Jackson, Stanford University, Stanford, CA

Published Material: This is an overview presentation based on several scientific publications on the environmental effects of shale gas exploration.

Abstract Body: The rise of unconventional shale gas development through horizontal drilling and high volume hydraulic fracturing has expanded oil and gas exploration in the USA. The rapid rate of shale gas exploration has triggered an intense public debate regarding the potential environmental and human health effects. Active research by the Duke team in different parts of the USA (Pennsylvania, West Virginia, New York, Arkansas, North Carolina, Texas) has identified four potential risks for impacts on water resources: (1) stray gas contamination of shallow aquifers near shale gas sites resulted in elevated methane levels in some drinking water wells located < 1 km from shale gas wells ; (2) contamination of surface water and shallow groundwater from spills, leaks, and disposal of inadequately treated oil and gas wastewater resulted in elevated levels of halides, ammonium, barium, radium among other contaminants in downstream waterways ; (3) accumulation of toxic and radioactive residues in soil and stream sediments near disposal or spill sites; and (4) over-extraction of water resources for drilling and hydraulic fracturing that could induce water shortages and conflicts with other water users, particularly in water-scarce areas. New state-of-the-art geochemical and isotopic techniques have been developed for delineating the origin of gases and contaminants in water resources. In particular, multiple geochemical and isotopic (carbon isotopes in hydrocarbons, noble gas, strontium, boron, lithium, radium isotopes) tracers have been utilized to distinguish (1) fugitive gas induced from leaking of shale gas wells relative to background naturally occurring methane flux in the subsurface; and (2) contamination from hydraulic fracturing fluids relative to produced water from conventional oil and gas wells and/or naturally occurring salinization. Overall, the environmental effects of unconventional shale gas exploration and hydraulic fracturing can be mitigated by improving the wells integrity and preventing leaking of stray gas, treating or preventing the release of flowback and produced waters to the environment, and using alternative water resources instead of fresh water for hydraulic fracturing.

Title: Gas Emissions from Energy Wells and the Groundwater Monitoring Problem

Presenter/First Author: Richard Ervin Jackson, Geofirma Engineering Ltd, Heidelberg, ON

Presenter/First Author Email: rjackson@geofirma.com

Co-authors: Dru Heagle, , ,

Abstract Body: There is accumulating evidence from the drilling and completion of some energy wells of free-phase gas emissions migrating considerable distances away from such wells (500 m or more) in structurally complex terrain. This information was obtained by regulatory agencies and geological surveys in structurally complex regions such as the Appalachian belt of eastern North American. Such migration distances pose real problems with respect to the monitoring of gas emissions that may affect shallow potable groundwaters. Information on wellbore leakage is only recently appearing in the technical literature reflecting what industry has long acknowledged, i.e., the difficulty of wellbore sealing with cement slurries when numerous strata contain hydrocarbon and hydrogen sulfide gases under varying in-situ pressures. Given (i) the transient nature of natural gas emissions from energy wells, (ii) the spatial and temporal variability of groundwater quality and (iii) the uncertain integrity of landowner wells, there is clearly a burden of proof on those sampling landowner wells to demonstrate that the 'pre-drill' data collected are robust and provide reliable information for use in dispute resolution. Not only can we expect gas emissions to be pulses, but we must anticipate that the discharge area, in which such gas 'daylights', might be distant from the energy well pad and its location therefore uncertain. For these reasons there is a clear need to link research concerning wellbore integrity with gas migration through fractured-rock networks. Similarly, groundwater monitoring has to be focused on potential gas-discharge areas that contain public groundwater supply wells. Such research and monitoring requires recognition from research-funding institutions, regulatory agencies and geological surveys.

Title: Paleozoic Brine and Gas Seeps on Anticosti Island: Impacts for Developing Unconventional Hydrocarbon Resources

Presenter/First Author: Ian Douglas Clark, University of Ottawa, Ottawa, ON

Presenter/First Author Email: idclark@uottawa.ca

Co-authors: Pascale Daoust, , , ; André Desrochers, , , ; Wilder Greenman, , , ; Danielle Fortin, Univ Ottawa, Ottawa, ON, Canada

Abstract Body: The Upper Ordovician Macasty shale on Anticosti Island hosts hydrocarbon potential currently being evaluated for non-conventional extraction. This study focuses on groundwaters in the region for evidence of deep groundwater discharge to shallow aquifers and at surface. Of particular interest is the high salinity spring, Source-de-Saumure-de-la-Chaloupe, situated near the Chaloupe River on Anticosti Island. At this spring, water is discharging at about 0.05 L s^{-1} with salinity of 3x seawater and accompanying gas ebullition at a rate of roughly 10 cc s^{-1}. The water precipitates calcite, forming a mound measuring about 1 m in height and 30 m in diameter around the main vent. Stable isotopes and geochemistry of the waters indicate them to be a mixture between shallow, meteoric waters and basin brines of evaporated seawater origin. The gas is dominated by methane with $\delta^{13}C$ values from –57.7‰ (June 2014) to –44.3‰ (July 2013) that suggests a mixture between biogenic and thermocatalytic methane. The dissolved inorganic carbon has an enriched $\delta^{13}C$ signature (+9.2‰) indicating that the DIC is affected by biogenic methanogenesis. Preliminary DNA sequencing results of biofilms growing in the brine suggest that bacteria and archaea likely play a role in carbon cycling. Our current hypothesis in this evolving study holds that shallowly circulating, methanogenic groundwater in the karstic aquifers of Anticosti Island acquires contributions of basin brine with thermocatalytic methane from the deep Paleozoic strata via a system of fracture permeability associated with the adjacent Jupiter fault. Ongoing research focuses on noble gases and ^{14}C with stable isotopes of the carbon pool to resolve the origins of the mixing fractions.

Title: Numerical investigation of methane and formation fluid leakage along the casing of a decommissioned shale-gas well: Application to the St. Lawrence Lowlands Basin

Presenter/First Author: Jean-Michel Lemieux, SNC-Lavalin Environment, Montreal, QC

Presenter/First Author Email: jmlemieux@ggl.ulaval.ca

Co-authors: Ali Nowamooz, Universite Laval, Quebec, QC, Canada; John W H Molson, Laval University, Quebec City, QC, Canada; Rene Therrien, Universite Laval, Quebec, QC, Canada

Published Material: This material has been presented at the IAH conference in Marrakech (fall 2014) and at the GSA annual meeting in Vancouver (fall 2014). It is also in submission to WRR (revisions pending).

Abstract Body: Numerical simulations are used to understand the role of the well casing annulus cementation and formation hydrodynamic properties on the migration of methane gas and formation fluids in the context of environmental risks related to shale gas development.

A conceptual model of a vertical decommissioned shale gas well is developed based on a geological sequence in the St. Lawrence Lowlands Basin (Quebec, Canada) containing from bottom to top, 200 m of Utica shale overlain by 750 m of low-permeable caprock (Lorraine Group), which is in turn overlain by a 50 m thick surficial unconsolidated sand aquifer. The geological sequence is intersected by a borehole with an external diameter of 200 mm and a cemented casing annulus thickness of 50 mm. A parametric study of leakage scenarios is then conducted, assuming isothermal multi-phase, multi-component flow. The model is not calibrated, but the simulations are used to identify the possible range of leakage rates and the time scale for gas and contaminant migration along the casing annulus. Although observed properties of the geological formations of the St. Lawrence Lowlands Basin are used, the results presented here have broad outreach due to the similarity of hydrodynamic properties of other shale formations.

The numerical results show that an adequately cemented borehole (with a casing annulus permeability $k_c \leq 1$ mD) can prevent methane and brine leakage over a time scale of up to 100 years. However, a poorly cemented borehole ($k_c \geq 10$ mD) can yield methane leakage rates ranging from 0.08 m^3/day to more than 100 m^3/day, depending on the hydrodynamic properties of the target formation and the quantity of mobile gas after abandonment. These leakage rates are consistent with Surface Casing Vent Flows (SCVF) reported for shale gas wells in Québec and Alberta. Simulated long-term brine leakage rates after 100 years for poorly cemented boreholes ($k_c \geq 10$ mD) are on the order of 10^{-4} m^3/day (0.1 l/day). Based on scoping calculations with a well-mixed aquifer model, these rates are unlikely to have a major impact on groundwater quality in a confined aquifer since they would only increase chloride concentrations by about 1 mg/l above background, a negligible increase relative to the commonly recommended aesthetic objective of 250 mg/l for chloride.

Title: Numerical Modelling of Methane Gas Migration from Decommissioned Shale Gas Wells into Shallow Aquifers

Presenter/First Author: Nicolas Roy, Laval University, Québec,

Presenter/First Author Email: nicolas.roy.17@ulaval.ca

Co-authors: John W H Molson, Laval University, Quebec City, QC, Canada; Jean-Michel Lemieux, SNC-Lavalin Environment, Montreal, QC, Canada; Dale Van Stempvoort, , , ; Ali Nowamooz, Universite Laval, Quebec, QC, Canada

Abstract Body: The behavior and fate of methane gas leaking from decommissioned shale gas wells into shallow aquifers is simulated in three dimensions. The main objective is to assess the efficiency of natural bacterially-driven processes to mitigate methane concentrations in both confined and unconfined aquifers. The conceptual model includes a shallow sandy aquifer pierced by a vertical well which is leaking gas-phase and dissolved-phase methane from a faulty cement seal within the underlying rock. The modelling approach couples the DuMux multi-phase simulator with the BIONAPL/3D flow and transport code for reactive transport and degradation of dissolved methane under oxygen and/or sulfate-reducing conditions. Methane behavior in the aquifer is evaluated for different leakage rates, background geochemistry and hydraulic gradients. In confined aquifers, methane will tend to persist longer than in unconfined aquifers from which the buoyant gas phase will more readily escape. Aquifers with a naturally high background sulfate concentration can significantly attenuate methane migration. Moreover, dissolved oxygen inflow through groundwater recharge in unconfined aquifers can also enhance methane oxidation. By-products of methane degradation reactions can also affect the groundwater geochemistry. The modelling approach can be extended to other contaminants emerging from deep decommissioned or abandoned wells or from natural faults and fractures such as brines, fracking fluids or hydrocarbons.

Title: A New User-Friendly Tool to Estimate Groundwater Recharge from Daily Weather Data and Well Hydrographs

Presenter/First Author: Jean-Sébastien Gosselin, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec,

Presenter/First Author Email: jnsebgosselin@gmail.com

Co-authors: Christine Rivard, Natural Resources Canada, , ON, Canada; Richard Martel, INRS-Eau Terre Environnement, Quebec, QC, Canada; Rene Lefebvre, INRS-ETE, Quebec, QC, Canada

Abstract Body: The estimation of groundwater recharge from well hydrographs is commonly done in groundwater resource assessment projects. However, this task can be cumbersome and time consuming, especially if there are several wells in the study area with many years of data. To address this issue, the open-source user-friendly application named WHAT (Well Hydrograph Analysis Toolbox) was developed. WHAT estimates groundwater recharge at the local scale using a method combining daily weather data and a well hydrograph. First, the application prepares a complete daily weather time-series representative of the well location. For this purpose, data from the Government of Canada website can be downloaded and automatically formatted. Furthermore, missing data can be filled with data from selected neighboring weather stations using a multiple linear regression model. Groundwater recharge is then estimated as the residual of a daily soil moisture balance (DSMB). In a second step, the daily recharge fluxes are substituted into a mathematical model of the aquifer groundwater balance to produce a synthetic well hydrograph. The third and final step of the method consists in the calibration of the DSMB model parameters, based on the comparison of synthetic and observed well hydrographs. WHAT offers several advantages: 1) gap-free weather datasets can be quickly and conveniently set up; 2) recharge is estimated with a rarely used approach combining well hydrographs and weather data; 3) groundwater levels and aquifer recharge can be calculated for the entire period covered by weather records; and 4) it includes a variety of functionalities useful for the interpretation of water level measurements, such as the plotting of air temperature, precipitation and water-level time series on the same graph. The software is available for download free of charge on GitHub (www.github.com/jnsebgosselin/WHAT).

Title: Rapid Recharge in a Shallow Bedrock Aquifer Having Minimal Overburden

Presenter/First Author: Kent S Novakowski, Queen's University, Kingston, ON

Presenter/First Author Email: kent@civil.queensu.ca

Co-authors: Owen Miles, , ,

Abstract Body: Rapid recharge events which occur as significant increases in hydraulic head following rainfall have been observed widely in fractured

bedrock aquifers. The response in hydraulic head often exceeds what would be observed in a porous aquifer by more than a factor of ten. These responses have been variously attributed to air entrapment, mechanical loading due to the rainfall, or due to the low specific yield of bedrock aquifers. In this study, a detailed investigation was conducted at a well-characterized field site in eastern Canada, to resolve the possible mechanisms. The bedrock is composed of gneiss covered by a thin veneer of drift materials having variable thickness (0-4 m). During an intensive monitoring period of approximately six months, a multi-level piezometer located on a bedrock outcrop which responded rapidly and in large magnitude to rainfall (> 1 m rise in hydraulic head to less than 20 mm of rainfall) was identified and used as a focus for numerical simulations. Contiguous measurements of transmissivity with depth (total depth equal to 15 m) were collected and a survey of fracture features was obtained via borehole camera, prior to completion as a multi-level piezometer. To determine the thickness of the drift materials in the vicinity of the outcrop, a GPR survey was conducted over a 40×40 m area. A total of eight infiltration experiments were also conducted over the same area using a novel infiltration system which covers an area of 10×10 m. Three-dimensional numerical simulations were conducted using HydroGeoSphere to reproduce the response in the piezometer for both the natural and simulated infiltration events over short (24 hour) and long (one month) timescales. The numerical simulations were used to evaluate the parameters most likely to impart rapid response and recharge. Based on this study it was concluded that the large magnitude head rises recorded in this piezometer are a result of recharge to steeply inclined fractures exposed on or immediately adjacent to the outcrop. The hydraulic head responds rapidly because of the low specific yield of the rock to which the transmissive features are connected. The modeling and infiltration experiments also showed that as little as 0.4 m of drift material can completely eliminate response in the well especially during times when evapotranspiration is high.

Title: Impacts of Snow Cover and Frozen Soil on Groundwater Recharge

Presenter/First Author: Sophie Guillon, GEOTOP-UQAM, Montréal,

Presenter/First Author Email: sophieguillon88@gmail.com

Co-authors: Florent Barbecot, UQAM, , QC, Canada; Marie Larocque, Univ du Quebec - Montreal, Dorval, QC, Canada; Daniele Luigi Pinti, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Eric Pili, CEA/DAM-ILE DE FRANCE, Arpajon, France

Abstract Body: In many Northern Hemisphere locations, groundwater recharge mainly occurs during the spring snowmelt and as a result of fall rain. In these cold environments, smaller recharge events also occur during the winter due to melting at the snow-soil interface and infiltration into frozen or thawed soil. But soil water dynamics and water infiltration before the onset of spring snowmelt are neither well studied nor constrained. The intensity and duration of these winter recharge events appear to be controlled by the thickness and permeability of frozen soil and its frozen water content. We present a case study based on the monitoring of water fluxes during the winter season at an instrumented site located on a sand deposit (esker), southwest of Montreal (Canada). Water content and temperature are measured in the first meters of soil and in the snowpack during winter season. Tracing experiments using D_2O-enriched water are performed to identify water infiltration, fluid velocity and transport mechanisms. Heat and hydraulic parameters are determined for the frozen soil and the snow cover. These data are used to validate and calibrate a numerical scheme to quantify water and heat budgets as well as water recharge fluxes. This work focuses on the availability of liquid water at the soil surface and on the influence of soil freeze/thaw events on the possibility and extent of winter infiltration as opposed to surface runoff.

Co-authors: Arthur Meauxsoone, Géosciences Montpellier, Montpellier Cedex 05, France; Sabrina Deville, Géosciences Montpellier, Montpellier Cedex 05, France; Jean Chery, Laboratoire Geosciences, Montpellier, France

Abstract Body: Recharge processes in a Mediterranean dolomite karst are studied on the basis of simulations and field measurements. Located 10 meters beneath the surface of a karst plateau, the Canalette's cave (Larzac, South France) offers a window on the karst vadose zone. To appreciate the various recharge processes, models are constrained with hydro-meteorological and gravity data, which are sensitive to the underground mass variation. The high weathering of the dolomite karst allows assuming that the vadose zone has a continuous porosity and permeability. Numerical simulations accounting for Richard's equations are performed; then, the influence of i) the matrix rock/cave interface and of ii) hysteresis and on the drip discharge and on the water content distribution within the vadose zone is assessed. The major water storage variations are clearly evidenced within the first 5 meters. A saturated zone is observed above the matrix rock/cave interface, which locally enhances permeability and generates downward flush mechanism. Finally, the recharge processes and the role of hysteresis evidenced from the local study are discussed at the basin scale to understand the dolomite karst singular recharge dynamic.

Abstract Body: Located in NE Morroco, the coastal Bou-Areg aquifer provides an illustration of hydrogeological consequences of the rapid development of irrigated agriculture in semi arid mediterranean areas. The main features are a saline water intrusion in the coastal zone, and elevated nitrate concentrations in agricultural areas, as a consequence of excessive withdrawals and increased recharge through irrigation return flow, respectively. While, the aquifer is expected to receive fresh water from

lateral recharge, the dissolution of messinian evaporites may provide another source for salinity. Here, more than elsewhere understanding the origin of groundwater and the global recharge pattern is a fundamental step for a sustainable groundwater management. To this end, eleven samples were collected in September 2014 for young-aged radiogenic (^{3}H), old-aged radiogenic (^{14}C) and stable (^{13}C, ^{2}H, ^{18}O) isotopes combined with additional young-age (SF_6, CFCs) tracers and noble gases (Xe, Ar, Kr, Ne). Preliminary results allow to distinguish between at least two groundwater masses, to estimate recharge rates in the plain and to provide insights on lateral groundwater inputs from the surrounding mountainous areas.

Title: Improvement of Land Surface Schemes for Cold Region Processes: Recent Results from the Changing Cold Regions Network in Western Canada

Presenter/First Author: Howard S. Wheater, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: howard.wheater@usask.ca

Co-authors: Naveed Khaliq, , , ; Kwok Pan Chun, University of Saskatchewan, Saskatoon, SK, Canada; Alan Barr, Environment Canada, Saskatoon, SK, Canada; Andrew M Ireson, University of Saskatchewan, Saskatoon, SK, Canada; Paul A Bartlett, Environment Canada, Toronto, ON, Canada; Murray MacKay, Environment Canada Toronto, Toronto, ON, Canada; Patricia Pernica, University of Saskatchewan, Saskatoon, SK, Canada; Yanping Li, University of Saskatchewan, Saskatoon, SK, Canada

Published Material: Findings have been previously reported in the following two publications: (1) Chun, K.P., Wheater, H.S. and Barr, A.G. 2014. A multivariate comparison of the BERMS flux tower observations and Canadian Coupled Global Climate Model (CGCM3) outputs. Journal of Hydrology, 519 Part B, 1537-1550, doi:10.1016/j.jhydrol.2014.08.059.(2) Khaliq, M.N., Sushama, L., MOnette, A. and Wheater H.S. 2014. Seasonal and extreme precipitation characteristics for the watersheds of the Canadian Prairie Provinces as simulated by teh NARCCAP multi-RCM ensemble. *Climate Dynamics,* doi:10.1007/s00382-014-2235-0.

Abstract Body: Recent North American Regional Climate Change Assessment Program (NARCAAP) Regional Climate Model ensemble results for Western Canada shows reasonable inter-model consistency for future precipitation change, but analysis of historical performance shows large (positive and negative) biases. Clearly there is need to understand and overcome model limitations to improve model performance. The Changing Cold Regions Network is maintaining a set of observatories across Western Canada, focussed on the Saskatchewan and Mackenzie River Basins, which provides a basis for model performance analysis and the development of improved land surface schemes. Results from a set of boreal forest flux towers are used to illustrate systemic differences between the inter-variable dependencies of observed and GCM simulations which show new insights into potential model limitations. The paper will also review results of ongoing comparisons between ground-based observation and land surface scheme performance over the CCRN network, and hence discuss the prioritisation of improvements in representation of cold region processes.

Title: Representation of high-latitude hydrology in climate models

Presenter/First Author: Laxmi Sushama, University of Quebec at Montreal UQAM, Montreal, QC

Presenter/First Author Email: sushama.laxmi@uqam.ca

Abstract Body: High-resolution regional climate model outputs, including surface hydrologic variables such as streamflows, are increasingly being used directly in many impact and adaptation studies. The realism of these RCM simulated surface variables for the high-latitude regions is dependent to a large extent on the representation of surface types and processes important for these regions and their atmosphere interactions. This will be demonstrated by comparing simulations performed with the fifth generation of the Canadian Regional Climate Model (CRCM5), with and without organic soil, near-surface permafrost, lakes and interactive phenology, for the Canadian high-latitude and Arctic regions. The comparison of simulations with and without organic soil, for example, indicates significant differences in the energy and water partitioning at the surface, leading to differences in both the regional climate and hydrology. The runoff and therefore streamflows are higher for the summer and fall seasons in the simulation with organic soil compared to the one without organic soil, while the inverse is noted for the spring season. The relatively higher value of runoff in summer and fall in the simulation with organic soil is mostly due to increased drainage contribution. Similarly, the differences in the surface climate, particularly the 2-m minimum temperatures, lead to differences in the hot spell characteristics in the two simulations. This talk will discuss the mechanisms leading to these differences as well as the comparisons between the other simulations performed to identify the impact of lakes and interactive vegetation on the surface hydrology/climate. Projected changes to selected hydrometeorological variables over Canada from the improved model simulations will also be presented.

Title: Toward a Better Understanding of Hydrological Impacts of Climate Change: Lessons Learned from Ouranos Hydroclimatic Studies Based on Regional Climate Model Simulations

Presenter/First Author: Biljana Music, Ouranos, Montreal, QC

Presenter/First Author Email: music.biljana@ouranos.ca

Abstract Body: Global warming is expected to alter the water cycle across the planet in multiple ways. Many studies indicate that hydrological regimes and extremes across different regions of the world will be affected differently bringing about various unfamiliar environmental risks. Understanding regional hydrological cycles and their variability and potential changes under an evolving climate requires the development and implementation of sophisticated modeling and data analysis tools. Numerical climate change experiments based on Regional Climate Model (RCMs) have proven to be powerful tools in assessing hydrological impacts of climate change over a region of interest. Constantly refining spatial resolution of RCMs promises better representation of small-scale processes and more reliable description of the interactions between the land-surface and the atmosphere, which have significant effects on the hydrological cycle. In the past years, the Ouranos Climate Simulation and Analysis team has produced a large number of regional climate simulations using the Canadian RCM (CRCM) at a spatial resolution of 45 km. Data from this vast databank has been very useful for hydrological impact and adaptation studies. Moreover, RCM simulations generated in the framework of several international collaborative RCM projects, such as NARCCAP, in which Ouranos made significant contributions, allowed construction of multi-model ensembles that are essential for analysis and quantification of various sources of uncertainties. Quantifying uncertainty associated with RCM simulations is an important part of hydrological projections and will be discussed in the first part of the presentation. Thereupon, several results where RCM hydrological outputs are used to assess impact of climate change on the probability of extreme events of the hydrological regime will be presented. Special focus will be given to projects aiming to assess Great Lakes Net Basin Supplies under a changing climate.

Title: Assessing Extreme Rainfall Characteristics in Future Climate for Canada

Presenter/First Author: Alain Mailhot, Institut National de la Recherche Scientifique, Québec, QC

Presenter/First Author Email: Alain.Mailhot@ete.inrs.ca

Co-authors: Karine Guinard, , , ; Gérémy Panthou, LTHE (UMR 5564), Saint Martin d'Hères, France

Published Material: I was invited to this session and I decide to present some of our recent works on extreme precipitation. These have been published in the following papers:Guinard K., Mailhot A., Caya D. (2014). Projected changes in characteristics of precipitation spatial structures over North America. Available on line, *Int. J. Climatol*. DOI: 10.1002/joc.4006.Panthou G., Mailhot A., Laurence E., Talbot G. (2014). Relationship between surface temperature and rainfall intensities - A multi-timescale and event-based analysis. *J. Hydrometeorology*, 15(5):1999-2011. DOI: 10.1175/JHM-D-14-0020.1Mailhot A., Beauregard I., Talbot G., Caya D., Biner S. (2012). Future changes in intense precipitation over Canada assessed from multi-model NARCCAP ensemble simulations, *Int. J. Climat*., 32:1151-1163. DOI:10.1002/joc.2343.

Abstract Body: Hazards associated to extreme rainfalls can cause important damages to infrastructures. In order to correctly designed water infrastructures, it is therefore important to correctly assess extreme rainfall frequency and intensity in historical and future climates. Considering the vastness of the Canadian territory, characterizing extreme rainfalls has also been a challenged due to the low density of stations especially in the northern regions. Assessing extreme rainfall statistics is even complicated by the fact available rainfall series are relatively short and that some applications (e.g. in urban hydrology) require sub-daily rainfall series for which available series are even more rare. Available projections from regional climate models suggest that extreme rainfalls will be more frequent and intense in future climate. Even if these conclusions seem robust, large uncertainties remain because of the (still) coarse resolution of climate model and the impact of unresolved convection processes. This presentation will discuss of: 1) projected changes on Intensity-Duration-Frequency curves for extreme rainfalls over Canada based on simulations from the *North American Regional Climate Change Assessment Program* (NARCCAP); 2) projected changes in characteristics of precipitation spatial structures (defined as a contiguous area of precipitation above a given threshold) over North America; 3) relationships between surface temperature and extreme rainfalls. Forthcoming challenges related to the simulation of extreme rainfalls in future climate will be finally addressed.

Title: Near-term projections of hydro-meteorological extremes over the United States

Presenter/First Author: Moetasim Ashfaq, Oak Ridge National Laboratory, Oak Ridge, TN

Presenter/First Author Email: mashfaq@ornl.gov

Co-authors: Deeksha Rastogi, Oak Ridge National Lab, Oak Ridge, TN; Rui Mei, Oak Ridge National Lab, Oak Ridge, TN; Shih-Chieh Kao, Oak Ridge National Laboratory, Oak Ridge, TN; Bibi S Naz, Oak Ridge National Lab, Oak Ridge, TN; Sudershan Gangrade, Oak Ridge National Laboratory, Oak Ridge, TN

Published Material: This work will be submitted for review in a few weeks.

Abstract Body: We present near-term projections of hydro-meteorological extremes over the U.S. from a hierarchical high-resolution regional modeling framework that consists of the dynamical downscaling of 12 Global Climate Models (CCSM4, ACCESS1-0, NorESM1-M, MRI-CGCM3, GFDL-ESM2M, FGOALS-g2, bcc-csm1-1, MIROC5, CanESM2, MPI-ESM-MR, IPSL-ESM-MR, CMCC-CM5) from the 5th phase of Coupled Model Inter-comparison Project at 4km horizontal grid spacing. Our modeling framework uses a combination of a regional climate model (RegCM4) and a hydrological model (VIC). All models' integrations consist of 41-years in the historic period (1965-2005) and 41-years in the near-term future period (2010-2050) under the RCP 8.5. RegCM4 domain covers the continental U.S., and the parts of Canada and Mexico at 18km horizontal grid spacing whereas VIC domain covers the continental U.S. at 4km horizontal grid spacing. We apply SOM cluster analysis technique to identify the atmospheric patterns associated with the hydro-meteorological extremes and effect of their future variations on the frequency and intensity of climatic extremes in the coming decades. The high-resolution ensemble shows substantially better skill in the simulation of hydro-meteorological extremes and associated atmospheric patterns in the historical period. Further, we find that while extreme heat waves show a significant increase in their occurrence in the coming decades, extreme cold waves are not projected to significantly decrease even when mean daily minimum temperatures are increasing. We also find an overall increase (decrease) in the inflows to the flood-controlling (hydroelectric) reservoirs across the United States. Such changes in the hydro-meteorological extremes could have substantial impacts on natural and human systems across the U.S.

Title: Projecting the Impact of Climate Change on Extreme Runoff in the Pacific Northwest

Presenter/First Author: Mohammad Reza Najafi, University of Victoria, Victoria, BC

Presenter/First Author Email: rnajafi@uvic.ca

Co-authors: Hamid Moradkhani, Portland State University, Portland, OR

Published Material: Part of this study is recently published in the journal of Hydrologic Processes however additional assessments will be included (covering basins in Canada) which are not published or presented previously.

Abstract Body: Changes in snowpack and snowmelt characteristics caused by warming temperature trends and the increased probability of extreme rainfall, due to climate change, will alter the frequency and intensity of extreme runoff. Understanding these changes is necessary before taking any adaptation plan. In this study the changes in extreme runoff over the Pacific Northwest (PNW) region are assessed based on suite of regional climate model simulations provided by North American Regional Climate Change Assessment Program (NARCCAP). Considering the limited number of available extreme events (30 years of historical/future simulations) the spatial hierarchical modeling framework is used to combine data from different locations to provide a more reliable assessment compared with single point analysis. Seasonal variations are investigated to detect possible shifts in extreme events. RCM output variables including precipitation, maximum and minimum temperature and wind speed are downscaled to 1/8° resolution for the regional assessment. Hydrologic modeling is performed using the Variable Infiltration Capacity (VIC) model and the results of these assessments are then merged using the Bayesian Model Averaging approach. Overall the results show increase in the

extreme runoff in the future for most seasons particularly during winter and over the high elevation areas. North of Rockies in particular experiences increase during spring. The reduction of extreme events in most dry areas in summer is also evident. Based on these results substantial shift in the seasonality of peak streamflow is expected from summer to spring in many regions of the PNW.

Title: The strengths and weaknesses of using hydrological connectivity to interpret stream biogeochemistry

Presenter/First Author: Christopher Spence, Environment Canada Saskatoon, Saskatoon, SK

Presenter/First Author Email: chris.spence@ec.gc.ca

Co-authors: Rosa Brannen, University of Saskatchewan, Saskatoon, SK, Canada; Newell Hedstrom, , , ; Steven V Kokelj, Northwest Territories Geoscience Office, Yellowknife, NT, Canada; Shawne Kokelj, , , ; Meg McCluskie, , , ; Cherie Westbrook, University of Saskatchewan, Saskatoon, SK, Canada

Published Material: Some of the results used in this review presentation were presented at the CGU annual general meeting in 2013.

Abstract Body: The concept of hydrological connectivity emerged with the broad acceptance that the non-linear streamflow response to precipitation or snowmelt inputs is partially due to heterogeneous landscape storage capacities, thresholds, and runoff pathways across a range of scales. Because hydrological connectivity is defined as the ability of water to transfer across the landscape, its nature could have implications for biogeochemical regimes. This presentation will discuss the advantages and disadvantages of using hydrological connectivity in the interpretation of biogeochemical connectivity with two examples from Canadian watersheds. It will be shown that peak hydrological connectivity is not necessarily synonymous with peak biogeochemical connectivity. Secondly, connectivity can be simultaneous, but not common to all constituents. These examples demonstrate that 1) the definition of metrics of both the connection presence and strength are crucial for integrated analysis of biogeochemical and hydrological connectivity; 2) the interplay of sources, sinks and pathways of water and constituents influences observed patterns; and 3) biogeochemical cycles are at least as important as hydrological connectivity to defining stream biogeochemical responses and regimes.

Title: Predicting seasonal stream chemistry from catchment topography: the importance of the near-stream zone.

Presenter/First Author: Nora J Casson, University of Winnipeg, Winnipeg, MB

Presenter/First Author Email: n.casson@uwinnipeg.ca

Co-authors: Catherine Eimers, Trent University, Peterborough, ON, Canada; S.a. Watmough, Trent University, Peterborough, ON, Canada; Murray C Richardson, Carleton University, Ottawa, ON, Canada

Abstract Body: Catchment topography influences stream nutrient export through regulation of such factors as hydrological flow paths and distribution of organic soils, and by determining connections between sources of nutrients across the landscape and the stream. Recent work has demonstrated that biogeochemical processes occurring in the near-stream zone exert a stronger influence on stream chemistry compared with catchment-averaged processes. This may be particularly true in dry seasons when there is less hydrological connectivity between upland source areas and the stream channel. In this study, we tested the hypothesis that near-stream topography is a better predictor of seasonal stream chemistry compared with whole-catchment averages. We evaluated relationships between catchment topography and 20-year average seasonal concentrations of nutrients at 10 forested catchments in south-central Ontario. 1 m resolution LiDAR derived digital elevation models were used to calculate average topographic metrics within 20m, 50m and 100m of the stream, as well as for the entire catchment. Dissolved organic carbon and nitrogen were strongly related to wetland coverage averaged across the entire catchment and these models were not improved by considering only the near-stream zone, perhaps because wetlands in these catchments are generally associated with the stream channel. Regression models predicting sulphate and nitrate concentrations using catchment slope and wetness indices were often improved by considering only the area within 50 m or 100 m of the stream network, particularly during the summer. This was in contrast to wetter seasons (e.g. spring and winter), when larger proportions of the catchment contributed to stream chemistry. In these forested headwater catchments, variable hydrologic connectivity of source areas to streams alters the role of the near-stream zone environment in regulating sulphate and nitrate concentrations in streamwater. During dry periods, the near-stream-zone catchment morphology should be included in landscape models to improve predictions of streamwater sulphate and nitrate concentrations.

Title: Using Streamflow Recession Analysis to Understand Variations in Hydrologic Connectivity During Baseflow

Presenter/First Author: Stephen B Shaw, SUNY College of Environmental Science and Forestry, Ithaca, NY

Presenter/First Author Email: sbshaw@esf.edu

Co-authors: Nicole Ng, , ,

Published Material: Some of this work is currently in a manuscript under revision in the journal Hydrological Processes. This presentation will incorporate new field work from 2014 that was not included in the manuscript.

Abstract Body: The concept that runoff generation occurs from temporally varying source areas in watersheds with steep terrain and shallow soils has been well established for decades. However, this same concept of time-varying source areas is often not considered for baseflow; in many cases baseflow is presumed to originate uniformly across a catchment's area from groundwater contributions. In this work, we use detailed observations of changes in the active channel network of head water streams in conjunction with recession analysis of aggregate flow at the catchment outlet to investigate seasonal changes in baseflow source areas. By linking discharge recession analysis to field observations, we suggest that insights into the degree of spatial variation in hydrologic activity during baseflow can potentially be inferred from stream discharge and does not necessarily require extensive field work. We present data from two watersheds in New York State as well as analysis of recession data from multiple sites with long-term discharge records. Besides providing insights into seasonal changes in hydrologic connectivity during baseflow, this work also supports new interpretations of stream flow recession analysis.

Title: Modelling the impacts of fine-scale spatial configuration and connectivity of soil and land use on water, sediment and nutrient flows

Presenter/First Author: Bethanna M Jackson, Victoria University of Wellington, Wellington,

Presenter/First Author Email: bethanna.jackson@vuw.ac.nz

Abstract Body: The delivery of water, sediment and chemicals across landscapes and to water bodies is a function of both the biophysical properties of individual landscape elements and their configuration. However, due to computational constraints, fine-scale landscape configuration has generally been neglected or grossly simplified in hydrological modelling. In this talk, we demonstrate a new approach designed to be fast-running while maintaining physical consistency and fine spatial detail. Hydrology, sediment and chemical routing algorithms are based on physical principles of hillslope flow, taking information on the storage and permeability capacity of elements within the landscape from soil and land use data and honoring physical thresholds, mass and energy balance constraints. Hydrological response units are delineated within the landscape according to similarity of their hydraulic properties, and spatially explicit topographical routing is preserved. Landscape response is then evaluated under different meteorological or climatic events (e.g. flood return periods, rainfall events, droughts), cascading water through the hydrological response units using a “fill and spill” approach. The computational efficiency of the approach combined with its focus on spatial detail allows the impacts of landscape connectivity from subfield level scale to national scale to be analysed simultaneously, and communicates the spatial patterns of mass flow within the landscape at detailed resolutions. Case studies from Wales and New Zealand will be presented in this talk, with a focus on how water, sediment and macronutrient delivery to water bodies is impacted by soil and land use configuration.

Title: The re-eutrophication of the Laurentian Great Lakes and the potential influence of changes in agricultural land use, climate, and transport pathways

Presenter/First Author: Mohamed Mohamed, Ontario Ministry of the Environment, Toronto,

Presenter/First Author Email: mohamed.mohamed2@ontario.ca

Co-authors: Georgina Kaltenecker, University of Waterloo, Waterloo, ON, Canada; William D Taylor, University of Waterloo, Waterloo, ON, Canada; Madeline Rosamond, , , ; Krista M Chomicki, Toronto and Region Conservation Authority, Toronto, ON, Canada

Abstract Body: Agricultural land use has a variety of effects on material and energy flow of receiving waters, some of which can be highly local, while others may be far reaching, with cumulative impacts extending to large, distant receiving waters such as oceans or large lakes. The impacts of land use, including agriculture, on the Laurentian Great Lakes (LGL) became a topic of intense study during the eutrophication of the lower LGL that occurred in the late 1960s and early 1970s. The Pollution from Land Use Reference Group (PLUARG) was formed to examine the relationships between land use and their impacts on the LGL, then to develop recommendations for changes in these practices to reduce impacts on the LGL. The agricultural studies of the PLUARG examined the interaction between types of agricultural land use and the sensitivity of those landscapes to lose nutrients and other materials to the streams that drain them, as well as to develop recommendations to mitigate these losses. In the ensuing years, water quality in the LGL improved dramatically, driven primarily by improvements in sewage treatment. More recently, there has been a resurgence of eutrophication in the western basin of Lake Erie, as well as widespread nearshore algal fouling occurring in all of the lower LGL. The mechanisms causing the re-eutrophication of the LGL are not yet quantified. However, it is known that a major driver is a shift in the food webs of the LGL, while changes in climate and tributary loading may also be important. On the agricultural landscape, several changes such as artificial drainage, climate change, and other land use practices have occurred that may influence not only the magnitude, but also the nature and timing of nutrient loss to watersheds. In this work, we provide an overview of the PLUARG approaches to examining the connection between agricultural land use and their impacts on the LGL as well as possible changes in the magnitude, timing, and hydrological connectivity that have happened since those studies. We will also describe a new study that will revisit many of the goals of the PLUARG agricultural studies to examine how these changes may be influencing the re-eutrophication of the LGL.

Title: Natural and anthropogenically-induced hydrological connectivity produces methylmercury hotspots in the Hudson Bay Lowlands, Canada

Presenter/First Author: Brian A Branfireun, Western University, London, ON

Presenter/First Author Email: bbranfir@uwo.ca

Abstract Body: The Hudson Bay Lowlands is the second largest contiguous peatland complex in the world, and is a critical source of water and solutes to the James and Hudson Bays. Water quality in this extensive, low-gradient catchment is strongly influenced by the saturated organic matter that comprises ~ the top 2 m extensive surficial deposits. The fish supported by this freshwater system are critical to human residents who rely on it in whole or in part for their subsistence, however it has been known since the 1970s that fish of edible size frequently exceed consumption guidelines for tissue methylmercury (MeHg) concentrations. In the absence of point sources in this remote landscape, the sources of Hg are entirely atmospheric.

We hypothesized that the source of MeHg was *in situ* methylation of atmospherically-deposited inorganic Hg in the extensive peatlands; a well-documented occurrence in more southern latitudes. Extensive sampling within both bog and fen peatland types in the Attawapiskat River catchment in the central James Bay Lowlands revealed that MeHg concentrations were vanishingly low in the peatlands, despite at least superficial similarity to strong methylating environments in other geographic regions. Instead, extremely localized zones of elevated MeHg concentrations were found in near-stream pore waters and surface pools associated with surface water-ground water convergence. These hotspots appear to play an important role in the flux of MeHg to streams, and food web exposure. Similar biogeochemical hotspots for Hg methylation were produced in both an operational and an experimentally-manipulated wastewater treatment wetland, with elevated sulphate and labile carbon generated localized MeHg concentrations 3 orders of magnitude higher than background. Hydrological connectivity supporting methylation is much more localized in this vast landscape than previously thought. Knowledge of relatively fine-scale hydrological processes is required to predict biogeochemical hot spots and understand the implications of future changes in hydrology due to land-use or climate change.

Title: Hydrochemical and isotopic end member mixing analysis to quantify snowmelt contributions to streamflow and lakes during arctic spring: application to hydrologic and mercury mass balance modelling

Presenter/First Author: Murray Richardson, Carleton University, Ottawa, ON

Presenter/First Author Email: murray_richardson@carleton.ca

Co-authors: Jamal Shirley, , ,

Abstract Body: Spring snowmelt is the most important hydrologic event of the year in arctic landscapes. During this relatively short period if time, fluxes of water and waterborne contaminants such as mercury to surface waters can far exceed those occurring during the remainder of the water year. Several important studies have reported relatively little mixing of snowmelt runoff with lake water over the melt period. However, on an annual basis, the extent to which catchment runoff mixes with lake water is believed to depend on the relative fractions of rainfall vs. snowfall throughout the year, and the fraction of annual runoff that occurs during the open-water season. This implies that seasonal and inter-annual differences in terrestrial-aquatic interactions may influence the "source-strength" of hydrological and biogeochemical source areas in relation to downstream water bodies.

As part of a broader study focused on these aspects of terrestrial-aquatic connectivity during spring runoff in arctic lake basins, we used hydrochemical and isotopic end member mixing analysis (EMMA) to help quantify the extent of mixing of snowmelt runoff within an 8 ha lake near Iqaluit, NU. Specifically, two and three-component hydrochemical and isotopic EMMA models were developed to calculate volumetric fractions of source waters in inflowing and outflowing streams of the lake over a 2 month period from early June to late July, 2014. Source water composition of inflowing streams ranged from 80% to 0% snowmelt-derived throughout the melt period, with concomitant changes in both mercury and dissolved organic carbon concentrations. Outflowing lake water largely tracked the hydrochemical and isotopic signature of the inflowing streams throughout the entire melt period, and according to EMMA, was dominated by this source water component (~50%). Contributions from melting lake ice and pre-melt lake water also comprised substantial fractions of the remaining 50% of the lake outflow, in approximately equal proportions. Overall, EMMA was found to be a useful tool for inferring interactions between snowmelt runoff, groundwater and lake water in an arctic lake basin, and for studying the mechanisms by which snowpack accumulation and melt serve to couple atmospheric sources of contaminants to arctic freshwaters.

Title: Physical, Chemical, and Biological Connectivity of Water Bodies in a Watershed Context – Lessons from Naked Watersheds

Presenter/First Author: Michael N Gooseff, Colorado State University Fort Collins, Fort Collins, CO

Presenter/First Author Email: mgooseff@engr.colostate.edu

Co-authors: Adam N Wlostowski, Colorado State University, Fort Collins, CO; Diane M McKnight, University of Colorado at Boulder, Boulder, CO; William B Lyons, Ohio State University Main Campus, Columbus, OH

Published Material: Less than 50% was presented at the JASM meeting last year in Portland Oregon. We have evolved this work since then.

Abstract Body: The connectivity of water bodies (streams, wetlands, lakes, etc.) is an important underpinning of terrestrial/aquatic ecosystem processes as well as water quality dynamics in space and time. In temperate watersheds, the study of the hydrologic, chemical, and biological connectivity of water bodies can be significantly complicated by land cover, complex hydrogeology, and management practices. Here we use a hydrologically-based framework to characterize the connectivity of water bodies through quantification of the frequency, magnitude, and duration of measured connections in a watershed with no vegetation cover and very little groundwater – the McMurdo Dry Valleys, Antarctica. The frequency, magnitude, and duration of connections of glaciers to lakes, via meltwater streams are well-quantified over this period, from an extensive stream gauging network. The connectivity and disconnectivity (periods of no flow) have significant influences on stream diatom and algal communities. In the past decade, we have observed increased connectivity of glaciers to soils and lakes outside of stream channels as new parts of the landscape are melting and thawing and providing new water that flows toward valley-bottom lakes.

Title: Geostatistical extrapolation of area-density relations of water bodies from local to regional scale

Presenter/First Author: Saskia L Noorduijn, University of Calgary, Calgary, AB

Presenter/First Author Email: saskia.noorduijn@ucalgary.ca

Co-authors: Masaki Hayashi, University of Calgary, Calgary, AB, Canada; Laurence R Bentley, University of Calgary, Calgary, AB, Canada

Abstract Body: The northern prairie landscape in North America is typified by topographic depressions which vary from small ephemeral ponds to large permanent lakes. These features are hydrologically and ecologically important because they providing habitats for migratory birds as well as focusing recharge to underlying aquifers. Quantifying the contribution of ephemeral ponds to groundwater recharge for large areas has proven challenging due to the difficulty in delineating the presence of topographic depressions within the landscape at a high enough resolution. Previous work has identified a power law relationship between the surface area of water bodies in depressions and their spatial density (i.e., number of water bodies per area). This power law relationship is influenced by landscape characteristics, in particular landform type (e.g., hummocky terrain). High-resolution (0.3 m) digital images were used to delineate water bodies in a 250-km^2 watershed of West Nose Creek (WNC) near Calgary, Canada. This dataset contains two well-defined power law relationships, one for hummocky and one for undulating terrains, which collectively comprise 75% of the watershed. Training images, based on the hummocky and undulating landform types within the WNC watershed were used to produce power law statistics for each of the landform types. The power law statistics were used to generate stochastic realizations of depression patterns which conform to the power law relationship determined from the WNC watershed. The stochastic images can then be used to generate distributions of the small ephemeral water bodies for larger areas with these landform types in order to investigate the spatial distribution of groundwater recharge.

- Montreal, Dorval, QC, Canada; Marina Gillon, 1114 UAPV-INRA EMMAH, University of Avignon, Avignon, France; François Hardy, , ,

Abstract Body: Groundwater recharge is largely known to be spatially heterogeneous especially on watersheds impacted by human activities (drained surfaces, urban areas, release of effluents of waste water treatment plant, etc.). Depending on land uses occurring in recharge areas, the quality of the groundwater can undergo a marked deterioration, inducing the degradation of related aquatic ecosystems in groundwater discharge areas. Both the location of recharge areas and the quantification of the recharge rates are then crucial for the management of watersheds and the preservation of the ecosystems. The objective of this work was to use isotopic and geochemical tools to locate recharge of the Fontainebleau Sands aquifer in the small watershed of the Rhodon stream (26 km²) southwest of the Paris Basin (France). In this region, groundwater recharge is often impacted by agricultural practices with high nitrates concentrations.

A water and mass balance model was developed to quantify groundwater inflows and mass fluxes to the river, based on the spatial evolution of the river chemistry (^{222}Rn, $\delta^{13}C_{TDIC}$, $\delta^{18}O_{water}$, $\delta^{2}H_{water}$ and major ions). Along the course of the stream (10.5 km), two important groundwater contribution areas were identified between 2 and 5.5 km and after 8 km from the spring. In sub-watersheds corresponding to drained surfaces discharging in the stream at each sampling point of the stream, the mean quality of the regional groundwater and the calculated quality of groundwater inflow to the river with mass balance approach have been compared. Despite mass fluxes strongly balanced for conservative tracers (Cl^-, K^+, Mg^{2+}), there are some significant differences for the non-conversative elements (NO_3^-, SO_4^{2-}). These differences were compared to land uses to constrain the most important areas of groundwater recharge. This approach allowed the estimation of recharge rates and quality for each area to determine the quality of the groundwater discharge.

Abstract Body: In karst, the heterogeneity of the transfer processes within the different compartments (soil, epikarst, unsaturated zone, saturated zone) control the recharge-discharge relationship. The MEDYCYSS observatory (www.medycyss.org), an observation site of the KARST (www.sokarst.org) and RBV (http://portailrbv.sedoo.fr/) multi-disciplinary research networks, has been set up to better understand these transfers in a Mediterranean climatic context. Within the Lez karst catchment (South of France), part of the MEDYCYSS observatory, a 333m deep borehole has been equipped with the PMPS Multi-level monitoring system (SolExperts). This borehole is located 100 m from an intermittent river and 500 m from the aquifer main outlet (Lez Spring) where intermittent pumping is performed. Continuous pressure and temperature monitoring is realized at 5 levels isolated by packers where discrete water sampling can also be achieved. The main objective of this karst monitoring, realized in the framework of the CRITEX project, is to assess the different mechanisms of the recharge at various time scales. The collected data will implement the existing spatial monitoring of the hydrodynamic and geochemical variations followed in bore-holes, karst features (cave and estavelles), perennial and temporal springs of the karst aquifer. In this study we aim at specifying the contribution of the different karst compartments, from the recharge zone towards the main outlets. The preliminary results obtained during a flash flood event show a contrasted hydrodynamic response for each compartment in agreement with the karst functioning assessed from the analysis of the chemical variations. These data are essential to better assess the recharge processes and specify the role of the vadose zone in the flow organization at short and long timescale.

Title: Are kettle lakes good objects to observe groundwater recharge?

Presenter/First Author: Marie Arnoux, GEOTOP-UQAM, Montréal,

Presenter/First Author Email: arnoux.marie_dominique_jeanne@courrier.uqam.ca

Co-authors: Florent Barbecot, UQAM, , QC, Canada; Elisabeth Gibert-Brunet, GEOPS-UMR 8148, Orsay, France

Abstract Body: It is known that the mean total annual volume of lacustrine groundwater discharge is closed to the mean total annual groundwater recharge in the whole catchment. All of hydrological interactions are not linear but the signal observed in lakes can be linked to recharge if lakes connections to groundwater are clearly determined. In Canada, the fractionated melting of the Laurentide ice sheet allowed the formation of kettle lakes. These lakes can be either (i) completely disconnected from groundwater, behaving like large rain gauges, or (ii) in direct connection with the underlying aquifer, being thus a opened window on groundwater. Twenty kettle lakes distributed in South Quebec were sampled in June-July and October-November 2014, and their water balances determined by using geochemical tracers. Those balances in conjunction with stable isotope signatures of system end-members allow the determination of the sensibility of lake water budgets regarding all components and thus groundwater discharge. It appears that some lakes can be very sensitive to change in groundwater-lake interactions. The seasonal response of water balance was also analysed to discuss groundwater-lake interaction dynamics and links between recharge dynamics. From these results a sensitive analyse of water budget parameters allow to discuss if kettle lakes may be sensitive systems to monitor recharge changes at the catchment scale.

Title: Recent advances in the on-site analysis and process-based interpretation of dissolved noble gases and biogeochemically active species in water bodies

Presenter/First Author: Matthias Stefan Brennwald, Swiss Federal Institute for Environmental Science and Technology (EAWAG), Duebendorf,

Presenter/First Author Email: matthias.brennwald@eawag.ch

Co-authors: Rolf Kipfer, EAWAG Swiss Federal Institute of Aquatic Science and Technology, Duebendorf, Switzerland

Abstract Body: The gas concentrations in water bodies are controlled by air/water exchange, sources/sinks in the water, and mixing of different fluids. Atmospheric gases originate from air/water partitioning at the water surface and (partial) dissolution of air bubbles entrained/entrapped in the water (excess air). This excess air component is commonly substantial in groundwaters. The noble gas concentrations in water allow quantification of excess air, which provides a robust basis for quantitative interpretation of reactive gases.

We developed a membrane-inlet mass spectrometer[1] for quasi-continuous on-site gas analysis in the field (He, Ar, Kr, N_2, O_2, CO_2, CH_4, etc). Most recently, we miniaturized this instrument and reduced power consumption to allow battery operation in the field. This instrument yields gas concentration time series, which provide the data basis for robust interpretation and quantification of gas dynamics in terms of physical *and* biogeochemical processes (e.g., respiration/O_2 or denitrification/N_2).

Currently available software tools for physical interpretation of noble gas data are, however, not adequate to interpret data sets containing both noble and chemically active gases. These tools are furthermore restricted to a limited and hard-wired set of physical gas-exchange processes. We therefore developed a new and flexible tool[2] (NOBLEFIT) for quantitative interpretation of dissolved gas data in terms of system-specific environmental processes and variables. NOBLEFIT covers the functionality of previous tools, but is designed to allow user-defined process models (e.g., physical conditions during atmosphere/water exchange, bubble/water interaction, strength and kinetics of internal gas sources and sinks, etc.).

Both on-site gas analysis and system-specific model fitting reflect significant improvements relative to currently available techniques. Moreover, the combination of both tools offers new avenues to study the interaction of physical and biogeochemical processes in water bodies.

Title: Geochemistry of sediment moisture in the Badain Jaran desert in Northwest China: Insights into groundwater recharge and past environmental changes

Presenter/First Author: Li Jin, SUNY College at Cortland, Cortland, NY

Presenter/First Author Email: li.jin@cortland.edu

Co-authors: W. Michael Edmunds, University of Oxford, Oxford, United Kingdom; Zunli Lu, Syracuse University, Syracuse, NY; Jinzhu Ma, , ,

Published Material: Some preliminary results from this study have first been presented at AGU in December 2012.

Abstract Body: Unsaturated zone pore water has the potential to record history of recharge and retain information related to environmental changes. In this study, two 6-meter cores from the Badain Jaran desert (Northwest China) were collected to explore this potential using directly extracted moisture. Pore waters in low moisture sediments (1-5%) were directly extracted using immiscible liquid displacement and then analyzed for major anions, cations and trace elements. The pore water chemistry was used to illustrate the recharge history, natural geochemical processes and anthropogenic influence. The calculated recharge rates at two sites from the conservative tracer Cl^- were low, 1.5-3.0 mm/year. Major cations in two profiles showed relative low concentrations in the unsaturated zone and high concentrations in the capillary fringe and into the water table. High nitrate and low iron concentrations indicate the overall oxidizing environment, which allows the mobility of oxy-anions, such as uranium, arsenic and chromium. The modern rainfall infiltration signature contrasts with that of the underlying groundwater body, which has a distant, regional recharge signature. In addition, ratios of SO_4^{2-} over Cl^- in two profiles showed increasing trends since 1990s, which might suggest higher industrial activity and sulfur emissions. This reconnaissance study demonstrates the potential for a new geochemical approach to studying geochemical processes in the unsaturated sediments in semi-arid environments due to both natural and human influences. The direct use of pore water improves the understanding of hydrological and geochemical processes as water moves from the surface to the capillary fringe zone and to groundwater.

Title: Developing Novel Techniques for In Situ Nitrate Sampling, Vertical Profiling, and Real-time Remote Groundwater Quality Monitoring

Presenter/First Author: Graeme MacDonald, University of Guelph, Guelph,

Presenter/First Author Email: gmacdo03@uoguelph.ca

Co-authors: Jana Levison, University of Guelph, Guelph, ON, Canada

Abstract Body: Certain hydrogeological settings in southern Ontario are particularly vulnerable to nitrate contamination of groundwater. Nitrate can leach into aquifers during recharge events, where it is subject to transport under spatially and temporally variable ambient flow conditions. Advancements in monitoring and data collection capabilities can improve understanding of these transport processes. Groundwater quality measurements are traditionally obtained by purging wells and analyzing samples ex situ. This “snapshot” data can disrupt the natural subsurface flow system and is not always detailed enough to determine critical water quality conditions. This research involved the application of innovative sensors to develop alternative groundwater sampling methods. Three unique methods were developed: flow cell spot sampling, depth-discrete downhole geochemical profiling and real time remote groundwater quality monitoring. While nitrate was the contaminant of focus, field parameters including temperature, DO, ORP, EC, and turbidity were also monitored. Research sites ranged from supply wells located in shallow overburden aquifers to deep fractured bedrock boreholes. Flow cell spot sampling results were compared to traditional sampling methods and were very strongly correlated ($R^2 = 0.99$). Depth-discrete profiling was used to identify groundwater quality zones corresponding to different formations. Real time remote monitoring methods were conducted by deploying sensor equipment downhole. Groundwater quality parameters were obtained every 15 minutes for several months, greatly improving the temporal resolution compared to traditional sampling. Data was transmitted in real time over the HSPA network, which allowed for remote monitoring, effectively reducing labour associated with traditional methods. The detailed datasets obtained will support future nitrate transport modelling initiatives and complement field projects in which in situ, detailed nitrate measurements are desired.

Title: *Pinus banksiana* growth responses to a soil water recharge controlled by the Lichen organic layer.

Presenter/First Author: Benjamin Gadet, Organization Not Listed, Québec,

Presenter/First Author Email: Benjamin.Gadet@NRCan-RNCan.gc.ca

Co-authors: David Paré, Natural Resources Canada - Canadian Forest Service, Québec City, QC, Canada; Yves Bergeron, Industrial Chair CRSNG-UQAT-UQAM in sustainable forest management, Rouyn-Noranda, QC, Canada

Abstract Body: The forest industry must continually improve the environmental performance of its activities while preserving the environment and the sustainability of its ecosystem so that the forest remains an asset for future generations. In the boreal forest, soils have widely developed on coarse textured deposits. Following natural or anthropogenic disturbance, this type of substrate provides a capacity of resilience of the ecosystem which strongly varies in time and space. At the level of the station, we often observe a bimodal distribution in productivity between patches of dense populations and unproductive land forests covered with Lichens. Such a parcelling out of these stands conveys a strong possible occurence of their change into an unproductive alternative stable state. As far as the Boreal shield is concerned, some recent studies have confirmed the expanding of this opening phenomenon of the canopy. Once set up, the opened Lichens woodlands are considered as being relatively stable. The origin of positive feedbacks supposed to enhance the irreversibility of this unproductive state was the subject of many studies but has not succeed in reaching meaningful conclusions permitting to guide future strategies. The forest industry has therefore become very vulnerable in front of the evolution of these ecosystems. The present work is part of a project which aims at bringing elements of understanding necessary to develop tools for predicting and maintaining the productivity of Pinus Banksiana stands. We postulate that the organic layer originating from Lichens contributes to maintaining unproductive stands by limiting plant available water recharge. Hydrodynamic properties of organic and underlying layered mineral soil horizons would induce capillary barrier effects. These effects could significantly decrease available water holding capacity and consequently forest productivity. Preliminary results show that low-productivity stands are characterized by high hydraulic conductivity of the organic layer with respect to the underlying mineral horizons. When the infiltration is not restricted by the organic layer, gradation and layering of different soil textures can significantly enhance the tree growth.

Title: Water and contaminant travel time through the unsaturated zone under an agricultural field in Prince Edward Island, Canada

Presenter/First Author: Serban Danielescu, Environment Canada Toronto, Fredericton,

Presenter/First Author Email: serban.danielescu@agr.gc.ca

Co-authors: Karl E. Butler, University of New Brunswick, Fredericton, NB, Canada; Shuang Wang, , , ; Mark Grimmett, Crops and Livestock Research Centre, Charlottetown, PE, Canada; Kerry T B MacQuarrie, University of New Brunswick, Fredericton, NB, Canada; Bernie Zebarth, , ,

Abstract Body: Knowledge of the travel time of water and contaminants through the unsaturated zone in intensive agricultural areas such as Prince Edward Island (PEI) is of crucial importance when assessing the impacts of Beneficial Management Practices (BMPs) on the quality of drinking water and of down-gradient aquatic ecosystems. This study was done at the Agriculture and Agri-Food Canada (AAFC) Research Farm in Harrington, PEI, in a field that has been under a potato production system since 2007. The unsaturated zone comprises a relatively thin soil layer (~1 m), underlain by a thick (~ 8 m) glacial till consisting of weathered local parent material (i.e., sandstone) and a 10-12 m thick layer of fractured sandstone. The estimated average downward velocities through the matrix of both till and bedrock has an upper limit of 12 m/year, however the estimated velocity of flow through the fractures can reach 280 m/year. In 2014, three boreholes disposed in an equilateral triangle (with 9 m long sides) were drilled and each equipped with an array of 11 Decagon 5TE sensors measuring temperature, moisture and electrical conductivity and 24 electrodes measuring resistivity to provide real-time vertical profiling of downward movement of water and solutes. A simplified flow and transport model has been developed in Finite Element Flow (FEFLOW) and the model will be refined using data resulting from a tracer test that is planned in the summer of 2015 as well as from the logging of the rock cores and overburden samples collected during the drilling of the three boreholes. The use of field data in combination with unsaturated flow and transport modelling as well as cross-hole three dimensional Electrical Resistivity Tomography (3D ERT) will provide insight into the travel times of water and solutes through the unsaturated zone as well as into the partitioning between fracture and matrix flow and the effects of heterogeneity in hydraulic conductivity of both till and bedrock materials.

Title: Recharge controls in arid and hyperarid piedmont - Example of the Pampa del Tamarugal basin, Northern Chile.

Presenter/First Author: Benoit Viguier, HydroSciences Montpellier, Montpellier,

Presenter/First Author Email: benoit.viguier@univ-montp2.fr

Co-authors: Hervé Jourde, CNRS HydroSciences Montpellier, Montpellier Cedex 5, France; Véronique Leonardi, Université Montpellier II - HydroSciences Montpellier, UMR5569, Montpellier, France; Elisabeth Lictevout, ciderh-Universidad Arturo Prat, Iquique, Chile

Abstract Body: The dryland areas cover 47.2% of the continents surface, whereas the pediments (or piedmont) are present on all the continents. In this study, we attempt to better understand the hydrogeological functioning and recharge processes in such areas.

The endorheic Pampa del Tamarugal basin (Northern Chile) is shaped in by a Central Depression (Northern extension of Atacama Desert). This depression contains the Pampa del Tamarugal lowland (1000 m a.s.l) and the Andean Piedmont, limited on his eastern side by the Precordillera mountain range (5000 m a.s.l). This area is one of the most arid areas of the world. The climatic context is arid and hyperarid, with an annual average precipitation close to 250 $mm.y^{-1}$ in the Precordillera and no precipitations in the lowland. This lowland contains the Pampa del Tamarugal regional aquifer, which is a strategic groundwater resource for the Northern Chile as a whole.

The study of water transfers from the Precordillera to the downstream aquifer highlights several geomorphological and geological controls on the recharge. This recharge also depends on climatic control such as El Nino/La Nina Southern Oscillations.

The geological and geomorphological settings of the piedmont area, such as the spatial distribution of aquifer geological layers and the outcropping of bedrock (acting as impermeable barriers), control the groundwater circulations and suggest preferential recharge locations in the piedmont. On this basis, it is shown that most of the potential recharge should occur during flooding, when high altitude precipitations generate surface runoff that reaches the downstream aquifer recharge zone. Based on the estimation of the flooded area surface, we attempt quantifying the recharge of aquifer in lowland area when flashflood occurs. Numerical modelling accounting for pedotransfer functions (based on in situ sampling) with Hydrus-1D is performed to quantify this transient recharge as a function of various flooding duration.

Title: The Effect of Inter-Basin Water Transfer on the Water Resources of Betwa Basin, India

Presenter/First Author: Shakti Suryavanshi, University in Allahabad, Allahabad,

Presenter/First Author Email: suryavanshi.shakti@gmail.com

Co-authors: Ashish Pandey, , , ; Umesh Chandra Chaube, , , ; Surendra Kumar Mishra, , ,

Abstract Body: This investigation has been carried out to analyse the effect of inter-basin water transfer on the water balance of the Betwa basin (43500 km²), India. The Providing Regional Climates for Impacts Studies - Regional Climate Model (PRECIS-RCM) data in conjunction with the Soil and Water Assessment Tool (SWAT) model (Semi distributed model) has been employed to examine the long term effects of inter-basin water transfer on the basin water resources. Analysis of water balance was carried out dividing the whole Betwa Basin into three parts. The upper basin was considered as rainfed and this area is denoted by "Area-A". In lower part of the basin, the existing major irrigation projects fulfilling irrigation and municipal/industrial needs are considered and this area is denoted by "Area-B". The third "Area-C" represents the Dhasan catchment irrigated also through small irrigation schemes. Assuming that the present situation of irrigation in the Betwa basin shall prevail till 2035 and Ken-Betwa Link Plan (KBLP) will establish afterwards, this study considers two scenarios: Long Term Part-I (LTP-I) for year 1976-2035 and Long Term Part-II (LTP-II) for year 2036-2095. Water resources of LTP-I (1976-2035) and LTP-II (2036-2095) scenarios were compared for all sub-areas, viz., Areas-A to C. Precipitation and evapotranspiration has been increased in all areas. Change in these parameters influences all the other water balancing parameters of the basin. The effect of implementation of the KBLP on different components of water balance during 2036-2095 was also evaluated considering that no man-made changes would occur in the basin. Results reveals that there will be a considerable decrease in surface runoff, transmission losses, and total water yield in Area-A (upper basin), largely because of trapping of water in upper basin through different (but likely) irrigation schemes. In addition, lateral flow, groundwater contribution and percolation will increase significantly. The water balance is almost similar for Areas-B and C in both scenarios. Thus, this study in different scenarios indicates significant effect of the KBLP in upper basin, but without affecting previous commitments of the water withdrawals from the lower basin.

Title: Hydrological impacts of the changes in simulated rainfall fields on the Nakanbe basin in Burkina Faso

Presenter/First Author: Boubacar Ibrahim, WASCAL West African Science Service Center on Climate Change and Adopted Land Use, Ouagadougou,

Presenter/First Author Email: ibrahim.b@wascal.org

Co-authors: Harouna Karambiri, International Institute for Water and Environmental Engineering, Ouagadougou, Burkina Faso; Jan Polcher, , ,

Abstract Body: Changes in rainfall regime during the last five decades over West African Sahel have significantly modified the hydrological regime of many rivers with a significant impact on water resources. In this study, the main hydrological processes on Nakanbe watershed in Burkina Faso are described with two hydrological models: GR2M (lumped and monthly model) and ORCHIDEE (distributed and half hourly model). The two models were calibrated on the watershed from the observed runoff at the outlet of Wayen (an area of about 22 000 km²) over the 1978-1999 period with a Nash-Sutcliffe efficiency criterion of more than 62%. The mean annual hydrological balance on the watershed over 1978-1999 period is composed from both models with 4% of runoff, 10% of groundwater recharge and 86% of actual evapotranspiration. The validated model of ORCHIDEE was then used to assess the hydrological impacts of the changes in the rainfall regime simulated by five regional climate models (CCLM, HadRM3P, RACMO, RCA and REMO) run under the intermediate scenario of A1B. ORCHIDEE simulations show that the hydrological impacts on runoff come mainly from the changes in the rainfall field with regard to the frequency and the intensity of the rain events. The impacts of the decrease in the two characteristics reveal different magnitudes of decrease in water resources. The decrease in the intensity of rainfalls is much more (10% more important) prejudicial to runoff and to groundwater recharge (two times more important) than a decrease in the frequency of rainfalls.

Title: Simulation of Hydrological cycle in Western Canadian regions using CLASS/Canadian Regional Climate Model

Presenter/First Author: Waqar Younas, University of Northern British Columbia, Prince George, BC

Presenter/First Author Email: vickyqau@gmail.com

Co-authors: Stephen J Dery, University of Northern British Columbia, Prince George, BC, Canada

Abstract Body: The climate of western North America, most notably British Columbia, has changed substantially over the past century and its impacts can be observed widely from its hydrological cycle. In this context, it is vital to monitor and simulate these changes and their impacts on the region's future hydrology. In this study, the Canadian Land Surface Scheme (CLASS) coupled with the Canadian Regional Climate Model (CRCM) will be implemented to simulate the snow modelling over the principal watersheds of western Canada, e.g. the Nelson, Mackenzie, Columbia and Fraser rivers basins. The emphasis will be placed on the development of a sub-grid scale snow (SSS) parameterization and its impact on representing land surface heterogeneities within the framework of CRCM version 6. The snow parameterization within CRCM will incorporate elevation bands, the consideration of slope and aspect and exposure to wind, among others. It is expected that this work will improve the depiction of snowpack evolution in western North America and will help to evaluate its impacts on regional hydrology.

This study will also focus on some other important issues related to snow modelling of above mentioned regions. For example, the impact of high resolution model integrations combined with SSS parameterizations on the simulation of snow in mountain regions will be assessed. The change in regional hydrology with multi-layer snow model together with the simulation of snow-albedo feedback in CRCM will also be addressed.

Title: Development of a Simple Framework to Assess Hydrological Extremes using Solely Climate Data

Presenter/First Author: Etienne Foulon, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, QC

Presenter/First Author Email: etienne.foulon@ete.inrs.ca

Co-authors: Patrick Gagnon, Organization Not Listed, Washington, DC; Alain N Rousseau, INRS-ETE, Neuville, QC, Canada

Published Material: AGU fall meeting 2014, 15-19 december, poster presentation

Abstract Body: Extreme flow conditions such as droughts and floods are in general the direct consequences of short- to long-term weather/climate anomalies. For example, in southern Quebec, Canada, summer 7-day low flows are due to summer and fall precipitations. Which prompts the question: is it possible to assess future extreme flow conditions from meteorological/climate indices or should we rely on the classical approach of using outputs of climate models as input to a hydrological model? The objective of this study is to assess six hydrological indices describing extreme flows at the watershed scale (Q_{max}, $Q_{min;7d}$, $Q_{min;30d}$ for two seasons: winter and summer) using local climate indices without relying on the aforementioned classical approach.

To establish the relationship between climate and hydrological indices, daily precipitations, minimum and maximum temperatures from 89 climate projections are used as inputs to a distributed hydrological model. River flows from five hydrographic regions in Québec are separately calibrated for winter and summer seasons and the watersheds are divided into upper-, middle-, and lower-sections. This allows to better take into account the different driving mechanisms behind the generation of high and low flows, as for the snow-melt or heavy convective rainfall events induced high-flows of late winter and summer. To identify the best predictors between 1961 and 2100, hydrological indices are extracted from the flow series, and climate indices are computed for different time intervals (from a day up to four years).

Overall, preliminary findings clearly illustrate that the change in the hydrological indices can be detected through the concurrent trends in the climate indices. The use of many climate projections ensures the relationships are not simulation-dependent and shows summer events are particularly at risk with increasing high flows (60% of the variability is explained on average) and decreasing low flows.

The development of a simple predictive tool to assess the impact of climate change on flows represents one of the major spin-off benefits of this study and may proove to be useful to municipalities concerned with source water and flood management. Future work includes the use of different sets of climate indices for watersheds clustered according to their physiographic descriptors.

First Author Student?: No

Co-authors: Antonio G. Camacho, Institute of Geosciences (CSIC-UCM), Madrid, Spain; Kristy French Tiampo, University of Western Ontario, London, ON, Canada

Abstract Body: Rapid population growth and overuse of groundwater contributes to severe land subsidence in Mexico City. For studying the subsidence phenomena we processed high resolution ascending and descending RADARSAT-2 images acquired during 2008/10/29-2010/12/11. The advanced analysis based on the Multidimensional Small Baseline Subset (MSBAS, Samsonov & d'Oreye, 2012) technique was applied to produce vertical and horizontal deformation time series and mean deformation rates. The vertical deformation rate reveals rapid subsidence with a rate over 30 cm/year at selected locations. The horizontal deformation with rate of up to 10 cm/year accompanies subsidence with motion directed towards subsidence center. It was observed that subsidence rate varies spatially over short distances. A few areas of steady ground are observed surrounded by fast subsidence. Such heterogeneity is likely due to the spatially varying. The nonlinear inversion methodology by Camacho et al. (2011) was used for modeling 3D pressure and mass sources with a free geometry. The geometrical description of the extended sources is developed by aggregation of point sources in a 3-D context, allowing for a very general description of the free geometry for the source bodies. For simplicity, it is assumed that anomalous pressure changes and density anomalies are nearly homogeneous within the sources. The inversion process fills cells with the prescribed pressure value (and/or density anomaly), giving rise to the aggregation structure. The nonlinear search is based on an exploratory approach. Simultaneously regional deformation patterns are obtained. Measured displacement and modeling results are described.

Title: Preventing the Next Disaster at Lake Nyos.

Presenter/First Author: Emmanual Asongacap Atemnkeng, University of Yaoundé, Kumba,

Presenter/First Author Email: asongacapemmanuel@gmail.com

Abstract Body: Lake Nyos is an active crater lake located in Menchum Division of the North West Region of Cameroon. This is one of only three volcanic lakes in the world (the others are Lake Monoun in Cameroon and Lake Kivu in Rwanda).

In August of 1986, there was a huge eruption at Lake Nyos that sent plums of Carbon dioxide (CO2) gas into the atmosphere killing 1700 people, livestock and practically all living things within a 15 miles radius of the lake. The explosion was the result of accumulation of a large amount of gas CO2 deep underneath the lake. It is believed that some 1.2 cubic km of gas was released to the environment in this one single event. CO2 concentrations are ok at about 3% but lethal in excess of 10%. The villagers around Lake Nyos literally suffocated under the heavy poisonous cloud of the gas. The lake was dubbed the deadliest lake by Guinness world record in 2008

Several efforts are being put in place to prevent a repeat of what happened here in 1986. Following the various scientific studies on the disaster that the lake was super-saturated and out-gassing could occur every 10-30years, there were proposals to reduce the volume of water in

the lake that could reduce pressure on the lake's CO2 and cause the gas to escape. Another research finding proposed the installation of a degassing column in the lake. To this effect, the U.S office of foreign Disaster Assistance funded a permanent installation of a degassing pipe at Lake Nyos.
On January 30th 2001, a spectacular 50 m high fountain soared above the peaceful surface of the lake.
The demonstration was a total success; a powerful soda spray jet - stable and safe - was switched on and off several times using a remote radio-controlled system. In 2011 two additional pipes were installed to assure the complete degassing of Lake Nyos.

Title: Mediterranean Network of Environmental Forcing Records In Travertines _ Med-NEFRIT Project: preliminary results

Presenter/First Author: Elisabeth Gibert-Brunet, GEOPS-UMR 8148, Orsay,

Presenter/First Author Email: elisabeth.gibert@u-psud.fr

Co-authors: Florent Barbecot, UQAM, , QC, Canada; Marina Gillon, 1114 UAPV-INRA EMMAH, University of Avignon, Avignon, France; Alina Tudryn, , , ; Jerzy Nitychoruk, University of Biala Podlaska, Biala Podlaska, Poland; Erdal Koşun, Akdeniz University, Antalya, Turkey; José Benavente, University of Granada, Granada, Spain

Abstract Body: While they support most of ecosystems, water resources are the first victim of climate and environmental changes. They are largely impacted over the world in terms of quantity as well as quality. Whatever are the modelling contributions, the lack of records of water resources responses to external forcing limits our understanding and capability to develop integrated management of these resources. In such a scheme, we proposed to organize a scientific network (Poland, Turkey, Spain, France) within the European Cooperation MISTRAL-ENVIMED Programme, to share and develop original approaches and enhance our knowledge of these systems.

The study of environmental changes over recent periods focuses on relationships and feedback effects between climate and human aspects, using a variety of archival sources and proxies such as ice cores, ocean sediments, tree rings or soils. However, with the development of novel proxies (physical, chemical or methodological), the calibration and validation of data have to be clearly evaluated on their own.

For developing a comprehensive overview of processes leading to reliable records of environmental parameters, we focuses our work on modern travertines that are seen as a link between hydrological balance (recharge *vs* discharge/abstraction) and climatic data (temperature, rainfall), *via* specific geochemical records.

Our research project is based on the study of recent travertine that potentially registers environmental conditions. It implies research developments to (i) accurately understand the geochemical processes between liquid-gas-solid phases (kinetic degassing, carbonate precipitation, fractionation out of equilibrium and water-rock partitioning), (ii) reconstruct hydrological fluctuations from annual to seasonal time scales during the last 100 years, and (iii) compare environmental records with recent available meteorological parameters, in relation with regional to global atmospheric trends of Mediterranean/Western Europe area.

Title: Kinetic isotope fractionation during rich-CO_2 water degassing: understanding the travertine geochemical record.

Presenter/First Author: Léonora Fleurent, GEOTOP-UQAM, Montréal,

Presenter/First Author Email: leonora.fleurent@u-psud.fr

Co-authors: Elisabeth Gibert-Brunet, GEOPS-UMR 8148, Orsay, France; Florent Barbecot, UQAM, , QC, Canada; Marina Gillon, 1114 UAPV-INRA EMMAH, University of Avignon, Avignon, France; Vincent van Hinsberg, McGill University, Montreal, QC, Canada

Abstract Body: The response of continental groundwater systems to recent climate fluctuations can be reconstructed via the continuous measurement of groundwater level, spring flow and climatic chronicles. When any data exist, recent reconstructions of groundwater dynamics may be reached through various recorders of environmental and hydrological conditions such as travertine. Although the relationship between geochemical records in travertine and environmental parameters seems to be accepted, the details of processes and their respective weight in the paleo-information are not clearly established.

Rate of CO_2 degassing in CO_2-rich spring likely influences calcite precipitation rate and the related $\delta^{18}O$ and $\delta^{13}C$ composition. Isotopic equilibrium is rarely maintained during travertine deposition and the degassing rate is the main controlling factor of the disequilibrium. Due to the lack of knowledge, fractionation processes, either kinetic or equilibrium, occurring between CO_2-rich water, gas and travertine required specific pH and temperature-controlled laboratory tests. These tests were conducted on synthetic water at different pH to focus only on the degassing processes. Other tests were conducted on trace elements partitioning during calcite precipitation, to identify the origin of isotopic signature variability, and to constraint the way of recording past conditions.

All these tests confirmed that during a degassing leading to travertine precipitation, the speciation of dissolved inorganic carbon species is a major parameter to be tackled since a linear relationship between $\varepsilon_{DIC-CO2(g)}$ and pH is observed. Indeed, we highlighted that for a high degassing rate, the isotopic equilibrium is not reached because the reaction greater involves light isotopes than heavy ones. There is thus different reaction rate between the species of dissolved inorganic carbon, the reactions occurring faster in the water than the one between water and gas, the latter being controlled by diffusion.

Title: Development and application of a decision support system for sustainable groundwater management: A case study of Rechna Doab basin, Pakistan.

Presenter/First Author: Azhar Inam Baig, McGill University, Sainte-Anne-De-Bellevue, QC

Presenter/First Author Email: muhammad.baig@mail.mcgill.ca

Co-authors: Johannes Halbe, McGill University, Montreal, QC, Canada; Jan F Adamowski, McGill University, Montreal, QC, Canada; Shiv O Prasher, , ,

Abstract Body: Sustainable aquifer management is often regarded as a significant challenge in the developing world. Factors such as low farmer awareness levels, scarcity of irrigation water supplies, high cropping

intensities and government policies such as flat electricity rates for tube well operations often hamper the adoption of effective management solutions. Over-abstraction results in lower groundwater depth, with a concurrent decrease in aquifer water quality and increase in pumping cost; in shallow zones, on the other hand, salt accumulation in the root zone is common due to high evaporation losses.

This presentation is part of a research project conducted in the Rechna Doab Basin of Pakistan and addresses such challenges via the development of a comprehensive but simple decision support system using a participatory modeling approach. The presentation evaluates different sustainable aquifer management solutions while taking into consideration surface water availability, crop water demand, and groundwater quality and socioeconomic conditions. To improve management effectiveness, an integrated modeling approach is develop by linking a system dynamics model of the socioeconomic system components with the SGMP module of the Spatial Agro Hydro Salinity Model (SahysMod). The system dynamics model controls tube well development and capacity according to demand-based irrigation, groundwater quality and availability of funds. The SGMP module estimates the water table depth by replicating the hydrological conditions of the study area. Final results indicate that uncontrolled human behaviors and activities are responsible for the degradation of groundwater resources. A brief summary of upcoming challenges and effective management solutions is presented for policymakers to use in the sustainable management of groundwater resources in this study area and others in similar areas.

Title: Hydrogeochemistry and isotopy of the groundwater intensely used in eastern Haouz and the area of Tassaout Upstream, Morocco.

Presenter/First Author: Samia Rochdane, Cadi Ayyad universitu, Marrakech,

Presenter/First Author Email: samia.rochdane@gmail.com

Co-authors: Abdennabi Elmandour, Cadi Ayyad university, Marrakech, Morocco; Paul Baudron, Polytechnique Montreal, Montreal, QC, Canada

Abstract Body: The Eastern Haouz and the Tassaout upstream area aquifer is the most stressed aquifer in the drinking water supply of cities, industrial processing and agricultural activity (more than 1000 wells and boreholes). This is an area where the demand for water is increasing year by year. Water levels measured in the study area shows a deep groundwater aquifer in the South and shallow in the North. The reservoir of the unconfined aquifer is characterized by a varying hydrodynamic parameters; the transmissivity varies between 1.10^{-4} to $3,6.10^{-2}$ m²/ s, and the storage coefficient is 2 to 10%. The piezometric map shows two areas of groundwater recharge; South from the High Atlas mountains and North from the Jebilets hills, two flows to the South West and the other to the North East.

A great variation is between the minimum and maximum values of the different ions, that variation is observed also in values of electrical conductivity, which varies between 761 and 7680 µS / cm, with an average of 2350 µS / cm. The analysis of several diagrams shows that there is a dominance of Na-Cl and Na-HCO3 facies with respectively a percentage of 48% and 12%. Groundwater of alluvial formations, surface water and also the water source have a slight dominance of Na-Cl, while the water circulating in the shales and Triassic formations show a high dominance of Na and Cl. Water samples from shale and Triassic formations are relatively mineralized and unfit for human consumption and for agricultural purposes. Groundwater in the central part circulating in the alluvium show low mineralization due to high power along the Tassaout River and infiltration of irrigation water from the water dam used to irrigate the agricultural area of the Tassaout upstream. Apart from salinity, about 25% of samples had nitrate concentrations above the allowable limits by WHO.

Measurements of stable isotopes show that the recharge of groundwater is controlled by local conditions that are feeding the unconfined aquifer by anastomosis in contact with limestone formations of the High Atlas and infiltration of the water dam used for the irrigation. The correlation between isotopic data and electrical conductivity has to distinguish isotopic differentiation characterized by three groups with a dominance of waters with the content of medium values of δ18O and electrical conductivities.

Title: Connectivity between wetlands and streams: patterns of phosphorus export in the Prairie Pothole Region

Presenter/First Author: Md Aminul Haque, University of Manitoba, Winnipeg,

Presenter/First Author Email: haquema@myumanitoba.ca

Co-authors: Genevieve Ali, University of Manitoba, Winnipeg, MB, Canada

Abstract Body: In the last 100 years, more than 50% of the wetlands in the Prairie Pothole Region have been lost or altered. The loss or alteration of these wetlands, which are usually considered as geographically isolated, has modified the frequency of water and pollutant exchanges between land and streams and thus affected regional water quality. Indeed, while intact wetlands act as nutrient sinks by effectively trapping runoff and associated pollutants, lost or altered wetlands are prone to release nutrients to nearby streams. Although the general impacts of wetlands loss or degradation at the regional level are well understood, little is known about local wetland properties that drive those changes. Hence, to evaluate stream-wetland connectivity and associated nutrient export, 10 intact and 10 altered/lost potholes were selected for study; they are located in Broughton's Creek Watershed (Manitoba, Canada) on both sides of a 5 km creek reach. Surface water was sampled from intact and consolidated wetlands while subsurface water was sampled below the ditches associated with drained potholes at least twice a month in 2013 and 2014. Creek water was sampled at the two extremities of the study reach at least once every two days during the same period, and all samples were tested for soluble reactive phosphorus (SRP). Initial data analyses show that SRP concentrations in the creek were strongly correlated to SRP concentrations in the altered wetlands and drainage ditches. In particular, SRP concentrations at the downstream end of the study reach closely followed SRP concentrations in the altered wetlands. Both extremities of the study reach showed considerable fluctuation in SRP concentrations, with notable increases at the downstream end following precipitation events. Future analyses will be carried to further characterize the role of wetland degradation on stream-wetland nutrient connectivity in different surface and subsurface runoff conditions.

Title: Storm-Based Tracer Response of a Mesoscale Precambrian Shield Catchment with Mixed Landuse.

Presenter/First Author: David Robert McCorkell, Nipissing University, North Bay,

Presenter/First Author Email: davidmc@nipissingu.ca

Co-authors: April Lynda James, Nipissing University, North Bay, ON, Canada; Krystopher J Chutko, Nipissing University, North Bay, Canada; Merrin L Macrae, University of Waterloo, Waterloo, ON, Canada; Sue Miller, , ,

Abstract Body: This poster presents tracer-based stormflow responses collected from the Wasi watershed, a 235 km^2 Precambrian shield catchment located upstream of Callander Bay, Lake Nipissing, Ontario. Total phosphorus (TP) levels have regularly exceeded provincial water quality objectives since monitoring began in 2009. Sampling has, however, focused on summer baseflow conditions, which typically account for less than 20% of TP loads, suggesting there could be significant uncertainty in estimates of riverine P loading to Callander Bay. Contemporary studies show that turbidity is a useful surrogate for TP concentrations although relationships may be harder to quantify during periods when dissolved P flux is relatively greater. The objective of this study was i) to extend monitoring of streamflow to a wider range of hydrologic conditions, ii) to evaluate turbidity as a surrogate for TP for this watershed, and iii) to use additional tracer responses to inform TP sources to streamflow. In this poster we present tracer response (TP, SRP, TSS, specific conductance, temperature, stable water isotopes (SWI)) for three summer/fall 2014 storm events. Stormflows were sampled at a frequency of 2-3 hrs using autosamplers triggered by change in stream stage. For each storm, TSS and turbidity show strong positive correlations; TP-turbidity relationships will be reported. Two of the three storms show a counter-clockwise TSS-Q hysteresis, while a third storm shows a clockwise hysteresis consistent with flushing and subsequent exhaustion of sediment from the channel prior to peak streamflow. Bulk rainfall SWI signatures are distinct from pre-storm streamflow, although individual storms can overlap with groundwater signatures (e.g. ~-12.5‰) and/or surface water (e.g. -8.4‰). Specific conductance is used to help evaluate contributing sources of water. Analysis presented here aims to improve characterization of TP fluxes and sources from this mixed land-use watershed to the downstream water supply.

Title: Modelling the frequency distributions of peak streamflows on the Canadian Prairies

Presenter/First Author: Kevin Shook, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: kevin.shook@usask.ca

Co-authors: John W Pomeroy, University of Saskatchewan, Canmore, AB, Canada

Abstract Body: The peak flows of streams in the Canadian Prairies are difficult to fit to existing frequency distributions for the design of hydraulic infrastructure. The problem is exacerbated by the very low density of stream gauging in most of the region, and by the short record lengths of most of the gauges. Furthermore, nonstationarity in the forcing climate and in the landscape (i.e. in vegetation, and drainage) prevents the use of historical data for estimating future design flows. Prior research has shown that the most commonly used method for estimating design flows for ungauged Prairie streams is hydrologically and statistically invalid, leading to poor designs for infrastructure in the region.

It is demonstrated that physically-based hydrological modelling using the Cold Regions Hydrological Modelling platform (CRHM) is able to reproduce the streamflows, and therefore their frequency distributions, of Prairie streams over their periods of record. Using downscaled climate data, the frequency distributions of Prairie streamflows could be simulated for any future interval. From the generated frequency distributions of peak flows, design flows could be extracted for any desired return period. The logistical requirements for producing return-period flows over the Prairie region are discussed.

Title: Testing the ability of a semi-distributed hydrological model to simulate streamflow and contributing area relationships in cold regions

Presenter/First Author: Samson Girma Mengistu, Environment Canada Saskatoon, Saskatoon, SK

Presenter/First Author Email: samson.mengistu@ec.gc.ca

Co-authors: Christopher Spence, Environment Canada Saskatoon, Saskatoon, SK, Canada

Abstract Body: A dry and cold climate, the prevalence of small depressions, and the lack of a well-developed drainage network are characteristics of environments with extremely variable contributing areas to runoff. These types of regions (e.g., the Prairie Pothole Region (PPR) of North America) arguably present the greatest challenge to properly understanding catchment streamflow generation processes. Previous studies from all types of regions have shown that contributing area dynamics are important for streamflow response, but the nature of the relationship between the two is not typically quantified. Furthermore, it is not known if hydrological models can properly represent contributing area while simulating streamflow. In this study, the relationship between streamflow and contributing area was first characterized using field and remote sensing measurements. We then tested the capacity of the PDMROF configuration of Environment Canada's MESH model to reproduce this relationship. The study focused on the St. Denis Creek watershed in central Saskatchewan, Canada, which with its considerable topographic depressions can be considered representative of much of the PPR, making it ideal for this type of investigation. Streamflow tended to scale with contributing area according to power law relationships (R^2 >0.75, p <0.001) for both model and remote sensing methodologies, and were in good agreement with each other. Ongoing challenges in defining quantitative relationships between streamflow and contributing area include data collection, and demonstrable hysteresis and spatial variation in the relationship among watersheds.

Title: Noah-MP Land Surface Model simulation for Boreal Forest (BERMS SK-OAS) Site

Presenter/First Author: Yanping Li, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: yanping.li@usask.ca

Co-authors: Liang Chen, , , ; Fei Chen, NCAR/RAL, Boulder, CO; Alan Barr, Environment Canada, Saskatoon, SK, Canada; Bingcheng Wan, , ,

Abstract Body: In this study, a 10-year Boreal Forest (BERMS SK-OAS) site measurements were used to evaluate and calibrate the multi-physics version of the Noah Land-Surface model (Noah-MP) . Those processes which are crucial for the simulation were identified. The performance of different combinations of the parameterization schemes was evaluated statistically. The best combination was identified by the most appropriate simulation (CTL) of surface heat and moisture fluxes as well as soil temperature and moisture at different depths.

Although organic matter is not normally included in the current Noah-MP land-surface model, an organic soil layer was added in our simulation of BERMS site. By adding an 100% organic matter to the top 10cm of the soil alters the soil's thermal and hydraulic properties, and significantly improved the simulation of the thermal and hydrological components. The organic soil layer reduces summer soil temperatures while increases the winter soil temperatures, which (OGN) matches the observation much better than CTL. By including the organic soil layer in Noah-MP also improves the deep layer soil moisture simulation. The increase of the porosity and hydraulic conductivity of the organic soil increases soil moisture while decreases the surface evaporation at the same time.

For the 10-year observation, dry (2002-2003) and wet (2005-2006) phases are identified. The diurnal cycle of surface sensible and latent heat flux was studied to see the contrast between the dry and wet phases. The annual cycle of surface fluxes, water components were also studied to examine the different characteristics for dry and wet phases.

Title: Comparing Observed and Simulated Interannual Variability in the Carbon and Water Balances of the Southern Boreal Forest

Presenter/First Author: Omer Yetemen, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: omer.yetemen@usask.ca

Co-authors: Andrew M Ireson, University of Saskatchewan, Saskatoon, SK, Canada; Jill F Johnstone, University of Saskatchewan, Saskatoon, SK, Canada; Alan Barr, Environment Canada, Saskatoon, SK, Canada; T. Andrew Black, University of British Columbia, Vancouver, BC, Canada

Abstract Body: There is a growing realization that Earth-system models must capture the linkages between climate, hydrology and vegetation dynamics. This study will focus on the southern boreal forest of western Canada, where the forest-grassland ecotone is controlled by the water balance and is therefore sensitive to climate change. Our goal is to evaluate and improve the quantification of the structural and functional responses of the southern boreal forest plant community in CTEM (the Canadian Terrestrial Ecosystem Model), which is coupled to CLASS (the Canadian Land Surface Scheme) in the Canadian GCM (General Circulation Model) framework. The long-term detailed ecological and meteorological observations at BERMS (Boreal Ecosystem Research and Monitoring Sites) in central Saskatchewan make an excellent test bed for the ecohydrological validation of CLASS-CTEM. The initial evaluation of CLASS-CTEM will be done at stand-level, based on observations from three mature forest: aspen, black spruce and jack pine. We will focus on seasonal and interannual variability in the carbon, water and energy fluxes with particular emphasis on vegetation phenology, freeze-thaw timing and summer soil-moisture limitation. We aim to reasonably represent the seasonal phenology of different vegetation types and to capture the interannual variations in the carbon, water and energy fluxes. The modeling results will improve our understanding of the ecosystem sensitivity to climate and hydrology, with important ramifications for the sustainability of fresh water resources and wildlife habitat.

Title: Simulation of Lake Heat Fluxes by the Canadian Small Lake Model: Offline Performance Assessment for Future Coupling with a Regional Climate Model

Presenter/First Author: Patricia Pernica, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: patricia.pernica@gmail.com

Co-authors: Murray MacKay, Environment Canada Toronto, Toronto, ON, Canada; Howard S. Wheater, University of Saskatchewan, Saskatoon, SK, Canada

Abstract Body: Lakes strongly influence local and regional climate especially in regions where they are abundant. Development of a lake model for the purpose of integration within a regional climate model is therefore a subject of scientific interest. Of particular importance are the heat flux predictions provided by the lake model since they function as key forcings in a fully coupled atmosphere-land-lake system. The first step to a coupled model, is to validate and characterize the accuracy of the lake model over a range of conditions and to identify limitations. In this work, validation results from offline tests of the Canadian Small Lake Model; a deterministic, computationally efficient, 1D integral model, are presented. Sensible and latent heat fluxes simulated by the model are compared with in situ eddy covariance (EC) observations from Landing Lake (NWT, Canada) for the 2007-2009 period. Agreement between the EC data and simulated heat fluxes is assessed in terms of atmospheric stability, closure fraction and model formulation. Minimal model error appears to occur for unstable atmospheric conditions. Theses results demonstrate the ability of the 1-D lake model to reproduce both diurnal and seasonal variations in heat fluxes and surface temperatures for the open water period.

Title: Long-term Changes in Distributed Precipitation Phase at Reynolds Creek Experimental Watershed, Idaho, USA.

Presenter/First Author: Patrick R Kormos, USDA Agricultural Research Service, Boise, ID

Presenter/First Author Email: pkormos.fs@gmail.com

Co-authors: Danny G Marks, USDA-ARS Boise, Boise, ID; Annelen Kahl, UNIVERSITY OF CALIFORNIA Santa Barbara, Santa Barbara, CA; David C Garen, NRCS, Portland, OR; Andrew R Hedrick, Agricultural Research Service Boise, Boise, ID; Scott Havens, USDA Agriculture Research Serv, Boise, ID; Hans-Peter Marshall, Boise State University, Boise, ID

Abstract Body: A warming climate poses significant challenges to water resource managers of the Western United States because the phase of precipitation often dictates hydrologic response. One of the few places in the world that we have sufficient measurements to accurately estimate precipitation phase is the Reynolds Creek Experimental Watershed. Distributed precipitation phase data are used to quantify changes in the volume of snow and mixed precipitation received over the past 30 years. We combine distributed air temperature and relative humidity from detrended kriging to obtain maps of dew point and wet bulb temperature. We then utilize a simple look up table to classify distributed precipitation as rain, snow, or mixed events.

Co-authors: Hans-Peter Marshall, Boise State University, Boise, ID; Adam H Winstral, WSL Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland; Rupesh Shrestha, Boise State University, Boise, ID

Abstract Body: Estimating the spatial distribution of snow water equivalent is often complicated by large spatial variability due to the effects of wind, vegetation, topography, and microclimate. In order to accurately capture important features of the snow distribution at local scale, measurements and models must be performed at resolutions that are often not practical over hydrologically significant scales. However, with recent increases in measurement technology and computational power, spatially distributed estimates of SWE at high resolution from both measurements and models are becoming feasible at the basin scale. We compare SWE estimates using traditional techniques (depth, core measurements) with estimates using ground-based radar, airborne LiDAR, and iSnobal model results for the Reynolds Creek Experimental Watershed, near peak SWE in March 2009. The combination of coincident high-resolution ground-based measurements, remote sensing, and modeling allows accurate quantification of the uncertainties in each technique, and this unique dataset is used to develop efficient data fusion strategies for accurate spatial estimates of SWE with quantified uncertainty.

Title: Fusing Basin-Scale Airborne Observations with Simulations to Quantify Mountain Snow Water Storage During a Severe Drought

Presenter/First Author: Kat Bormann, NASA Jet Propulsion Laboratory, Pasadena, CA

Presenter/First Author Email: katbormann@gmail.com

Co-authors: Danny G Marks, USDA-ARS Boise, Boise, ID; Adam H Winstral, WSL Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland; Bruce J McGurk, Self Employed, Washington, DC; Andrew R Hedrick, Agricultural Research Service Boise, Boise, ID; Thomas H Painter, NASA Jet Propulsion Laboratory, Pasadena, CA

Abstract Body: One of the great unknowns in mountain hydrology is how much water is stored within a seasonal snowpack at the basin scale. Quantifying mountain water resources is critical for informed water resource management, but has proven elusive due to high spatial and temporal variability of mountain snow cover, complex terrain, accessibility constraints and limited in-situ networks. The Airborne Snow Observatory (ASO, aso.jpl.nasa.gov) uses airborne LiDAR techniques to derive snow depth combined with snow densities from a physically-based snow model to provide unprecedented basin-wide estimates of snow water mass (snow water equivalent, SWE). ASO was operational over selected basins in the Sierra Nevada in California during 2013 and 2014. Both years were very dry, with precipitation in 2013 at 75% of average, and 2014 – the driest year on record, 50% of average. Using over 10 weekly ASO acquisitions from peak SWE thru spring each year, we were able to provide water managers with reliable estimates of SWE volume, snow cover depletion and surface water input over the basin. However, shallow snow presents many difficulties for both LiDAR measurement of snow depth and for simulation modelling of precipitation distribution and snow density. The analysis presented here attempts to quantify and analyse these uncertainties. Our findings show that even during a drought year the LiDAR depth fields combined with the simulation model provide improved estimates of SWE volume in the basin. We also show the potential for the LiDAR depth fields to be used to improve precipitation estimates over this complex mountain region, and to update the snow distribution for improved density simulations. The NASA/JPL ASO program is the most important coupling of LiDAR remote sensing and snow hydrology in the last 50 years.

Title: Statistical analysis of flow dimension occurrences in natural aquifers from various geological environments: input on their conceptual interpretation

Presenter/First Author: Anouck Laura Ferroud, Unversité du Québec à Chicoutimi, Chicoutimi, QC

Presenter/First Author Email: anouck.ferroud1@uqac.ca

Abstract Body: Interpretation of pumping tests with conventional models (e.g. Theis) can lead to an erroneous estimation of hydraulic properties in complex aquifers such as fractured, faulted, karstified, glacial deposits, heterogeneous and with a variable geometry.

The *Generalized Radial Flow* (GRF) model developed by Barker (1988) opens new avenues for pumping well test interpretation by introducing non-radial behaviors as defined by values of the flow dimension *n* different from two (Theis-like assumption). This parameter *n* expresses the influence of the aquifer's physical and hydraulic features on drawdown transient evolution. In fact, the temporal evolution of *n* represents the diffusion of the frontal equipotential wave of drawdown. It comes to realize a "scan" of the hydraulic conditions in the reservoir. However, the GRF model remains seldom used due to the difficulty to relate flow dimensions to conceptual aquifer conditions, in spite of its high diagnostic potential.

Flow dimensions sporadically reported in the literature in support of original models are not representative of their statistical distribution in nature. A systematic analysis of their occurrence, through the compilation of several pumping test databases, emphasizes the importance of multi-stage responses formed by temporal combinations of linear, radial, spherical and/or fractional flow regimes. Cross-comparison with bulk geological information provides valuable insights on the conceptual interpretation of flow dimensions. For instance, the frequency of fractional flow dimension into granular aquifer tends to invalidate their common interpretation as fractured media. Moreover, linear flow regime is dominant in glaciofluvial aquifers, which can be attributed to channels, deeply differing from their common interpretation as relating to highly conductive faults.

The field results are also coupled with numerical simulations to investigate the 3D front pulse diffusion in diverse heterogeneity conditions. This composite strategy is designed to highlight the influence of geological features, boundary conditions, wellbore characteristics or hydraulic properties on the flow patterns induced by a constant-rate pumping test. This approach illustrates especially the usefulness of the developed interpreting tools.

Title: Characterization of fractured and karstic reservoir by Spot imagery and Geophysical prospecting (Middle Atlas Causses, Morocco)

Presenter/First Author: Khaoula Qarqori, Moulay Ismail University, Sidi Yahia el Gharb,

Presenter/First Author Email: khqarqori@gmail.com

Co-authors: Mohamed Rouai, University of Moulay Ismail, Faculty of Sciences of Meknes, Meknes, Morocco; Ginette Saracco, , , ; Mustapha Boujamaoui, , , ; Ahmed Manar, , ,

Abstract Body: The Liassic Middle Atlas Causses, and their junction with the Saïs Basin, is the most interesting fractured and karstic reservoir in the northern Morocco. However, it is less studied and poorly understood.

This study presents a multidisciplinary approach for the characterization of this kind of discontinuous reservoirs. The application of remote sensing has overcome the challenge of the oldest state of the data and the large scale of the studied areas, the analysis of SPOT images and new ASTER elevation data has led to establish draw a new fracturing map of the Causses.

The characterisation of fracture networks, their spatial clustering and connectivity, have facilitated the detection of potential hard-rock aquifers. These ones were taken into account for the application of geophysical prospecting techniques at small scale.

The « Aïn Bittit » area, around an important karstic spring, and lying at the junction between the Causses and the Saïs basin, has been chosen as target for geophysical imaging such as Electrical Resistivity Tomography and microgravimetry. These geophysical methods showed high reliability in the detection and mapping of the structure of the underground organization and probable hydrological flow paths.

The overall results of spatial and geophysical studies validated by field measurements and by the drilling of a 100m borehole showed a convergence and complementarities. The reservoirs of Causses and their junction with the Saïs Basin are characterized by heterogeneous and high clustering fracturing which is predominated by NE-SW and NW-SE directions.

At «Aïn Bittit » area, a « mini-graben » structure-like has been identified. The geometrical modelling suggested, in addition to vertical groundwater flows through faults, the existence of horizontal drained zone in karstic Quaternary travertine at shallow depth. Locally, the preferential circulations depend upon the direction of fractures.

Title: Characterizing Complex Aquifers Using Flow Dimension Diagnostic Sequences

Presenter/First Author: Silvain Rafini, CONSOREM, Chicoutimi, QC

Presenter/First Author Email: silraf@hotmail.com

Co-authors: Romain Chesnaux, , , ; Ferroud Laura Anouck, Unversité du Québec à Chicoutimi, Chicoutimi, QC, Canada

Abstract Body: In hydrogeology, transient hydraulic tests are still interpreted assuming Theis-like conditions, involving gross approximations of natural aquifers heterogeneities, and inducing errors in hydraulic parameters estimation which relevance depends on various hydrogeological and practical factors. The petroleum industry adopted for decades the drawdown log-derivative analysis for reservoir characterization, as part of the diagnostic plots approach that integrates a panel of analytically-derived interpretative models handling non-purely theisian conditions. Our numerical experiments corroborate how drawdown log-derivative interpretation allows identifying subtle changes in hydrodynamic conditions that are totally invisible on conventional drawdown plots. Such changes relate to different flow regimes produced by heterogeneities of various types (faults, lateral variations, irregular boundary geometry etc.), indicated by changes in the flow dimension as calculated using the GRF model. These changes succeed one another as the front pulse propagates outward from the pump well and reaches successive heterogeneities, resulting in some temporal sequences of flow dimensions. Taking numerical examples, we investigate how these flow dimension sequences provide efficient diagnostic tools for aquifers heterogeneities.

Presented examples of heterogeneous flow simulations are: inclined substratum, laterally juxtaposed and faulted aquifers. In all cases, log-derivative analysis allows detecting heterogeneities by visualizing flow regime changes, with varying flow dimension values. For instance, a conductive fault crosscutting the aquifer generates a highly diagnostic flow dimension sequence, which varies if the fault is inclined and/or connected to the well. Also, variable-thicknesses aquifers or punctual connections to underlying leaky bedrock domains generate responses identical to a recharge barrier on conventional semi-log drawdown plots, leading to erroneous interpretations that may be avoided using the suggested methods. Several flow dimensions diagnostic sequences are presented, related to conceptual heterogeneous flow models. This constitutes a pioneer typological catalogue of refined interpretative tools available for an advanced analysis of pumping tests data.

Title: Permanganate Natural Oxidant Demand and Its Retarding Effect on Diffusion in Sandstone

Presenter/First Author: Jiujiang Zhao, University of New Brunswick, Fredericton,

Presenter/First Author Email: jzhao1@unb.ca

Co-authors: Tom Anthony Al, University of New Brunswick, Fredericton, NB, Canada; Beth L Parker, University of Guelph, Guelph, ON, Canada; Mark Vangel, University of new brunswick, Fredericton, NB, Canada

Abstract Body: Sandstone samples were collected from drill core at the Santa Susanna Field Laboratory in southern California where an In Situ Chemical Oxidation (ISCO) experiment is planned to test the efficacy of permanganate for remediation of chlorinated solvent contamination in groundwater. The permanganate natural oxidant demand (PNOD) was measured with batch experiments on a representative group of samples from above (oxidized) and below (unoxidized) the water table. Diffusion measurements were also conducted on the samples using a conservative tracer (tritiated water, HTO) and permanganate in separate experiments. The PNOD results indicate a dependency on the initial concentration of permanganate and the duration of the experiment, but in general PNOD values are highest for unoxidized samples. Mineralogical investigations indicate that organic carbon is the solid component that is most reactive with permanganate, whereas pyrite shows no indication of reactivity. The effective diffusion coefficients (D_e) for HTO are consistent with medium to coarse grained sandstone, ranging from 6.4×10^{-12} to 3.8×10^{-11} m^2/s. The apparent diffusion coefficients (D_a) for permananganate diffusion in the oxidized samples range from 1.1×10^{-12} to 2.8×10^{-11} m^2/s, but these values are subject to significant uncertainty because the permanganate diffusion flux was not stable during the experiments. In contrast, permanganate breakthrough was not observed during diffusion experiments conducted on unoxidized samples with 5g/L $KMnO_4$ tracer, thus it was not possible to obtain D_a values. Subsequent mineralogical analysis demonstrated that the permanganate tracer penetrated only 2.5 mm over a four month duration. These results indicate that the NOD may have a profound influence on the penetration of permanganate into the rock matrix during attempts to use ISCO for remediation of fractured porous bedrock systems.

Title: Trace element concentration and distribution in groundwater of Talcher coal field areas, Odisha, India

Presenter/First Author: Ajit Kumar Behera, Indian Institute of Technology Roorkee, Roorkee,

Presenter/First Author Email: akbehera.geol@gmail.com

Co-authors: Rudra Mohan Pradhan, Indian Institute of Technology Roorkee, Roorkee, India

Abstract Body: A study was carried out in and around Talcher coal field areas of Odisha to evaluate the current status of trace elements, their concentration and distribution in groundwater. The excess presence of trace elements concentration in groundwater affects different parts of human body. So there is a growing concern over the potential accumulation of trace elements concentration of Fe, As, Pb, Ni, Cr, Cd, Mn, Co, Cu and Zn in groundwater due to mining of coal and metal deposits. For the present study a total of 36 nos. of groundwater samples were collected in two different seasons (pre monsoon period and post monsoon period) from some parts of Talchir Coal field, Odisha, India. The water samples were analysed for nine trace elements using inductively coupled plasma mass spectrometry (ICP-MS). Among these trace elements the toxic elements like Pb and As are within permissible limit (WHO, 1984). But some other trace elements like Fe, Mn and Cr are significantly higher than other trace elements. The concentration of Fe, Mn and Cr ranges from 114-1262 µg/l, 0-263 µg/l and 2-21 µg/l respectively during pre monsoon period and during post monsoon period the concentration ranges from 81-1218 µg/l, 1-385 µg/l and 1-30 µg/l respectively. The higher concentrations of Fe, Mn and Cr in groundwater may be due to increasing of urbanization, industrialization and leaching from natural geological formations.

Keywords: Trace elements, Talchir coal field, groundwater

Title: Assessment of the impact of land cover and beneficial management practices on water quality in complex watersheds – challenges and research opportunities ahead

Presenter/First Author: Alain N Rousseau, INRS-ETE, Neuville, QC

Presenter/First Author Email: alain.rousseau@ete.inrs.ca

Co-authors: Silvio Gumiere, Laval University, Québec, QC, Canada; Yang Ou, , , ; Maxime Fossey, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, QC, Canada

Abstract Body: Many watersheds are characterized by heterogeneous or mixed land cover. As such, urban, agricultural, industrial and forested areas are often found in the same watershed. In the urban portion, water quality tends to be governed by variability in both dry and wet conditions; while in the agricultural and forested portions, it is mostly governed by wet conditions producing significant runoff. When mobilized sources of contaminants are transported, impaired water quality conditions can arise in surface and ground waters. The transport can be altered by managing sources and/or modifying both hydrological and sedimentlogical connectivity. From a surface hydrology point of view, the watershed represents the basic unit to assess the impact of various land covers and Beneficial Management Practices (BMPs) on water quality and ultimately on sustainable development. One way to accomplish this task is to apply an integrated modelling framework at the watershed scale. Several applications of such a modelling framework have demonstrated that evaluation of the effects of land covers and BMPs cannot be solely based on analysis of overland loads but must also focus on in-stream concentrations and loads as non-linear behaviors characterize the outcomes. A comprehensive cumulative impact assessment must further be performed and based on cost and environmental benefit analysis, as well as on biological integrity indices and probability of exceeding ecotoxicological criteria. Although models are continuously improved, recent field surveys highlight the need for further investigate sediment dynamics in the stream network as well as in the riparian zone. This is one example of the real challenges ahead. This presentation will discuss the challenges and research opportunities of modelling key processes at meaningful spatial and temporal scales with an emphasis on the modelling of vegetated filters and wetlands.

Title: The Influence of Surface Coal Mining on Hydrology and Solute Transport in the Elk Valley, British Columbia, Canada

Presenter/First Author: Christopher C Wellen, McMaster University, Toronto, ON

Presenter/First Author Email: christopher.wellen@gmail.com

Co-authors: Sean Kevin Carey, McMaster University, Hamilton, ON, Canada

Abstract Body: Surface mining of coal in the Elk Valley, British Columbia, involves blasting of overburden rock to access mineable ore. Waste rock is placed in adjacent valleys, where it interacts hydrologically and chemically with the environment. As part of a multi-year R&D program examining the influence of surface mining on hydrological and water quality responses in the Elk Valley, this study investigated the relationship between mining practices, stream flows and solute concentrations. This work focused on the interplay of hydrology, water quality, and mining practice. Concentration-discharge relationships from catchments covered by waste rock show virtually no change of weathering ion concentration with increases in flow. This suggests solute export is transport-limited. Bayesian networks of empirical models were used to calculate annual loads of selenium, a weathering solute, as well as estimate their uncertainty. Load estimates are used to drive a SPAtially Referenced Regression On Watershed attributes (SPARROW) model of selenium, the first known application of SPARROW to a metalloid. The significance of a range of variables associated with waste rock placement techniques were assessed, with most not significantly affecting selenium release rates. Reclaimed area on waste rock spoils was identified as a variable that influenced selenium release rate, with increasing reclaimed area associated with decreasing selenium release. Annual selenium release rates tracked annual runoff, providing evidence that selenium release is largely transport-limited.

Title: Regulation of the Distribution of Anthropogenic Contaminants by Physical Limnological Processes in a Relatively Pristine Watershed: the Breach of the Mount Polley Mine Tailings Impoundment, British Columbia, Canada

Presenter/First Author: Ellen L Petticrew, Univ Northern British Columbia, Prince George, BC

Presenter/First Author Email: ellen@unbc.ca

Co-authors: Philip N. Owens, University of Northern B.C., Prince George, BC, Canada; Sam J. Albers, Univ Northern British Columbia, Prince George, BC, Canada; Svein Vagle, Institute of Ocean Sciences, Sidney, BC, Canada; Jacob Duros, Univ Northern British Columbia, Prince George, BC, Canada; Kristin Rasmus, Univ Northern British Columbia, Prince George, BC, Canada

Published Material: preliminary data has been submitted to GRL and is currently under review

Abstract Body: On 4th August 2014, the tailings impoundment of the Mount Polley copper and gold mine in British Columbia failed. Material from the impoundment (surface area = 2.7 km^2) flowed into nearby Polley Lake and Hazeltine Creek, before discharging into Quesnel Lake, a large (ca. 100 km long, >500 m deep), relatively pristine lake. Estimates suggest that approximately 25 Mm^3 of tailings (water and solids) and eroded soils and surficial materials from Hazeltine Creek were delivered to Quesnel Lake, raising the lake by 7.7 cm. Much of this material was deposited at the bottom of Quesnel Lake but a plume of fine-grained sediment (D_{50} of ca. 1 µm) remained suspended in the water column. The distribution of this sediment was monitored over several months using water column profiling for temperature, conductivity, fluorescence, turbidity and oxygen with depth. The plume movement was regulated by natural processes associated with the physical limnology of this large fjord lake, specifically, seiche events which transferred suspended particles both up-lake, against the flow regime and down-lake into the Fraser River. Documentation of the distribution of the plume in the first few months following the spill is presented and indicates the value of background knowledge of natural systems in the vicinity of mining operations and other facilities where significant inputs of contaminants could occur.

Abstract Body: On 4th August 2014, the tailings impoundment of the Mount Polley copper and gold mine in British Columbia failed. Material from the impoundment (surface area = 2.7 km^2) flowed into nearby Polley Lake and Hazeltine Creek, before discharging into Quesnel Lake, a large (ca. 100 km long, >500 m deep), relatively pristine lake. Estimates suggest that approximately 25 Mm^3 of tailings (water and solids) and eroded soils and surficial materials from Hazeltine Creek were delivered to Quesnel Lake, raising the lake by 7.7 cm. Much of this material was deposited at the bottom of Quesnel Lake but a large plume of fine-grained sediment (d_{50} of ca. 1 µm) moved both up-lake towards important salmon spawning areas and down-lake into Quesnel River, which in turn flows into the Fraser River. Samples of lake water and sediment samples taken from the impacted area show elevated levels of metals and other elements, which may have important implications for the ecosystem in this watershed. Indeed, the breach occurred at a time when a peak run of sockeye salmon were returning to their natal streams in this watershed. This presentation describes the failure of the impoundment dam and presents preliminary findings of the aquatic impacts of this environmental disaster.

Abstract Body: Understanding the impacts of human activities on the water environment is a grand challenge for hydrological science; effects include land-atmosphere feedbacks, as well as changes to surface water and groundwater systems. There is therefore a need to understand local impacts and also their larger scale effects, with associated implications for observations and modelling. Urbanisation remains one of the most dramatic changes to the natural environment, but changes to flood runoff processes are relatively well understood, are identifiable from regional analysis of catchment response and are routinely accounted for in urban storm-water design. However, the representation of basin-scale impacts of urbanisation remains a challenge, as local detail of urban development and drainage design are important factors in determining larger scale response. Other unresolved issues include quantification of urban water balances, land-atmosphere interactions, and water quality impacts. Agricultural land management effects are more subtle and often poorly understood. Regional hydrological analyses have failed to identify large-scale effects on runoff response, but have provided some insights into nutrient processes. There is an urgent need for detailed monitoring and modelling of fine scale processes, and the development and application of appropriate models at basin and regional scales, to guide management and policy. Recent developments in modelling the effects of agricultural land management change across scales are discussed; outstanding challenges for observations and modelling are identified.

Title: Net Evaporation Resulting from the Creation of a Boreal Hydroelectric Reservoir

Presenter/First Author: Ian B Strachan, McGill University, Montreal, QC

Presenter/First Author Email: ian.strachan@mcgill.ca

Co-authors: Alain Tremblay, Hydro-Québec, Montreal, QC, Canada; Simon Tardif, , , ; Christian Turpin, , , ; Luc Pelletier, McGill University, Montreal, QC, Canada

Published Material: An earlier version is published in Tremblay, A., Tardif, S., Strachan, I.B., and Turpin, C., 2014. Net water evaporation from the

Eastmain-1 reservoir. *Hydro Review* 33(5): 52-60. The information has been reworked and expanded.

Abstract Body: The creation of hydroelectric reservoirs results in a land-use change through the flooding of ecosystems and the environmental footprint of this change is of interest. In particular, there is increasing debate as to whether hydroelectric reservoirs are a significant consumer of water through evaporation. To date, most studies evaluating this change have used gross evaporation (indicating consumption). However, such studies neglect to account for the water loss that would have occurred through the pre-flooded ecosystem evapotranspiration (ET). Instead, the net ET is required to assess the net impact of the creation of a hydroelectric reservoir on the water consumption. We studied net ET loss in the Eastmain-1 hydroelectric reservoir located 800 km north of Montreal, QC from 2006-2012. The reservoir has a surface area of 600 km² and resulted from flooding of mature coniferous forest, peatlands, burned forest and aquatic systems. In contrast to the limited number of previous studies, we used eddy covariance (EC) towers to directly measure evaporation from the reservoir itself and ET from representative forests and wetlands at the same time. As expected, our results show that the ET rates were higher during the warmer months than during fall-winter time and that the gross ET and evaporation rates for the natural ecosystems and the reservoir were similar to those measured in other northern systems. Overall, we found the net evaporation [(reservoir – pre-flooded ecosystem ET) / kWh] to be on the order of 5-25% of gross. If the reductions in reservoir water level that normally occur through management are considered, this number reduces further indicating that northern reservoirs are small net consumers of water.

Title: Estimating the Impact of Depressional Storage Drainage on the Hydrology of a Canadian Prairie Basin using Physically Based Modelling

Presenter/First Author: John W Pomeroy, University of Saskatchewan, Canmore, AB

Presenter/First Author Email: john.pomeroy@usask.ca

Co-authors: Xing Fang, University of Saskatchewan, Saskatoon, SK, Canada; Kevin Shook, University of Saskatchewan, Saskatoon, SK, Canada; Cherie Westbrook, University of Saskatchewan, Saskatoon, SK, Canada

Published Material: Some of these findings were reported in Centre for Hydrology Report No. 14: *Pomeroy J.W., Shook K., Fang X., Dumanski S., Westbrook C. and Brown T.* Improving and Testing the Prairie Hydrological Model at Smith Creek Research Basin (2014). Some of these findings have been reported in the media: Globe and Mail, CBC The National, CBC The Current, Winnipeg Free Press, Regina Leader Post, CTV National News, PostMedia News.

Abstract Body: The impact of depressional storage change on the hydrology of small Canadian Prairie basins has been unclear because of conflicting conclusions on the degree of impact between studies of runoff in very small scale drainage systems and those of multi-year streamflow characteristics of larger basins. To better understand and predict the impact of depressional storage drainage (DSD) on prairie streams, the Cold Regions Hydrological Modelling platform was used to create the Prairie Hydrological Model (PHM) which simulates blowing snow redistribution, snowmelt, infiltration to frozen soils and the fill and spill of networks of ponds at multiple scales. The PHM was used to simulate the hydrology of Smith Creek Research Basin, Saskatchewan (~400 km²) with various DSD scenarios. Smith Creek basin has undergone substantial DSD from 1958 when it contained 96 km² of ponds covering 24% of the basin area to 43 km² covering 11% of the basin in 2008. This model simulations show that DSD can increase annual and peak daily flows substantially, and that notable increases to estimates of the annual volume and peak daily flow of the flood of record have derived from DSD to date and will proceed with further DSD. Restoration of depressional storage from the current extent back to that of 1958 decreased the simulated 2011 flood peak by 32% and the 2011 yearly volume of streamflow by 29%. Overall, Smith Creek total flow volumes over six simulation years increased by 55% due to complete DSD from the current (2008) state, and decreased by 26% with restoration to the 1958 state. Whilst the greatest proportional impacts on the peak daily flows are for dry years, substantial impacts on the peak daily discharge of record (2011) from DSD (+78%) or restoration (-32%) are notable and important in Smith Creek and downstream.

Title: Hydrologic and Thermal Responses to Rapid Retreat of a Lake-Terminating Glacier

Presenter/First Author: Robert Dan Moore, University of British Columbia, Vancouver, BC

Presenter/First Author Email: dan.moore@ubc.ca

Co-authors: Lawrence Bird, University of British Columbia, Vancouver, BC, Canada; Matt Chernos, , , ; Alexis Moyer, University of British Columbia, Vancouver, BC, Canada; Michele N Koppes, University of British Columbia, Vancouver, BC, Canada

Published Material: Some initial results based on thesis research were presented by Matt Chernos and Lawrence Bird (then MSc students) at the CGU 2014 Annual Meeting. This presentation draws upon more complete analyses, along with material that has not yet been presented. There are two manuscripts currently in preparation based on Bird's and Chernos' thesis research, but neither has been submitted.

Abstract Body: There has been increasing concern about the effects of ongoing glacier retreat and its influences on downstream river flows and aquatic habitat, including water temperature. Few studies have focused on the downstream effects associated with the formation of proglacial lakes, and no studies to our knowledge have focused on the effects of icebergs calved from lake-terminating valley glaciers. To address this knowledge gap, we are studying Bridge Glacier in the Coast Mountains of British Columbia, Canada, which currently terminates in a proglacial lake with a maximum depth of ~180 m. Analysis of Landsat imagery and application of an inverse linear response model indicate that the rate of retreat increased by two- to three-fold over predicted rates when the glacier terminus retreated into an over-deepened basin ca 1991. Field observations and energy-balance analysis for summer 2013 demonstrate that the presence of icebergs reduced summertime warming of the lake, as a result of a) the reduced area of water surface exposed to energy exchange and b) the consumption of thermal energy to drive sub-aqueous melting. During the 2013 field season, iceberg calving represented about 25% of the total mass loss of the glacier, and an energy balance analysis suggested that iceberg melting accounted for 6-7% of the total discharge recorded downstream of the lake. Once Bridge Glacier retreats to the point it becomes land-terminating, the loss of iceberg production will result in increased summertime lake warming and a reduction in meltwater runoff, with

implications for downstream aquatic environments. Ongoing research is focused on generating longer-term estimates of iceberg dynamics and their influence on summer streamflow trends.

Title: Geophysical Approaches to Improve Holocene Ice Core-Based Hydroclimate Reconstructions in the Northeast Pacific

Presenter/First Author: Karl J Kreutz, Univ Maine, Orono, ME

Presenter/First Author Email: karl.kreutz@maine.edu

Co-authors: Seth W Campbell, University of Maine, Orono, ME; Erich C Osterberg, Dartmouth College, Hanover, NH; Cameron P Wake, University of New Hampshire Main Campus, Durham, NH; Dominic Winski, Dartmouth College, Hanover, NH; Samuel G. Roy, University of Maine, Orono, ME; Peter Ortquist Koons, Univ Maine, Orono, ME; Steven A Arcone, US Army Engineer Research and Development, West Lebanon, NH

Published Material: I will present some of the Alaskan results of this work at the March 2015 Northeast Geological Society of America meeting, but will focus here on our work in the Yukon Territory.

Abstract Body: Paleoclimate data from the Pacific basin show significant hydroclimate changes over the past millennium, possibly in response to changes in the mean state of the El Niño Southern Oscillation. One hypothesis invokes a change from a persistent La Niña-like state during the Medieval Climate Anomaly (MCA) to a persistent El Niño-like state during the Little Ice Age (LIA). A test of this hypothesis is to reconstruct and evaluate the spatial precipitation anomaly pattern in the Northeast Pacific across the MCA-LIA transition, because modern observations show an enhanced (weaker) coastal-inland precipitation gradient in the region during La Niña (El Niño) conditions. We therefore predict that the NE Pacific precipitation anomaly pattern will weaken across the MCA-LIA transition. For the past decade, we have been developing an ice core array in the NE Pacific that targets the two nodes of this precipitation dipole (i.e., St. Elias Range and Central Alaska), most recently (2013) with the recovery of two surface-to-bedrock 210-meter ice cores from Mt. Hunter (Denali National Park). To determine precipitation variability at the Mt. Hunter site over the past millennium, we rely on a suite of supporting geophysical data to constrain glacier geometry (including digital elevation models and bedrock topography from ground penetrating radar), velocity, boundary conditions, and rheological properties in a 3-dimensional finite element numerical model. The combined observational and model datasets will allow us to remove influences of ice flow (which causes layer thinning) and spatial variability in snow accumulation rate to estimate temporal accumulation variability from the two ice cores. Here we focus on our overall approach and plans for future work in the St. Elias Mountains, where ice cores were recovered in 2002 (Eclipse Icefield and Mt. Logan). In particular, we highlight results of ground penetrating radar and terrestrial laser scanning (TLS) conducted on the Mt. Hunter plateau during May-June 2014 with the goals of producing a high precision DEM as input for the glaciological model and evaluating surface elevation change through time.

Title: Melt Processes at Glacier Margins: High-Resolution Ground-Based IR Imagery in the Cordillera Blanca, Peru

Presenter/First Author: Caroline Aubry-Wake, McGill University, Montréal, QC

Presenter/First Author Email: caroline.aubry-wake@mail.mcgill.ca

Co-authors: Jeffrey M McKenzie, McGill University, Montreal, QC, Canada; Michel Baraer, Ecole de Technologie Superieur, Montreal, QC, Canada; Bryan G Mark, OSU-Byrd Polar Rsrch Ctr, Columbus, OH; Oliver Wigmore, OSU-Byrd Polar Rsrch Ctr, Columbus, OH; Robert Hellstrom, Bridgewater State University, Bridgewater, MA

Published Material: About 25% of this material had been presented at the 2014 AGU Fall Meeting.

Abstract Body: Alpine glaciers provide water resources to some of the most populated regions on Earth. However, these resources are threatened by ongoing and accelerating glacier retreat. To properly understand the impact of this retreat on water resources downstream, we need to understand the processes driving the ablation of these headwater glaciers. Due to their remote location and often complicated access, obtaining in-situ, glacier-wide data for alpine glaciers is challenging. An emerging technique to investigate melt processes in these complex settings is ground-based infrared imagery. Infrared images, captured simultaneously with traditional weather stations monitoring on and off the glacier, can be processed to obtain high spatial and temporal resolution temperature maps of the glacier surface. This spatially distributed temperature data allows for the investigation of small scale surface processes such as the impact of surface cover and temperature gradient at glacier margins. These processes are investigated for a tropical glacier in the Cordillera Blanca, Peru. Daily time-lapse infrared imagery (5-30 minute spacing) of the glacier and close-up images of the margin, were acquired for the 2013 and 2014 dry season. The results indicate that the temperature gradient between the surrounding rocks and the glacier margins is highly dependent on topographic shading in addition to atmospheric and meteorological conditions. In clear sky conditions, incoming shortwave radiation heats the exposed rock faster than the adjacent ice, leading to a net radiation flux toward the glacier. This effect is also seen in late afternoon, when there is no more direct solar forcing. These energy transfers at the glacier margins appear to be a small but significant contribution to the overall melt generation for small alpine glaciers. This study shows the potential utility for collecting and analyzing ground based infrared imagery for glacier studies, with implications for hydrologic and water resource applications.

Title: Post Peak Water in the Cordillera Blanca, Peru: Toward a Redistribution of Water Resources.

Presenter/First Author: Michel Baraer, Ecole de Technologie Superieur, Montreal, QC

Presenter/First Author Email: michel.baraer@etsmtl.ca

Co-authors: Bryan G Mark, OSU-Byrd Polar Rsrch Ctr, Columbus, OH; Jeffrey M McKenzie, McGill University, Montreal, QC, Canada; Kyung In Huh, The Ohio State University, Houghton, MI; Oliver Henry Wigmore, The Ohio State University, Columbus, OH; Alfonso Fernandez, The Ohio State University, Columbus, OH

Abstract Body: Recent researches have shown that the upper Rio Santa and some of its tributaries that drain the western slopes of the glacierized Cordillera Blanca in Peru have already passed peak water, the moment of maximum water availability, and now exhibit decreasing dry season discharge as a consequence of glacial retreat. In addition, it was suggested that the glacier retreat impact of stream discharge is not uniform across the watershed. For instance, two different points along the Rio Santa were shown facing two different levels of glacier retreat impact on dry season discharge.

In the present study, we extend the exploration of the peak water situation spatial repartition by dividing the Rio Santa watershed into 26 sub

catchments and analyzing the impact of the glaciers retreat on these sub catchments dry season hydrology. We measured stream discharge at 11 locations along the entire course of the Rio Santa and sampled water at 33 locations to analyze for major dissolved ions and the stable isotopes of water. We interpreted the sample characteristics using a distributed hydrochemical watershed mapping tool called the Hydro-chemical Basin Characterization Method (Baraer et al., 2014). Glacier retreat simulations were then used to project future hydrological changes as a function of glacier mass loss and evaluate the downstream repercussions.

The results confirm that the entire Rio Santa watershed has passed the peak water. An overall decline of the dry season discharge of 30% of the actual level is anticipated just upstream of the major coastal diversions installations, a level that situates below the present demand for coastal uses. The geospatial heterogeneity in glaciers hydrological influence on stream discharge is explained by differences in glacier cover as well as in glaciers retreat rates. The most pronounced discharge reduction should be observed in the central part of the Cordillera Blanca where towns like Huaraz, the province capital, should be deeply affected.

Title: Using isotopic and geochemical tracers to determine the contribution of glacier meltwater to streamflow in a headwater catchment of Heihe River Basin, Northwestern China

Presenter/First Author: Qixin Chang, China University of Geosciences Wuhan, Wuhan,

Presenter/First Author Email: changqixin@hotmail.com

Co-authors: Ziyong Sun, China University of Geosciences, Wuhan, China; Rui Ma, China University of Geosciences Wuhan, Wuhan, China; Xiang Long, China University of Geosciences, Wuhan, China; Yalu Hu, China University of Geosciences Wuhan, Wuhan, China; Jieyue Li, China University of Geosciences, Wuhan, China

Abstract Body:
Glacier meltwater contributes significantly to the rivers flowing off the cold mountains to the arid basins in inland area, Northwest China. However, th e processes and mechanisms that control runoff generation in the cold hig h mountains where glacier meltwater, permafrost and frozen ground pred ominate have undergone few studies. Our objective is to determine the co ntribution of glacial meltwater to the streamflow in the Hulugou catchmen t, a headwater catchment of the Heihe River Basin, NW China. Water samp les from glacier meltwater, rainfall, stream and groundwater were collecte d between June and September 2012 and then were analyzed for isotopic and hydrochemical composition in laboratory. Three-
component hydrograph separations were used to identify the spatial and t emporal water sources of streamflow based on the data of stable water iso topes (δD) and chloride ion (Cl-
). Our results show that base flow dominates the streamflow, contributing 42% to the streamflow in rainy season (June to August) whereas glacier me lt water (24%) and rainfall runoff (34%) contribute the rest of streamflow. I t is an interesting finding that base flow increases in both amount and prop ortion following relatively insensitive rainfall events. During the study perio d, the contribution rate of glacier meltwater varies significantly, ranging fro m 0% to 40%. An obvious increase in contribution rate of glacier meltwater was also observed when rainfall event was over. There is a significant nega tive correlation between the contribution rate of glacier meltwater and rai nfall. Result from this research could improve our understanding of source waters in alpine catchments where discharge is dominated seasonally by gl acier meltwater, and consequently provide the theoretical basis for the de velopment of distributed runoff model.

Title: The hydrology of biological hotspots in a glacierized catchment: developing conceptual understanding of spatiotemporal variation in water sources and flow paths

Presenter/First Author: Michael Grocott, University of Birmingham, Birmingham, B15

Presenter/First Author Email: mxg269@bham.ac.uk

Co-authors: Nicholas Kettridge, University of Birmingham, Birmingham, United Kingdom; Chris Bradley, University of Birmingham, Birmingham, United Kingdom; Alexander Milner, University of Alaska, Fairbanks

Abstract Body: Stream emergences on floodplain terraces in glacierized catchments are often widespread and act as important 'biological hotspots', typically supporting elevated in-stream biotic diversity, and abundance. However, the water sources and flow paths supporting these stream systems and their spatiotemporal variation remains poorly understood, particularly in the context of a changing climate. It is important to understand how changes in the water balance, given glacial retreat, melting permafrost, and shifting precipitation patterns will affect their structure and function. Here we present the results of a hydrogeomorphic and hydrologic study of one such terrace on the Middle Fork Toklat River, Denali National Park, Alaska (63° 29' 38.2"N, 149° 58' 6.0"W), in which a network of 22 nested piezometers and environmental tracers (major ion solutes and stable isotopes) were used to track water sources and establish flow paths. A number of hydrofacies units were identified across the terrace thereby indicating a heterogeneous structure. Groundwater recharge occurred consistently through the spring and summer and the terrace aquifer did not display a flashy response to storm or melt events. We present water chemistry and stable isotope data (δD & $\delta^{18}O$) which suggest that hillslope runoff processes, and associated water sources (snowmelt, discontinuous permafrost, and summer rainfall), are the dominant control upon terrace aquifer recharge, and not meltwater from up-valley glaciers. Findings suggest colluvial deposits on the slopes above the terrace act as small, but significant temporary storage aquifers, and are an important flow path that supports terrace aquifer recharge. Finally, the heterogeneous structure of the terrace fluvio-glacial deposits and associated spatial variation in water chemistry observed indicate the presence of multiple flow paths in the terrace subsurface and potential significance of preferential flow pathways (PFPs) to the existence of stream emergences. The work highlights the importance of hillslope runoff processes, rather than up-valley glacial retreat, when considering the implications of a changing climate upon these systems.

Title: Assembly of a twenty-year record of hourly meteorological data for Peyto Glacier basin with modelled mass balance and runoff time series.

Presenter/First Author: D Scott Munro, University of Toronto, Toronto, ON

Presenter/First Author Email: scott.munro@utoronto.ca

Abstract Body: The first complete year of recorded hourly global radiation, air temperature, relative humidity, wind speed and precipitation for the Peyto Glacier basin was obtained in 1992, continuing to the present day, thus distinguishing it as one of the longer such glacierized basin records in the world. One air temperature sensor has remained the same throughout this period, never to change position, but all others have changed due to sensor failure, fatigue and equipment updates. Also, there are significant gaps in the records of 1998, 1999 and 2009 due to power failures, thus requiring substitute values for modelling purposes. Most problematic is the precipitation record, the first half of which comes from an old Fischer-

Porter gauge, using unconventional procedures, the second from a modern Geonor gauge with standard data processing rules.

Discounting the three years when data gaps occurred, mean annual air temperature from 1992 to 2011 is -1.27 ±0.68 ˚C, the first decade of record almost 0.5 ˚C colder than the second. Mean yearly total precipitation is 1159 ±239 mm, approximately 64 ±11 % of which falls as snow according to a <1.5 ˚C threshold. The first ten years of record, solely from the Fischer-Porter gauge, suggest 1205 ±302 mm a^{-1} of precipitation, while the Geonor record of the second ten years indicates 1118 ±175 mm a^{-1}, the larger deviation a possible reflection of procedural differences. The data are used in conjunction with a LiDAR derived DEM to drive a 25 m resolution raster based mass balance model of the glacier surface which is applied cumulatively to estimate winter and summer mass balances over the twenty-year period, as well as daily summer runoff.

Title: Developing a Glacier Hydrology Model for the Canadian Rockies

Presenter/First Author: Dhiraj Pradhananga, University of Saskatchewan, Canmore,

Presenter/First Author Email: dhiraj.pradhananga@usask.ca

Abstract Body: Mountain snow and ice play important roles in hydrological cycle of alpine regions by regulating water availability downstream in terms of both quantity and its seasonal variations. Many hydrological models have been developed, but very few explicitly calculate the snow and ice energy-budget and snow redistribution to estimate melt rates and mass balance. In this study, a model was developed in the Cold Regions Hydrological Model platform (CRHM) to calculate the hydrology of a glaciated stream influenced by the energy and mass balance of Peyto Glacier Research Basin in the Canadian Rockies. The model includes a new energy-budget glacier module, a new avalanche module, novel deployment of a layered energy balance snowmelt model, and a blowing snow model to a glacier surface. The model considers redistribution of snow by wind and avalanche as well as full radiation and turbulent transfer energetics to snow and ice. The model was set up using hydrological response units that consider elevation bands, slope and aspect units, wind exposure and avalanche runout as well as the heterogeneity of non-glaciated terrain. Meteorological observations from the stations within the basin and nearby locations were used to drive the model. The model was tested by comparing the simulated mass balance to observations from snow and ice depth on ice and off ice stations. Snow redistribution components of the model were evaluated by falsification of the model. This evaluation process is used to assess the uncertainty in comprehensive, physically based glacier melt modelling. Such a modelling approach is important for quantifying the melt rates in a glaciated basin in the context of climate change and variability.

Title: A survey of physically-based catchment-scale modeling over the last half century

Presenter/First Author: Claudio Paniconi, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, QC

Presenter/First Author Email: claudio.paniconi@ete.inrs.ca

Co-authors: Mario Putti, University of Padua, Padua, Italy

Abstract Body: Integrated, process-based based numerical models in hydrology and connected disciplines (ecohydrology, hydrometeorology, hydrogeomorphology, biogeochemistry, hydrogeophysics, etc) are rapidly evolving, spurred by advances in computer technology, numerical algorithms, and environmental observation, and by the need to better understand the potential impacts of population, land use, and climate change on water and other natural resources. At the catchment scale, simulation models are commonly based on conservation principles for surface and subsurface water flow and mass transport (e.g., the Richards, St. Venant, and advection-dispersion-reaction equations, and approximations thereof), and need to be resolved by robust numerical techniques for space and time discretization, linearization, interpolation, etc. Model development through the years has continually faced physical and numerical challenges arising from heterogeneity and variability in parameters and state variables; nonlinearities and scale effects in process interactions and interface dynamics; and complex or poorly known boundary conditions and initial system states. We give an historical perspective (past 50 years) on some of the key developments in physically-based hydrological modeling, examining how these various challenges have been addressed and providing some insight on future directions as catchment modeling enters a highly interdisciplinary era.

Title: Generalizing the Seepage Face Boundary Condition

Presenter/First Author: Carlotta Scudeler, University of Padua, Padova,

Presenter/First Author Email: carlotta.scudeler@gmail.com

Co-authors: Damiano Pasetto, University of Padua, Padua, Italy; Claudio Paniconi, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, QC, Canada; Mario Putti, University of Padua, Padua, Italy

Abstract Body: The seepage face is a non-linear dynamic boundary. The way it is handled in groundwater modeling strongly affects the pressure head distribution, the water table configuration, and the flow field. In addition, under conditions of heterogeneity and surface flow, complex scenarios may arise. In this study we address four specific questions: 1) When are seepage face boundary conditions critical and when, instead, is it acceptable to use a simpler fixed Dirichlet boundary condition? 2) How do strong vs weak constraints on seepage face convergence affect the accuracy and efficiency of the overall subsurface flow solution procedure? 3) How do we resolve seepage face outflow under conditions of layered and random heterogeneity? 4) In integrated surface-subsurface modeling, how does a seepage face boundary interact with the catchment outlet boundary condition used in overland and channel flow models? This last case is especially intriguing as the two conditions are diametrically opposed: a catchment outlet cell causes convergent flow patterns towards the land surface while a seepage face is typically used to represent outflow from the base of a hillslope. The analysis is performed with the CATHY (CATchment HYdrology) model, a physically-based model for the solution of the three-dimensional Richards equation coupled to a diffusion wave equation for surface flow propagation. The simulations will be conducted for synthetic hillslopes under various configurations (rainfall rate, slope angle, degree of heterogeneity, etc) and for the specific conditions represented by the convergent landscapes at the Biosphere 2 facility in Arizona.

Title: Improvement of Designs for Enhanced Infiltration Rates in MAR (Managed Aquifer Recharge) Technique at the Coastal Aquifers of South-Western Bangladesh

Presenter/First Author: Nazia Nawrin, University of Dhaka, Dhaka,

Presenter/First Author Email: nnawrin29@gmail.com

Abstract Body: Increasing salinity of natural drinking water sources has been reported as one of the many problems that affect low-income countries, but one which has not been fully explored.

Drinking water from natural sources in coastal Bangladesh has become contaminated by varying degrees of salinity due to saltwater intrusion from rising sea levels, cyclone and storm surges, upstream withdrawal of freshwater and increased shrimp and crab farming along the coastal areas. This crisis is also exacerbated owing to climate change. The problem of salinity can have serious implications with regard to rising rates of hypertension and other public health problems.

There are very few options of safe drinking water for more than 2 million people living in these regions. During dry period people of those areas rely largely on surface or pond water, PSFs and RWHs which can be vulnerable to pathogens and thus suffer largely from lack of safe potable water and health problem.

A potential solution was very much needed to overcome the fresh water scarcity problem of the area. Managed Aquifer Recharge (MAR) is an alternative, cost effective and durable option to store fresh water (roof top rain water and filtered pond water) into shallow brackish aquifer during the monsoon and subsequent recovery of fresh water from storage and its supply to the community people during the dry period.

About 70 percent rainfall occur during the monsoon period in the coastal belt of Bangladesh (Khulna-Satkhira) is potential for MAR. MAR techniques operate to store the rain water into underground aquifer, reduce the salinity and then get recovery of fresh water from groundwater storage which is provided to local people as a safe source of drinking water throughout the year particularly during dry season.

The successful implementation of MAR technique has brought “the solution” of drinking water problems in some extent in the SW coastal areas of Bangladesh. The improvement of design in MAR is required for enhanced infiltration rates. So the expected result would be the maximum infiltration as it ensures more freshwater storage, better quality improvement of groundwater and more availability of safe drinking water with minimum management cost for the community people.

Title: Multi-Observation Calibration of a Regional Scale Groundwater Flow Model

Presenter/First Author: Sylvain Gagné, Universite Du Quebec A Montrea, Montréal,

Presenter/First Author Email: gagne.sylvain@uqam.ca

Co-authors: Marie Larocque, Univ du Quebec - Montreal, Dorval, QC, Canada; Daniele Luigi Pinti, University of Quebec at Montreal UQAM, Montreal, QC, Canada; Marion Saby, GEOTOP-UQAM, Montréal, Canada; Genevieve Vautour, , Longueuil, QC, Canada; Diogo Barnetche, GEOTOP-UQAM, Montreal, Canada

Abstract Body: Since 2009, a regional groundwater characterization program is ongoing in the province of Québec (Canada). Among the numerous results from these projects, regional distributed groundwater recharge rates, groundwater ages from isotopic tracers and hydraulic properties were obtained. Integrating these data into a regional groundwater flow model has not yet been attempted in the St. Lawrence Lowlands. The objective of this work was to use multiple source data to calibrate a regional scale groundwater flow model. The study area is located in the central part of the St. Lawrence Lowlands and in the Appalachian mountains on the south shore of the St. Lawrence River (SLR) (7750 km²). Between 2009 and 2014, groundwater was sampled for ^{3}He, ^{3}H and ^{14}C analyses (42 samples). A distributed water budget calculation based on the Runoff Curve Number was used to calculate recharge for the entire study area. Groundwater outflow to peatlands was estimated based on a local Darcy approach. The steady-state 3D groundwater model was developed using Modflow, based on 100 m x 100 m cells and six vertical layers. The first layer represents the Quaternary sediments and the five others represent the fractured bedrock aquifer. The model was calibrated to reproduce 11 300 measured water levels, 22 measured river baseflows, estimated groundwater seepage to peatlands and groundwater ages obtained from $^{3}H/^{3}He$ and ^{14}C. The calibrated model shows that the majority of the recharge water is discharged at the scale of local watersheds, that regional groundwater flow is limited, and that almost no deep groundwater flows to the SLR. This confirms data from the regional water budget. Groundwater outflow to peatlands represent the range of flows estimated from local hydraulic gradients and hydraulic conductivities. The average and maximum particles travel times at the sampled wells compare favorably to the results from isotopic tracers with ages ranging from 2 to 22 000 years. Using different types of calibration data provided a model that simulate adequately a wide range of processes.

Title: Groundwater modeling of three hydrogeological contexts on St-Lawrence Lowlands and Appalachian foothills (southern Quebec, Canada)

Presenter/First Author: Olivier Ferland, University of Quebec at Montreal UQAM, Montreal,

Presenter/First Author Email: olivierferland1@gmail.com

Co-authors: Marie Larocque, Univ du Quebec - Montreal, Dorval, QC, Canada; Michel Lamothe, GEOTOP-UQAM, Montreal, QC, Canada

Abstract Body: Regional scale groundwater flow dynamics are influenced by local flow conditions which are rarely characterized thoroughly. In glaciated regions, complex surface geology conditions often create highly

variable flow conditions within small distances. The objective of this study is to understand local groundwater flow in different hydrogeological contexts of a regional scale aquifer. The study area is located on the south shore of St. Lawrence River between Montreal and Quebec (4500 km²). In this region, groundwater is the drinking water source for half of the population and is used for agricultural activities. Three different environments are specifically studied: 1) a U-shape valley upstream of watershed filled with glacial sand, till and silt on a fractured rock aquifer, 2) a partially unconfined granular sandy aquifer, linked with the bedrock aquifer with lenses of fine sediments, and 3) a confined/semi-confined bedrock aquifer downstream of the region with till, silt and silty sand. Each context has been simulated in a 2D cross-section having 3 to 8 km in length. The models were developed in Modflow with 1 m X 10 m X 10 m cells over 50 m. The steady-state models were calibrated based on groundwater levels, recharge and field-measured hydraulic conductivities. The transient-state models were further calibrated and run on a daily time step over one year. The three models reproduce well the seasonal variations of groundwater levels. Groundwater recharge is 10 times more important for section one compare to section three. The results show that groundwater dynamics are determined by the hydraulic properties of the different materials on each transect, as well as by the topography variations. The transect located in the granular unconfined sandy aquifer reacts five times faster to hydraulic stresses than the other two transects, and is more sensitive to recharge decreases. The model complexities help to understand discharge to rivers, to detect vulnerable areas and to locate precisely small recharge zones that are imperceptible at the regional scale.

Title: Alberta's 2013 flood: Response of a mountain peatland

Presenter/First Author: Cherie Westbrook, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: cherie.westbrook@usask.ca

Co-authors: Angela Bedard-Haughn, University of Saskatchewan, Saskatoon, SK, Canada

Abstract Body: In mid-June 2013 heavy rainfall in the Canadian Rocky Mountain foothills led to severe flooding in western Alberta. Consequently, there is interest from flood risk managers and scientists in exploring the role of foothill wetlands and beaver ponds in storage of floodwaters. Sibbald is a 0.63 km² foothills peatland in the foothills of the Rocky Mountains where a series of three beaver ponds, one groundwater well and the stream were instrumented with automated level recording devices one day before the onset of rainfall. A meteorological station recorded standard hydrometeorological variables throughout the event. The total rainfall over 20-22 June was 190 mm, with a 6-hr break in the rain occurring the afternoon of 21 June. Soil coring in the three days preceding the rain event revealed that the peat was frozen in many locations at a depth of 20-60 cm but was not frozen beneath the beaver ponds. Available peat storage above the frost table was filled in the first few hours of the rain event, causing the water table to rise well above the ground surface where it remained until after 22 June. The three beaver ponds offered 10-50 cm of water storage in the initial stages of the rain event. The pond hydrograph recessions during the break in rain indicate that they were losing water to the groundwater system. Although the middle beaver pond in the series outburst through a 10-m long breach during the first wave of rain, it stored 15 cm of water during the second wave. The results suggest that temporary storage of floodwaters offered by beaver ponds can enhance recharge to the groundwater system and attenuate downstream peak flows during flood events.

Title: An Assessment of Past and Projected Future Hydro-Climatic Extremes over Key Watersheds within Western Canada

Presenter/First Author: Barrie R Bonsal, Environment Canada, Saskatoon, SK

Presenter/First Author Email: barrie.bonsal@ec.gc.ca

Co-authors: Charles Cuell, , ,

Abstract Body: Since human activities and ecosystem health are dependent on adequate, reliable water supplies, hydro-climatic extremes, including the occurrence of severe droughts and excessive moisture pose a serious threat to society and the environment. Western Canada is a region with high natural hydro-climatic variability, including the periodic occurrence of drought and excessive moisture conditions, however, recent dramatic shifts between extreme drought and extreme wet conditions have suggested that this variability may be increasing. This investigation assesses the occurrence and atmospheric causes of both the past and projected future hydro-climatic variability and extremes over key watersheds within western Canada. Incorporation of the Standardized Precipitation Evapotranspiration Index (SPEI) reveals considerable decadal-scale variability in hydro-climate over many regions of western Canada with no discernible long-term trends. In addition, an assessment of the mid-tropospheric (500 hPa) circulation patterns associated with identified hydro-climatic extremes indicate that major drought episodes were associated with significantly higher frequencies of circulation types that included distinctive ridging patterns over the Prairie region, and lower incidences of zonal and mid-tropospheric troughing patterns. Excessive moisture conditions had opposite responses. Model output from a suite of Regional Climate Models (RCMs) from the North American Regional Climate Change Assessment Program suggests a drier summer climate in the region with likely increases to inter-annual hydro-climatic variability. In addition, preliminary results indicate that those atmospheric circulation patterns associated with extreme dry and wet conditions will continue to occur in the future and in some cases, increase in frequency. Results from this analysis have increased the understanding of historical synoptic-scale controls of hydro-climatic extremes in western Canada and have provided insight into potential future changes to these extremes as driven by changes to key, synoptic-scale atmospheric circulation patterns.

Title: Threshold Responses in Regional Runoff from a Heterogeneous Low Relief Terrain – Western Canada's Boreal Plains

Presenter/First Author: Kevin J Devito, University of Alberta, Edmonton, AB

Presenter/First Author Email: kdevito@ualberta.ca

Co-authors: Kelly J Hokanson, University of Alberta, Edmonton, Canada; Paul Moore, , Hamilton, ON, Canada; Axel Anderson, , , ; Nicholas Kettridge, University of Birmingham, Birmingham, United Kingdom; Carl A Mendoza, University of Alberta, Edmonton, AB, Canada; Richard M Petrone, University of Waterloo, Waterloo, ON, Canada; Uldis Silins, University of Alberta, Edmonton, AB, Canada; James Michael Waddington, McMaster University, Hamilton, ON, Canada

Published Material: European Geosciences UnionGeneral Assembly 2014Vienna | Austria | 27 April – 02 May 2014Not currently under review

Abstract Body: Runoff from larger catchments (>500km) in the continental Boreal Plains (BP) eco-region of western Canada, although low, can range over 2 orders of magnitude (4 to 350 mm/yr) among years and be difficult to predict. This region is experiencing unprecedentedly rapid and large

scale industrial resource extraction. There is a need to assess and understand the dominant controls on the temporal and spatial threshold responses of regional runoff generation to be able to predict and mitigate the potential impacts of land use and effectiveness of reclamation practices on surface water quantity and quality.

The BP climate has a regional moisture deficit (P< PET) and decadal wet and dry cycles. There are dynamic and complex surface and groundwater interactions because the landscape is made up of large Hydrologic Response Areas (HRAs) characterized by heterogeneous deep glacial deposits with different storage and water transmission properties. These HRAs are below a mosaic of surface Hydrological Units (HUs) of deciduous and coniferous forests and wetlands, with some areas having greater than 50% peatland coverage. We examine the interaction among the wetland (peatland) and forest HUs, the HRAs and decadal climate cycles on the threshold response of regional runoff in 30 meso-scale catchments in the BP of Alberta. Annual runoff and efficiency were poorly correlated with annual precipitation, but showed a strong threshold relationship with multi-year cumulative moisture deficit (CMD). Changes in precipitation patterns result in decadal cycles of dry (CMD < -200 mm) and mesic (CMD ~ 0 mm) states, with wet (CMD > 200 mm) states occurring every 2-3 decades. The differing CMD states altered the hydrologic connectivity among different HRAs and HUs within catchments. During dry states, base flow conditions ranged by over an order of magnitude (2 to 80 mm/yr), and increased with percent area of coarse textured HRAs. During mesic conditions, runoff coefficients were positively correlated with percent peatland area. During the infrequent wet states, runoff coefficients were similar among all catchments. Integrating the CMD with the configuration of HUs and HRAs rather than topographic drainage networks appears to better represent water cycling and sink source dynamics controlling runoff in low relief glacial landscapes such as the BP.

Title: State of Flood Forecasting in Canada

Presenter/First Author: Paulin DL Coulibaly, McMaster University, Hamilton, ON

Presenter/First Author Email: couliba@mcmaster.ca

Co-authors: Peter F Rasmussen, University of Manitoba, Winnipeg, MB, Canada; Donald H Burn, Professor, Waterloo, ON, Canada; Alain Pietroniro, Environment Canada Saskatoon, Saskatoon, SK, Canada

Abstract Body: The analysis of the results of two independent nationwide inquiries along with literature review is used to assess the state-of-the-art in flood forecasting in Canadian Provinces and Territories. Flood forecasting falls under provincial jurisdiction and each province has a hydrologic forecasting center tasked with that responsibility. In addition, some municipalities also have their own flood forecasting agencies. Water survey and meteorological services of Environment Canada are the main data providers although some provinces and municipalities maintain local water and weather monitoring stations. Operational flood forecasting is essentially deterministic and based on a single model. There is no common hydrologic model used by the various flood forecasting centers. However, the common needs across provinces are better flood forecasting system, better tools to facilitate data processing, and probabilistic forecasts to apprehend forecast uncertainty. New initiatives on real-time data dissemination by Environment Canada and the development of adaptive flood forecasting systems by a strategic network – FloodNet will help to fill the gaps and enhance flood forecasting and management capacities in Canada.

Title: A Modified Technique for Measuring the Unsaturated Hydraulic Conductivity in Moss and Peat Soils

Presenter/First Author: Colin Patrick Ross McCarter, University of Waterloo, Waterloo,

Presenter/First Author Email: cmccarte@uwaterloo.ca

Co-authors: Scott J Ketcheson, University of Waterloo, Waterloo, ON, Canada; Sarah Scarlett, University of Waterloo, Waterloo, ON, Canada; Pete N Whittington, Brandon University, Brandon, ON, Canada; Jonathan S Price, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Currently, there are two methods for measuring unsaturated hydraulic conductivity (K_{unsat}) in *Sphagnum* mosses: the original method developed by Price et al., (2008) and a modification of this method by McCarter and Price (2014) (herein referred to as the “original” and “modified” methods, respectively). The original method has a soil-water pressure (ψ) gradient across the sample and requires 1-2 days to complete, whereas the modified method maintains a constant ψ within the sample but requires ~3 weeks to parameterize. The concern is that the gradient in original method may result in a distribution of K_{unsat} in the sample that is not represented by the mid-depth pressure. Twenty samples (10 cm diameter, 5 cm height) of horticultural peat were compressed to a target bulk density (0.19 ± 0.01 g cm³). Measurements of K_{unsat} were conducted at ψ = -5, -10, -15, and -25 mb using both the original and modified method. The volumetric soil water content (VWC) was lower (t-test: df = 19, p<0.001) at both -10 and -15 cm using the modified method, while no statistical difference was found (t-test: df = 19, p>0.1) at -5 and -25 cm. However, the K_{unsat} was lower with the modified method at all ψ tested (Wilcoxon signed rank test: V = 210, p<0.001). A general linear model used to elucidate factors controlling K_{unsat} found VWC (p<0.001) and the method (p<0.01) were the only significant relationships; thus, the ψ distribution in the original method was partly driving the difference in K_{unsat}. Although the original method is appropriate for representation of field conditions where a *ψ* gradient is typically imposed, the modified method appears to be representative of the actual K_{unsat} of the sample.

Title: Response of Peatland Ecohydrology to Changing Precipitation Frequencies

Presenter/First Author: Danielle Radu, University of Toronto Mississauga, Mississauga, ON

Presenter/First Author Email: danielle.radu@mail.utoronto.ca

Co-authors: Timothy Peter Duval, University of Toronto Mississauga, Mississauga, ON, Canada

Abstract Body: *Sphagnum* moss, the primary peat-forming vegetation in ombrotrophic peatlands, require sufficient surface moisture for growth and survival. Climate change projections for some regions include more intense but less frequent precipitation events that are predicted to lead to lower water tables and drier surface conditions. Recent studies have highlighted the importance of precipitation in these systems; however, few studies consider how the temporal distribution of rainfall will impact moisture within the moss layer, particularly among different land cover types. As such, the main objective of this study was to investigate the feedbacks between soil moisture, evapotranspiration (ET), and the rates of photosynthesis and respiration of *Sphagnum* moss under varying precipitation frequencies, and in the presence of common vascular vegetation. Soil cores were taken from a pristine Southern Ontario

peatland containing three different plant communities (*Sphagnum*, *Sphagnum* and sedges, *Sphagnum* and ericaceous shrubs) and watered at varying frequencies (3X/week, 1X/week, 0.5X/week) while maintaining a constant total water supply between treatments. To assess the importance of changing precipitation frequencies on the moisture state of *Sphagnum* moss, the vertical distribution of soil moisture and ET rates were measured among the different plant cover types. Preliminary results suggest that precipitation frequency is particularly important for the moisture state of *Sphagnum* in cores with ericaceous shrubs, as higher ET rates led to drier surface conditions than in cores without shrubs. The implications of varying moisture conditions under the three precipitation regimes for rates of photosynthesis and respiration of *Sphagnum* is also discussed. This study highlights the importance of considering the temporal distribution of precipitation when predicting climate change impacts on ecohydrological feedbacks in Northern peatlands, and indicates that this response can vary among different land cover types.

Title: Evaporation from *Sphagnum* monoliths under controlled water table and humidity conditions

Presenter/First Author: Jonathan S Price, University of Waterloo, Waterloo, ON

Presenter/First Author Email: jsprice@uwaterloo.ca

Co-authors: Scott J Ketcheson, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Despite a long interest in characterizing evaporation from bryophytes there remains a poor understanding of the mechanisms of water delivery, and of the rates of loss according to species and setting. We sampled three shallow (25 cm) monoliths (15 cm diameter) each of *Sphagnum fuscum* and *S. rubellum*. Along with an open water "column", the evaporation rate (*E*) from each *Sphagnum* monolith was monitored in an environmental chamber with relative humidity (*RH*) at 80, 50 and 30%, with water table (*wt*) set at 0, 5, 10 and 20 cm below the *Sphagnum* surface for each humidity level. Total *E* over the 65-day period encompassing all *RH* and *wt* levels was the most variable for *S. rubellum*, which ranged from 63 to 128 mm (avg. 100 mm), whereas *E* was between 59 to 98 mm (avg. 76 mm) for *S. fuscum*. Open water evaporation was 89 mm. *E* was far more sensitive to *RH* than *wt*. For example, the variation of $E_{rubellum}$ at different *wt* when *RH* was 30%, was ±0.3 mm/d. In contrast, $E_{rubellum}$ dropped from 2.9 to 0.7 mm/d as *RH* increased from 30 to 80%. The hydraulic properties of *S. rubellum* within a profile and between monoliths was much more variable than in *S. fuscum*. In fact, the variability in *E* in all monoliths was easier to explain on the basis of the hydraulic properties of individual monoliths, rather than by species. *S. rubellum* had higher bulk density than *S. fuscum*, so at a soil matric potential of -30 cm their respective water retentions averaged 0.45 and 0.35. Therefore, with more water in the pores the geometric mean unsaturated hydraulic conductivity across all depths and samples (ψ = -5 to -30 cm) was higher for S. rubellum (1.2e-03 cm/s) compared to *S. fuscum* (and 0.6e-03 cm/s), facilitating more effective water transport in *S. rubellum*, hence higher *E*. While the *E* behavior for given *RH* and *wt* settings was best explained by the monolith's hydraulic properties, a much larger sample size is required to generalize about differences between these two species.

Title: Determining the Impacts of Sub-Surface Irrigation on *Sphagnum* Moss Carbon Uptake in a Reclaimed Peatland

Presenter/First Author: Catherine Brown, University of Waterloo, Waterloo, ON

Presenter/First Author Email: c5brown@uwaterloo.ca

Co-authors: Maria Strack, University of Calgary, Calgary, AB, Canada; Jonathan S Price, University of Waterloo, Waterloo, ON, Canada

Abstract Body: *Sphagnum* biomass production is a feasible and sustainable alternative to current peatland harvesting practices; however, maintaining optimal hydrological conditions for fiber accumulation (i.e. net carbon sequestration) can be challenging, and water requirements remain uncertain. The objectives of the research are to evaluate the efficacy of different sub-surface irrigation techniques on water distribution within *Sphagnum* fiber production plots, and to assess the optimal hydrological conditions for *Sphagnum* biomass accumulation. An abandoned block-cut peatland in Shippagan, New Brunswick, has been manipulated to control the water table in six *Sphagnum* biomass production basins. The hydrology of each basin is controlled by a change in irrigation arrangement or position of the water table (-20cm or -10cm) below the surface. Instantaneous CO_2 fluxes under various light conditions were measured to calculate the gross ecosystem productivity (GEP) of each basin. GEP values were compared to various hydrological variables, such as water table level, soil water tension, and volumetric soil moisture content. Preliminary data suggests that there is a weak relationship between instantaneous water table and carbon flux measurements, but there is a strong relationship between the average seasonal mean water table and productivity values between basins with sub-surface irrigation. The most productive site had an average seasonal water table of -7.8 cm and GEP of -4.1 g C m^{-2} d^{-1}. The two least productive sites were the only basins without sub-surface irrigation, and had average seasonal water table of -14.1 cm and -8.1 cm, and GEP of -3.0 C m^{-2} d^{-1}. and -2.5 C m^{-2} d^{-1}, respectively. The least productive site had a high water table (-8.1 cm), but combined with saturated soil conditions and frequent pooling of water at the surface, could indicate that frequent saturation may decrease productivity, and that sub-surface irrigation is a better method of water management.

Title: Evaluation of snow dynamics in a basin fen-bog complex in the Western Boreal Plains, Canada.

Presenter/First Author: James Sherwood, University of Waterloo, Waterloo, ON

Presenter/First Author Email: jsherwoo@uwaterloo.ca

Co-authors: Scott J Ketcheson, University of Waterloo, Waterloo, ON, Canada; Jonathan S Price, University of Waterloo, Waterloo, ON, Canada

Abstract Body: In the Western Boreal Plains (WBP) region of Northern Alberta, snow represents ~25% of annual precipitation and is, therefore, a potential recharge water source for landforms (e.g. bogs, coarse textured hillslopes) during spring thaw. Influences on snow accumulation and redistribution during winter include canopy openness, tree-stem density and wind fetch. These are not consistent across landform/peatland types in the WBP, where contrasting tree density, size and species may influence accumulation, redistribution and ablation dynamics. Inclusion of snow dynamics is essential for understanding water availability in the sub-humid WBP climate. Few studies focus on snow dynamics in the WBP and distribution of over-winter precipitation stores across upland-peatland systems remains unclear. Snow distribution, ablation, radiative forcings, basin dynamics and controls are quantified for a poor fen-bog complex, situated in an elongated, sloped perimeter basin. Field measurements, taken March-May, 2012-2014, found snow depth lowest in the sparsely treed, open fen, and highest in the densely treed bog and at changes in slope, suggesting wind to be the dominant snow redistribution control.

Increased tree density and height correlated with decreased ablation in the bog-complex. Canopy/stem density decreased wind speeds above the snow pack, making aeolian redistribution negligible. Beyond developing a better understanding of snow dynamics in natural basin-fen systems, it is also of particular relevance to landscape reclamation design, given basin features on post-mined landscapes are targeted as future wetlands.

Title: Evolution of a Saline Fen near Fort McMurray, Alberta: Applications from Paleoecology to Wetland Reclamation

Presenter/First Author: Olena Volik, University of Waterloo, Toronto,

Presenter/First Author Email: volik.olena@gmail.com

Co-authors: Corey Wells, University of Waterloo, Waterloo, ON, Canada; Richard M Petrone, University of Waterloo, Waterloo, ON, Canada; Jonathan S Price, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Wetland reclamation, which is crucial for Canada's oil sands industry, is greatly challenged by salinization. Thus, understanding the origin and development of boreal saline wetlands, the most suitable natural models for potential reclamation pathways, could be of paramount importance for enhancing wetland construction design, providing a basis for setting reclamation targets. Preliminary investigation of the evolution of a saline fen in the Fort McMurray area (56°34'28.84" N, 111°16'38.39" W) confirms the usefulness of paleoecological data for the creation of wetland reclamation strategy. Variations in physicochemical properties and microfossil (pollen, non-pollen palynomorphs, and diatom) assemblages in pond sediment cores demonstrate paleoenvironmental changes associated with the saline fen initiation and its further development. The transition from clay sediments, characterized by low concentration of microfossils, to gyttja indicates that the drainage of large and deep proglacial Lake McMurray preceded the fen establishment. Further detailed studies of primary succession that took place at that time can provide a framework for the transformation of mineral tailings lacking vegetation, into peatlands tolerant of saline conditions. Upcore shifts in microfossil assemblages reflect change in salinity suggesting the existence of periods of higher salinity (recorded by a dominance of brackish diatoms) followed by period of decreased salinity (indicted by a rise in freshwater species) with gradual increases in salinity thereafter. In-depth paleoecological research should help to identify natural drivers of salinity variation that can be used to reduce salinity at contracted wetlands; on the other hand, assessment of temporal changes in ecosystem functioning associated with differences in level of dissolved salts may lead to different reclamation approaches capable of dealing with the higher salinity conditions.

Title: The Hydrological Function and Connectivity of a Basin Fen-Bog Complex in Northeastern Alberta, Canada

Presenter/First Author: Corey Wells, University of Waterloo, Waterloo, ON

Presenter/First Author Email: c2wells@uwaterloo.ca

Co-authors: Scott J Ketcheson, University of Waterloo, Waterloo, ON, Canada; Jonathan S Price, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Within the Western Boreal Plains (WBP) wetlands comprise up to 65% of the landscape, the majority of which are peatlands. However, hydrologic interactions between classes within peatland complexes are not as thoroughly understood and the influences of regional-scale connections beyond the local-scale and over the long-term are required. Accordingly, this research aims to advance our understanding of the hydrological function of peatland classes within a peatland complex and to place this into the context of regional connectivity within the WBP setting. We examined the hydrology of a ~11 ha basin fen-bog complex situated within the Stony Mountain range ~40 km south of Fort McMurray. The low-lying basin depression forms an elongated hourglass-shaped configuration and is bordered by upland slopes. The bog is located at the topographic high within the peatland system and a small mineral upland marks the sharp transition between the bog and fen. Within the fen, peat thickness ranged from >12 m in the lower lobe to ~3 m in the bog. For the entire basin, the peat profile thinned rapidly towards the bordering uplands. Water table levels were typically close to or above the surface for most years and mirrored surface topography along the bog-fen sequence, with ground and surface water flowing from the bog towards the fen for the majority of the season. However, during dry periods, groundwater flow direction temporarily reversed and the water table sloped towards the bog. During precipitation events, the bog water table exhibited a ~12 hour lag in response compared to the water table within the fen. While vertical hydraulic gradients indicated that the basin was a groundwater recharge feature, the rate of recharge was minimal due the low hydraulic conductivity of the surrounding slopes and mineral substrate underlying the peat. The large storage capacity of the upland moss layer was rarely exceeded and shallow groundwater and surface flow was also low. Precipitation totals for the growing season were always well above the regional average and was the dominant input for the basins water balance. This study highlights the hydrologic function and varying interactions that can take place within bog-fen complexes in the subhumid Boreal Plains.

Title: Can an invasive species alter the hydrologic regime of a wet prairie?

Presenter/First Author: Enrique Gomezdelcampo, Bowling Green State Univ, Bowling Green, OH

Presenter/First Author Email: egomezd@bgsu.edu

Co-authors: Katybeth Coode, , Louisville, KY

Published Material: Preliminary analysis of the data was presented in the Ecological Society of America annual meeting in August 2014. These findings are not under review for publication by a scientific journal.

Abstract Body: , which have altered the natural flow making it an unusually variable and artificial system. Groundwater and ditch levels were monitored at six wet prairie restoration sites during three years. Each site consisted of a clustered set of five piezometers positioned on a transect perpendicular to the main ditch. Within each ditch reach, a surface water monitoring location was also set. Of the six sites, two were set as control sites, where the glossy buckthorn was not removed for a period of time. Results show a different response in the groundwater level of the control sites, but only under certain hydrologic conditions. The longer growing season of the buckthorn depressed groundwater levels until the beginning of November during dry years, though not under wet or normal years.

Title: Ice Storm Damage in an Ash- and Maple-Dominated Swamp of Southern Ontario: An Investigation of Precipitation Partitioning

Presenter/First Author: Matthew Malone, University of Toronto, Mississauga,

Presenter/First Author Email: matthew.malone@mail.utoronto.ca

Abstract Body: Interactions between vegetation and the hydrologic cycle are important to investigate for determining the effects of climate change, land-use change, and a growing human population on water resources in and around wetlands. Changes in precipitation (P) regimes (frequency and magnitude) or stand characteristics, such as a loss in canopy due to natural or anthropogenic sources, can all have major influences on the amount water received by a wetland. The hydrological input of throughfall (TF) and stemflow (SF) are especially important to quantify for swamps, as small changes in P have the ability to induce shifts and/or losses of species present within wetland communities. This study presents the investigation of the quantity of TF and SF during P events in two swamps of southern Ontario. With the aid of this research, wetland conservation and management authorities can obtain important information regarding the fluxes of water into swamp ecosystems pre- and post- ice storm. This study was designed to determine the quantity of understory P (as TF and SF) in two mixed-deciduous swamps and how these fluxes differ between the two distinct canopy types as well as to how these fluxes differ between years separated by a major ice-storm. Additionally, an analysis of P characteristics (i.e. amount of P, duration and intensity) was performed to determine how they may dictate TF and SF amounts in the two wetland sites.

TF quantities for the ash-dominated swamp averaged 5-10% higher than TF at the maple-dominated swamp over the course of both growing seasons (2013-2014), while SF was only slightly higher in the ash than maple site. The results indicate that even though there was less rainfall in 2014 than 2013, the amount of TF increased at both sites, suggesting that canopy loss after the ice storm significantly increased TF amounts. Additionally, a positive linear relationship was found between amount of P, duration of rain events and P intensity to both TF and SF depths.

Title: Analysis of Precipitation and Temperature of the Lower Liard River Basin, using Wavelet Transform

Presenter/First Author: Bhaleka Persaud, Wilfrid Laurier University, Waterloo,

Presenter/First Author Email: pers3479@mylaurier.ca

Co-authors: Paul H Whitfield, University of Saskatchewan, Saskatoon, SK, Canada; William L Quinton, Wilfrid Laurier University, Waterloo, ON, Canada

Abstract Body: Since the mid-90s, discharge from streams and rivers draining the discontinuous permafrost zone of the southern Northwest Territories has increased and these rates have accelerated in recent years. Work done by Connon and others suggested two hypotheses; one is related to meteorology and other to landscape changes and feedbacks caused by the permafrost thaw. To address the meteorological hypothesis wavelet transforms of observations were used to explore the dominant oscillations of precipitation and temperature in the Lower Liard River Basin between 2004 and 2014. Wavelets provide information about the nature and time– frequency localization of oscillations. Preliminary results show considerable similarity among individual series from ten climate stations for temperature and for precipitation. As expected, there are differences in the interannual between temperature and precipitation variability; for temperature, there were significant oscillations of about 4, 8, 16 and 256 to 365 days in all stations, for precipitation the significant oscillations were at 16 to 32 days. These results suggest that the temperature signal has a large spatial domain, while the precipitation signal has a smaller spatial domain

Title: Diagnosis of Current and Future Shifting of Hydrological Regimes of the Changing Upper Salween and Mekong River Basins

Presenter/First Author: Suxia Liu, Chinese Academy of Sciences, ,

Presenter/First Author Email: liusx@igsnrr.ac.cn

Co-authors: Wenhao Ding, , , ; Xingguo Mo, Key Laboratory of Water Cylce and Related Land Surface Processes, Institute of Geographical Sciences and Natural Resources Research, Beijing, China; Sheng Wang, , , ; Changming Liu, , , ; Sagar Ratna Bajracharya, ICIMOD, Kathmandu, Nepal; Arun Bhakta Shrestha, , , ; Neera Shrestha Pradhan, , ,

Abstract Body: The upper Salween and Mekong River Basins, flowing parallel from cold mount glacial primitive area to warm cultivation area through Tibet-Yunnan Plateau, is one of the most sensitive areas to global climate change. It is also data scarce. By detail simulation with Vegetation Interface Processes (VIP) model, co-run Hydro-Information Modelling System (HIMS),with detail field investigation to determine parameters, daily water availability and water demand by vegetation are obtained from 1981 to 2012. It is shown that seasonal patterns of discharge within the cold region are more similar to each other than the patterns within the basin. The increasing rate of temperature in the cold region is much higher than that in the warm region. The rate in recent years is much higher than that in previous years. The cold region is drier than the warm region. Over the next 20 or 50 years, there is a tendency that dry cold region will become wetter and wet warm region will be drier. Understanding of and predictive capacity for the dynamics of the twin cold regions processes and systems will be helpful to provide scientific suggestions, such as to local people living in downstream comparatively to adopt suitable and different adaptation countermeasures to possible climate change.

Title: Verification of winter precipitation forecasts and analyses

Presenter/First Author: Michael Schirmer, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: michael.schirmer@usask.ca

Co-authors: Bruce Jamieson, , ,

Published Material: Similar oral presentation on the ISSW 2014 in Banff. Submitted to The Cryosphere and published in The Cryosphere Discussions doi:10.5194/tcd-8-5727-2014

Abstract Body: Numerical Weather Prediction (NWP) models lack verification for mountainous regions during the winter season, although they are providing input for hydrological modelling and for decision makers. Winter precipitation from two NWP models (GEM-LAM and GEM15) and from a precipitation analysis system (CaPA) was verified at approximately 100 stations in the mountains of western Canadian and northwestern US. Instead of rain gauges which have a systematic undercatch for solid precipitation and a rather unknown performance in complex terrain, ultrasonic snow depth sensors and snow pillows were used to observe daily precipitation amounts. Another advantage of these sensor networks are that they are available in relevant elevations in Canada. A detailed objective validation scheme highlights many aspects of forecast quality. Overall, the models underestimated precipitation amounts, although low precipitation categories were overestimated. This is oppositely to former verifications of these models, which were mainly performed in the summer and in flat terrain and/or with rain gauges. The finer resolution model GEM-LAM performed best in all analysed aspects of model performance, while the precipitation analysis system performed worst. An analysis of the economic value of large precipitation categories showed that only mitigation measures with low cost/loss ratios (i.e. measures that can be performed often) will benefit from these NWP models. This means that measures with large associated costs (relative to anticipated losses when the measure is not performed) should not or not primarily depend on forecasted precipitation.

Title: Detecting the effects of atmospheric rivers on glacier mass balance: a case study in Denali National Park, Alaska

Presenter/First Author: Abigail Alice Bradford, University of Maine, Orono, ME

Presenter/First Author Email: abigail.bradford@maine.edu

Co-authors: Seth W Campbell, , , ; Karl J Kreutz, Univ Maine, Orono, ME; Erich C Osterberg, Dartmouth College, Hanover, NH; Cameron P Wake, University of New Hampshire Main Campus, Durham, NH; Douglas Introne, , , ; Robert A Burrows, National Park Service, Denali Park, AK; Denny Capps, Denali National Park, Denali National Park, AK

Published Material: The field work portion of this study was featured in NSF and PBS videos early this fall:http://www.nsf.gov/news/special_reports/science_nation/denaliglaciers.jsphttp://www.pbs.org/newshour/bb/scientists-read-layers-alaskas-ice-snow-track-climate-change/

Abstract Body: An atmospheric river made landfall over Alaska on January 23, 2014. This system advected moisture and heat from the Pacific Ocean east of Hawaii to Alaska over the course of two days causing anomalously high temperatures, heavy rainfall, avalanching, and disruption of human infrastructure. There likely was also rainfall at higher elevations, which would cause a significant change in the mid-winter energy and mass balance of regional glaciers. To investigate whether there is a detectable physical and chemical signature of the atmospheric river event in Central Alaska glaciers, we collected geophysical and geochemical data on the Ruth, Kahiltna, and Mt, Hunter Plateau Glaciers during May-June 2014. High-frequency (400 MHz) ground penetrating radar (GPR) transects over a total of 10 Km were collected on the Ruth Glacier to determine the spatial continuity of an ice layer potentially created by the event. Two snowpits on the Ruth Glacier (1.2 and 3.5 meter depths), one on the Kahiltna Glacier (3 m depth), and one on the Mt. Hunter Plateau (4.05 m depth) were sampled for $\delta^{18}O$ and δD analysis. Based on simple isotope fractionation modeling, we hypothesize that moisture from the atmospheric river event would be isotopically heavy relative to typical mid-winter precipitation in the area. We observe a positive $\delta^{18}O$ deviation in the Mt. Hunter and eastern Ruth Amphitheater snowpits at 3-3.5 meter depth, which given estimated snow accumulation rates may be consistent with the river event. We will discuss ongoing statistical comparison of snowpit physical and isotope data, processing and interpretation of the GPR data, and detailed time-series analysis of the river event using climate reanalysis and station data.

Title: Regional monitoring and online publication of winter snowpack to spring and summer water levels by integrating satellite and aerial remote sensing data

Presenter/First Author: Chris Hopkinson, University of Lethbridge, Lethbridge, AB

Presenter/First Author Email: c.hopkinson@uleth.ca

Co-authors: Brian Brisco, Natural Resources Canada, Ottawa, ON, Canada; Shane Patterson, Government of Alberta, Edmonton, AB, Canada

Published Material: Initial results of the open water classification routine were presented at 2014 Fall AGU (poster) but not the snowpack or portal components. Approx 25% of the presentation material will be recycled. None of this work has been otherwise published or submitted for review.

Abstract Body: The ability to map and monitor headwater snowpacks, and downstream spring and summertime open water storage at regional scales allows improved estimates and simulation of watershed water balance and flood inundation potential. The study presents early development stages of an online Provincial monitoring framework for snowpack and wetland open water storage. Winter snowpack assessments in mountainous catchments in the Rockies, urban and wetland environments in Alberta will be presented for 2013 to 2015, as will summertime open water classifications for a prairie watershed in Alberta, western Canada. Airborne lidar data were used to map baseline and snow surface data in headwaters while temporal satellite image stacks from the RapidEye and RadarSat satellites were integrated with high-resolution lidar to delineate water inundation extents. GIS techniques were developed to extract lidar-derived water surface elevations and track the spatio-temporal variation in pond and lake levels. Water bodies were assigned unique identifiers so that levels could be tracked and linked to their associated watershed channel reach. The procedure of optical image classification through to merging of individual water bodies into watershed channel topology and extracting reach water levels has been automated with python scripts. The presentation will describe the methods, early results, existing challenges, as well as the anticipated online delivery of this Alberta cloud-based water monitoring portal. Future efforts will be directed towards integration of the cloud-based system with existing provincial and federal hydrometric data sources and models to supplement operational resource management needs whilst supporting more rapid and open access to data.

Title: Hazard Assessment of Glacial Lake Outburst Flood and Potential of ICTs for Coping: A Case of Eastern Himalaya of Nepal

Presenter/First Author: Dilli RAM Bhattarai, Tribhuvan University, Kathmandu,

Presenter/First Author Email: bhattarai.dilli@gmail.com

Abstract Body: Retreat of glaciers and formation of glacial lakes in Nepal Himalaya have been reported to be related with the temperature rise in the region. Glacier Lake Outburst Floods (GLOF) are the growing climate induced hazards in the Himalaya. GLOF has increased the vulnerability of community and fragile ecosystem in the mountain valleys. This study has analyzed the potential impacts from GLOF in the highland of eastern Nepal and the potential role of Information Communication Technologies (ICT) to cope with such impacts. I analyzed the trend of climatic pattern (temperature and precipitation) of the Eastern Himalaya Region of Nepal available from the Department of Hydrology and Meteorology, Government of Nepal, and prepared the latest location map of the glacial lakes using google earth and ArcGIS applications in the highland of the Kanchanjungha Conservation Area of the region. Tiptala glacial lake, located at an elevation of 4950 m, within the conservation area, was selected for the GLOF hazard assessment. I used semi-structured questionnaire survey and key informants' interviews in the community in order to assess the potential hazard of GLOF. With the varying sizes, 46 glacial lakes were located in the region, which covers over 2.57 sq. km in

total. Though the larger portion of the downstream area of the Tiptala glacial lake fall in the remote location away from major residential area, few villages, major pasture lands for Yaks, foot trails, and several bridges across the Tamor River below the lake are in risk of GLOF. Poor access due to extreme geographical remoteness and capacity to afford the modern technologies in the community are the major limiting factor to the knowledge and information about the climate change and related impacts. Modern ICTs has high potential to reduce the risk of climate related hazards in the remote area by information dissemination and awareness.

Title: MASS BALANCE MEASUREMENT OF RIKHA SAMBA GLACIER, HIDDEN VALLEY, MUSTANG, NEPAL

Presenter/First Author: Bikas Chandra Bhattarai, Kathmandu University, Kavre,

Presenter/First Author Email: bikasc.bhattarai@ku.edu.np

Co-authors: Rijan B Kayastha, Kathmandu University, Dhulikhel, Kavre, Nepal; Sanjay Gurung, , , ; Sharad Joshi, International Center for Integrated Mountain Development, Kathmandu, Nepal; Dorothea Stumm, ICIMOD, Kathmandu, Nepal; Pradeep Mool, , ,

Abstract Body: Various studies suggest that most of the Himalayan glaciers are retreating though the rate of retreat varies from glacier to glacier, depending upon the terrain and climatological condition. Relation between climatic and mass balance studies remains unclear and almost nonexistent in this region. In this study, climatic and net mass balance analysis was performed using in situ measurements of stakes and meteorological parameters in Rikha Samba Glacier, Hidden Valley. Stake measurements are taken at two separate periods. Long-term temperature and precipitation trend are calculated by using the data recorded at Jomsom. The glacier shows net mass balance of -1.80 ± 0.097 m w.e. for the lower part of the glacier below 5800 m altitude from 10 September 2011 to 3 October 2012 and - 0.206 ± 0.019 m w.e. for the entire glacier from 4 October 2012 to 30 September 2013. The equilibrium line altitude (ELA) of Rikha Samba Glacier is estimated at 5800 m a.s.l. in 2013. Average temperature trend of 0.023 °C/yr at 5% level of significance is observed from 1980 to 2012 with no significant trend in precipitation in that period.

Title: Evaluation of SMOS Frozen Ground Flags

Presenter/First Author: Tracy L Rowlandson, University of Guelph, Guelph, ON

Presenter/First Author Email: trowland@uoguelph.ca

Co-authors: Melanie Dawn Chabot, University of Guelph, Guelph, ON, Canada; Aaron A Berg, University of Guelph, Guelph, ON, Canada

Abstract Body: The Soil Moisture Ocean Salinity (SMOS) L2 soil moisture product is provided with science flags to indicate the reliability of the soil moisture estimates based on the surface conditions which may impede the ability to accurately estimate the soil moisture for a region. During periods of soil freezing, the soil dielectric decreases as the water in the soil freezes, resulting in an increase in measured brightness temperature by passive microwave sensors. Inaccurate estimates of frozen soil conditions could result in an assumption that there is a decrease in soil moisture. SMOS uses modelled data from the European Centre for Medium-Range Weather Forecasts (ECMWF) soil temperature level 1 (0-7cm) (STL1) depth as a flag for frozen soil conditions. The flag is set when the STL1 indicates a temperature below 270K. These flags were evaluated against data collected at the Kenaston soil moisture network, south of Saskatoon, Saskatchewan. For this analysis, data were collected during 2012, with data used from January to April, 2012 to monitor the spring thaw, and data from October to December 2012 to monitor the winter freeze. Flags were examined for both ascending and descending SMOS pass times. It was found that there was greater agreement between the in-situ probe installed horizontally that 5cm than the vertically installed probe (which provides soil surface temperature) with greater agreement occurring for descending passes. When using the threshold of 270K to indicate frozen soil conditions (as is used for the SMOS frozen ground flag), the SMOS flag indicated a false positive (SMOS flag indicates thawed soils when the network indicates frozen) rate of 32.9% for ascending passes (compared to the 5cm sensor) and 18.8% for descending passes. If the threshold were increased to 273.15K, the false negative rate would be reduced considerably, to 15% for ascending passes and 2.8% for descending passes.

Title: Preliminary study of stable isotope in Chhota Shigri glacier (H.P) India

Presenter: AL Ramanathan, Jawaharlal Nehru University, New Delhi,

Presenter Email: alrjnu@gmail.com

First Author: Naveen Kumar, Kathmandu University, New Delhi,

First Author Email: naveen86pandey@gmail.com

First Author Student?: No

Abstract Body: To infer the variation in isotopic composition, stable – water isotope data ($\delta^{18}O$ and δD) from five groups of samples (Fresh snow, old snow, snow core, rain water and melt water samples) collected from Chhota Shigri glacier during summer (2013) were presented. Snow core sample traces the variation of $\delta^{18}O$ with depth. Fresh snow, old snow and melt water collected at different altitude has been focused to explore the altitudinal effect on isotopic composition of these samples. Altitude effect on the variation of isotopic composition is best marked by fresh and old snow while melt water did not encounter such effect. Different pattern of $\delta^{18}O$ variation is observed with altitude for the fresh and old snow. Different trend in the depletion of $\delta^{18}O$ of fresh snow and old snow with altitude shows clear demarcation of changes for winter and summer snow

fall. This study shows that large variation of d-excess (-1.14‰ to 24.9‰) of all rain water events reflects the influence of local climatic factors as well as south-west monsoon precipitation. Deuterium excess (d-excess) value (1.92‰ to 7.41‰) of fresh snow confirms influence of south-west monsoonal precipitation. Linear regression analysis was applied to stable hydrogen and oxygen isotope data sets for snow core, precipitation and melt water samples in order to establish the local meteoric water line (LMWL) for Chhota Shigri glacier (HP) India. The LMWL was derived with a regression value of 0.99. The LMWL shows an equation $\delta D = 8.5\ \delta^{18}O+12.9$.

Title: Measurement and modeling of the surface conductance of boreal aspen and black spruce stands

Presenter/First Author: Jilmarie Stephens, The University of British Columbia, Vancouver,

Presenter/First Author Email: jilmariestephens@gmail.com

Co-authors: Thomas A Black, University of British Columbia, Vancouver, BC, Canada; Nicholas Grant, University of British Columbia, Vancouver, BC, Canada; Zoran Nesic, University of British Columbia, Vancouver, BC, Canada; Alan Barr, Environment Canada, Saskatoon, SK, Canada

Abstract Body: Boreal forest accounts for 30% of the Canadian landscape and plays an important role in the global water and carbon cycles. How these processes will change with respect to climatic variability is poorly understood. Our goal is to improve our understanding of the integrated system response of the southern boreal forest to variation in climate. Continuous measurements have been made since 1996 at Old Aspen (OA) and 1999 at both Old Black Spruce (OBS) as part of the Boreal Ecosystem Research and Monitoring Sites (BERMS) program and Fluxnet Canada/Canadian Carbon Program. In addition to climate variables, we have high-quality year-round eddy-covariance measurements of evapotranspiration (*E*), and related micrometeorological fluxes of momentum, sensible heat, and CO_2. From 1996 to 2013, *E* at OA and OBS has ranged from 264 mm y^{-1} to 450 mm y^{-1} and 271 mm y^{-1} to 331 mm y^{-1}, respectively. The lower average *E* at OBS has resulted in a significantly higher contribution to groundwater (i.e., precipitation (*P*) - *E*), especially over the 10 years after the drought that occurred in 2001-2003. During the drought years the difference between the sites was much greater, with mostly negative *P - E* values at OA. As part of research to improve models of forest *E,* data analysis is under way to compare two surface conductance models. Variations in the conductance are evaluated through comparisons of the models' controlling variables on the conductance, such as photosynthetically active radiation, vapour pressure deficit, CO_2 concentration, soil water matric potential and leaf are index. The relationship between the controlling variables and conductance is being monitored for changes over the long term, including drought and wet periods. This research contributes to improving the parameterization of hydrologic processes in land surface models such as CTEM and CLASS.

Title: Towards running a physically-based snow model for near real time operational water forecasts

Presenter/First Author: Scott Havens, USDA Agriculture Research Serv, Boise, ID

Presenter/First Author Email: scotthavens@u.boisestate.edu

Co-authors: Adam H Winstral, WSL Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland; Danny G Marks, USDA-ARS Boise, Boise, ID; Patrick R Kormos, USDA Agricultural Research Service, Boise, ID; Andrew R Hedrick, Agricultural Research Service Boise, Boise, ID

Abstract Body: Traditional operational modeling tools for forecasting water inflow to reservoirs are challenged by more frequently occurring uncharacteristic flow patterns caused from climate change. To tackle these uncharacteristic events that do not follow historical patterns, water managers must turn to new models based on the physically based, energy balance modeling techniques. Currently, the USDA-ARS produces near real time snow water equivalent (SWE) maps using *Isnobal* for two mountain basins, the Boise River Basin in southwest Idaho and the Tuolumne Basin in California that feeds the Hetch Hetchy reservoir. However, both basins have minimal weather data from automatic weather stations, making model input and model validation difficult. This presentation will examine how *Isnobal*, coupled to a water routing model, has performed over the past three years of near real time water forecasting. Input data to drive the modeling in these data sparse areas will be derived from the sparse weather station network and high resolution weather forecast models, providing new distributed forcing data for modeling.

Title: Streamflow Response During Rapid Retreat of a Lake-Calving Mountain Glacier

Presenter/First Author: Alexis Moyer, University of British Columbia, Vancouver, BC

Presenter/First Author Email: moyeal03@gmail.com

Co-authors: Robert Dan Moore, University of British Columbia, Vancouver, BC, Canada; Michele N Koppes, University of British Columbia, Vancouver, BC, Canada

Abstract Body: There has been increasing attention over the last decade to the potential effects of recent and projected future glacier retreat on downstream discharge and aquatic habitat. Of particular interest is the timing of "peak water," the time at which the reduction in ice area associated with retreat begins to offset the increased rate of ice melt associated with climatic warming. This study examines the streamflow variability downstream of Bridge Glacier, located in the southern Coast Mountains in British Columbia. The glacier currently terminates in and calves icebergs into a proglacial lake, and has been retreating rapidly since 1991, when the terminus retreated into an overdeepened basin. The glacier's area has decreased from 92 km^2 in the early 1990s to 81 km^2in 2013. Despite this decrease in area, there has not been any clear reduction in late-summer streamflow. The objective of this study was to diagnose the relative contributions of snowmelt, ice melt, and off-glacier runoff to streamflow. Snow and ice melt were estimated using a semi-distributed melt model, supported by snow-covered area determined from MODIS imagery and the area of the glacier as determined from Landsat imagery. Surface melting from icebergs was computed using a melt model and the area of the lake surface occupied by icebergs, as determined by linear spectral unmixing of Landsat and MODIS imagery. Sub-aqueous iceberg melt was estimated by assuming that net radiation received by the portion of the lake occupied by icebergs was consumed by sub-aqueous melt rather than heating of the water column, based on results of fieldwork conducted in 2013. Rainfall-runoff from both glacierized and non-glacial portions of the catchment were estimated using a semi-distributed hydrologic model. The results from this study contribute to our understanding of streamflow response for retreating valley glaciers, many of which will likely experience a transient lake-terminating phase as the terminus retreats into over-deepened basins.

Title: Towards a large scale modelling of wetlands water dynamics in northern basins.

Presenter/First Author: Vanessa Pedinotti, , Toulouse,

Presenter/First Author Email: vanessa.pedinotti@gmail.com

Co-authors: Gonzalo Sapriza, University of Saskatchewan, Saskatoon, SK, Canada; Lindsay Stone, Wilfrid Laurier University, Waterloo, ON, Canada; Bruce Davison, Environment Canada, Saskatoon, SK, Canada; Alain Pietroniro, Environment Canada Saskatoon, Saskatoon, SK, Canada; William L Quinton, Wilfrid Laurier University, Waterloo, ON, Canada; Christopher Spence, Environment Canada Saskatoon, Saskatoon, SK, Canada; Howard S. Wheater, University of Saskatchewan, Saskatoon, SK, Canada

Abstract Body: Understanding the hydrological behaviour of low topography, wetland-dominated sub-arctic areas is one major issue towards the improvement of large scale hydrological models. These damp organic soils cover a large extent of Northern America and have a considerable impact on the rainfall-runoff response of a catchment. Moreover their strong interactions with the lower atmosphere and the carbon cycle make of these areas a noteworthy component of the regional climate system. In the framework of the Changing Cold Regions Network (CCRN), this study aims at providing a model for wetland water dynamics that can be used for large scale applications. The modelling system is made of two main components : a) the simulation of surface runoff using the Modélisation Environmentale Communautaire – Surface and Hydrology (MESH) land surface model driven with several gridded atmospheric datasets and b) the routing of surface runoff using the WATROUTE channel scheme. As a preliminary study, we focus on two small representative study basins in Northern Canada : Scotty Creek in the lower Liard River valley of the Northwest Territories and Baker Creek which is located just a few kilometers north of Yellowknife. Both areas present characteristic landscapes dominated by a series of peat plateaus, channel fens, small lakes and bogs. The challenge of the wetland model is to represent the hydrological functioning of these different types of landscape units and their interactions using rather simple numerical formulations that can be later extended to larger basins such as the Mackenzie river basin. The performance of the model will be assessed using in-situ discharge datasets.

Title: Trends and Projections for North American Lake Ice

Presenter/First Author: Laura Brown, University of Toronto, Toronto, ON

Presenter/First Author Email: lc.brown@utoronto.ca

Co-authors: Claude R Duguay, University of Waterloo, Waterloo, ON, Canada

Abstract Body: Lakes comprise a large portion of the surface cover in North America forming an important part of the cryosphere. Recent studies have demonstrated that ice break-up dates, in particular, have been occurring earlier in many parts of the Northern Hemisphere over the last 50 years in response to warmer climatic conditions in the winter and spring seasons. The timing of lake ice phenological events (e.g. break-up/freeze-up) are useful indicators of climate variability and change. The Canadian Lake Ice Model (CLIMo) was used to simulate the contemporary and future lake ice conditions for the northern hemisphere, with a focus on North America. The contemporary climate simulations were driven by both ECMWF ERA-Interim and ERA-40 reanalysis data, while the future climate simulations were driven by the Canadian Regional Climate Model (CRCM5, provided by UQAM) and the CCCma Canadian Regional Climate Model (CanRCM4: CORDEX domain Nam-22, 1951-2100) with the RCP 4.5 and 8.5 emission scenario for the future climate conditions. The simulations were run for multiple lake depths to represent both shallow and deep lakes, and with and without snow cover to represent the effects of snow redistribution over the ice surface. The 30-year mean ice break-up, freeze-up, and thickness was compared between the scenarios for Canada for 1981 – 2010 and 2071 – 2100 to examine the possible changes to the ice cover regimes. Additionally, comparisons between the simulations and available in situ data for the contemporary climate were explored at selected locations. This work will examine the preliminary results from the modelled North American lake ice dataset under present day climate and projected future conditions.

Title: Assessing the Sensitivity of the Soil Moisture and Ocean Salinity (SMOS) Observed Brightness Temperature for Soil Freeze- Thaw Detection during Wet Snow Conditions

Presenter/First Author: Matthew Williamson, University of Guelph, Guelph,

Presenter/First Author Email: williamm@uoguelph.ca

Co-authors: Tracy L Rowlandson, University of Guelph, Guelph, ON, Canada; Jaison Thomas Ambadan, University of Guelph, Guelph, ON, Canada; Aaron A Berg, University of Guelph, Guelph, ON, Canada; Warren Helgason, University of Saskatchewan, Saskatoon, SK, Canada

Abstract Body: The soil freeze-thaw cycle imparts a major control on the seasonal hydrology of cold regions. Understanding the soil freezing state is critical to accurately estimating runoff rates, water storage and predicting spring flooding. One of the most promising techniques for monitoring frozen soils is passive microwave remote sensing. Passive microwave satellites, like the Soil Moisture and Ocean Salinity (SMOS) satellite, offers the ability to capture the landscape soil freeze/thaw state. This L-band satellite is sensitive to the changes in the landscape dielectric which dramatically decrease from thawed to frozen state. Though it is widely accepted that L-band passive microwave satellites are sensitive to frozen soils, literature has indicated that the sensitivity may be hindered during wet snow conditions. This study was conducted during the winters of 2012 and 2013 in southern Saskatchewan. The study site, Environment Canada's Brightwater Creek Soil Moisture Network, is densely instrumented with 22 soil moisture stations over a 10x10km grid. The ability of the SMOS satellite to detect frozen soils was initially accessed by comparing passes with frozen and thawed soil. The results indicated that brightness temperature during frozen soil conditions was significantly ($p<0.05$) different from thawed soil. Following this comparison, periods with frozen soil and either wet or dry snow conditions were analyzed, using air temperature and snow albedo as an indicator of wet/dry snow conditions. The study found that the brightness temperature during wet and dry snow conditions was not significantly different ($p>0.05$). Polarization index was also examined, and it too indicated a significant difference between frozen and thawed soils but no significant difference during wet and dry snow conditions. These results suggest that L-band passive satellites like SMOS may be less sensitive to snow conditions in this region.

Title: On Conceptualization and Routing Dynamics of a Glacierized Catchment

Presenter/First Author: Anna Chesnokova, Ecole de Technologie Superieure, Montreal, QC

Presenter/First Author Email: chesnokovaanna@gmail.com

Co-authors: Francesca Pellicciotti, ETH Zurich, Zurich, Switzerland; Marco Carenzo, ETH Swiss Federal Institute of Technology Zurich, Zurich, Switzerland

Published Material: This study was partly presented before during poster session of Alpine Glaciological Meeting, Innsbruck, February 2014.

Abstract Body: Assuming that glaciers can be represented as linear reservoirs that transform surface melt into runoff, we investigate their dynamic behaviour by rewriting the differential equation of linear reservoirs to derive the storage coefficients (Ks) from input and outputs to the reservoir system. We use hourly ablation rates simulated by a distributed energy balance model (input) and hourly runoff at the glacier snout (outputs) and study the system characteristics derived from the linear proportionality between the time derivative of runoff and the difference between input and output. We derive the storage coefficients from the relationship between measured runoff and known inputs to the system and investigate their seasonal and interannual variability. We compare the resulted Ks with those obtained from time series analysis. We use data from three ablation seasons with different characteristics (extensive snow cover throughout the ablation season in 2001, limited/absent snow cover in 2006 and a 'middle case' in 2010) from Haut Glacier d'Arolla, Switzerland. Storage coefficients exhibit a similar general pattern of decline over time with local peaks corresponding to snowfall events with higher absolute values for the season with extensive snowcover and lower for the season with limited snowcover. Given the observed temporal evolution in storage characteristics, we modify the conventional reservoir approach in two ways. In the first type of models, we explore multiple reservoirs (from 1 to 5) with constant in time constant storage characteristics, while in the second approach we use one reservoir with varying in time storage coefficients, parameterised as a function of snow covered fraction or of the snowpack water equivalent (SWE). In the first category, models that separate the contribution of snowmelt from the glacierised area from that over the non-glacierised areas perform better, especially when applied to season with limited snowcover. In the second category, models based on SWE of the snowpack have a higher performance.

Title: Recent changes in glaciers within the upper Yukon River basin and their contribution to discharge at Whitehorse

Presenter/First Author: Chris Michael DeBeer, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: chris.debeer@usask.ca

Co-authors: Jeffrey L Kavanaugh, , , ; Sarah C Laxton, , Whitehorse, YT, Canada

Abstract Body: Glaciers represent a significant source of stored water, and meltwater released during the spring through fall period provides runoff that can be regionally important. In the headwaters of the Yukon River above Whitehorse, YT, there is uncertainty on how much glaciers contribute to total discharge and how this will change in future under different scenarios of climate change. To begin to address these issues, we examined changes in glacier cover here based on remotely sensed imagery from various periods between 1948 and 2010, and estimated the current glacier volume by applying a volume–area scaling approach with locally derived parameters based on ice-thickness data collected in 2011. Glaciers in 2010 covered an area of 1002 km^2 and had an estimated total volume of 187 km^3; between ~1990–2010 glacier cover declined by about 6% overall, while some individual glaciers lost over 25% or more of their area. We set up the HBV-EC hydrological model over the upper Yukon River basin and some smaller tributary basins using the Green Kenue software tool, and forced the model using extrapolated observations from nearby climatic stations. The model was able to reliably reproduce the magnitude and timing of river discharge along with local snow accumulation, melt, and glacier mass balance. By separating glacial and non-glacial sources of simulated runoff, we estimated that snow and ice melt from glaciers has supplied an average of about 20% of the annual flow volume of the Yukon River above Whitehorse in recent decades, with 30% of this as a result of the net mass loss (i.e. wastage) of glaciers. The model also indicates that the region's largest glacier, the Llewellyn Glacier (433 km^2), was the single most significant contributor of glacially-sourced water, highlighting the importance of this ice mass. Further work will consider future climate scenarios and glacier dynamic modelling to project impacts into the remainder of the 21st century.

Title: Spatial Variability of Snowmelt Rates at Scotty Creek, NWT

Presenter/First Author: Emily Haughton, Wilfrid Laurier University, Barrie,

Presenter/First Author Email: haug6220@mylaurier.ca

Co-authors: William L Quinton, Wilfrid Laurier University, Waterloo, ON, Canada; Oliver Sonnentag, University of Montreal, Montreal, QC, Canada

Abstract Body: At high latitudes, snow has a significant influence on hydrological and atmospheric processes. Portions of these regions are dominated by evergreen coniferous forests which affect energy and mass exchanges between the atmosphere and the land surface. Beneath a forest canopy, energy budget dynamics are strongly influenced by the large spatial variability of radiative and turbulent fluxes. The spatial variation of shortwave irradiance to snow is important to quantify as it can affect the depletion of snow covered area and areal melt rates. Currently, the magnitude of this variation has been sparsely quantified by field measurements during melt and hence, limits the physical basis with which spatial distributions of melt can be estimated. This study was conducted in the high-Boreal zone of discontinuous permafrost at Scotty Creek, NWT for the purpose of addressing these discrepancies. The specific objectives were to 1) compute the snowmelt energy balance in a high-latitude forested environment; and 2) determine the relative importance of the energy balance terms with respect to controlling the spatial distribution of melt energy and partitioning of radiative and turbulent fluxes. Point measurements of snowmelt were used in combination with aerial remote sensing, including high-resolution LiDAR, and the Cold Regions Hydrological Model to examine the spatial distribution of snowmelt rates. Preliminarily analysis suggests that under most circumstances, net radiation provides the majority of melt energy below the tree canopy.

In subarctic peatlands permafrost is found under peat plateaus, while fens and flat bogs remain permafrost free, thus creating heat source. In stable environment permafrost and permafrost free terrain are in thermal equilibrium, which is affected just by climatic fluctuations. At the same time, surface disturbance may initiate anomalous heat flow. In case of linear disturbance over peat plateaus, such as seismic lines, this flow is narrowly directed along the borders of the seismic line accelerating permafrost thaw. The objectives of this study was to assess the influence of the year round unfrozen water body (*i.e.* channel fen and flat bogs) on frozen peat plateau disturbed by seismic line, which was cut in winter 1985. The findings suggest that the presence of such heat source, such as channel fen and flat bog, in close proximity of the disturbed permafrost terrain has a profound effect on temperature distribution along the linear disturbance, causing accelerated thaw from the top as well as from the bottom of permafrost. The heat flux is coupled with mass flux and can be observed all year round, being on its peak during summer months.

The study was conducted in the Scotty Creek basin (at 61.31N and 121.30W), approximately 60 km SE from Fort Simpson, North West Territories. A number of geophysical surveys were performed to delineate permafrost, peat and mineral soil borders. Temperature and water level observations were carried out throughout two years period in order to understand the influence of heat storage on the temperature distribution along the seismic line and consecutive permafrost degradation.

Title: Statistical and analytical approach for stream-aquifer interaction in the lower Nakdong River basin, Korea

Presenter/First Author: Yun-Yeong Oh, Pusan National University, Busan,

Presenter/First Author Email: magojina@naver.com

Co-authors: Se-Yeong Hamm, Pusan National University, Busan, South Korea; Gyoo-Bum Kim, K-water Institute, KWATER, Daejeon, South Korea; Chung-Mo Lee, , , ; Ming Liang Wei, , ,

Abstract Body: Stream water (SW)-groundwater (GW) interaction demonstrated seasonal and areal changes in the vicinity of the upstream of the Changnyeong–Haman river barrage due to the construction of the river barrage. Statistical and analytical approaches examined the relationship of the stream water level (WL_S)–groundwater level (WL_G) and the electrical conductivity of GW (EC_G)–electrical conductivity of SW (EC_S) in the river barrage area of the lower Nakdong River basin from June 2011 until September 2014. The response time change of the SW-GW interaction by using the cross-correlation function (CCF) was verified by 1D unit step rise flood wave response model considering river resistance (R). The optimal value of the aquifer diffusivity (α) was obtained by pumping test analysis. The simulated groundwater levels were compared with the observed levels for verification. By the result of the statistical methods, the SWL-GWL and EC_S-EC_G response time showed an increase while CCF showed a decrease since the construction of the river barrage. Also, maximum CCF fairly well corresponded to the α of 5000 m^2/hour and R of 750-8000 m in analytical model. The values of R in observation well which distance of 500 m away from the stream has estimated to 1450 m (2011), 1000 m (2012), 750 m (2013), and 8000 m (2014), respectively. This result shows that the long-term operation of the river barrage can lead to weakening of the hydrologic stress propagation on the aquifer by decreasing of stream water level fluctuation and increasing of clogging on the bottom and walls of the stream-aquifer boundary.

KEY WORDS: Stream water–groundwater interaction, groundwater level, groundwater electrical conductivity, cross-correlation function, flood wave response model, hydrologic stress propagation.

Title: Estimating Groundwater Inflows to Small Streams Using ^{222}Rn and Argon

Presenter/First Author: Floriane Moreira, GEOTOP-UQAM, Montréal,

Presenter/First Author Email: moreira.floriane@gmail.com

Co-authors: Marie Larocque, Univ du Quebec - Montreal, Dorval, QC, Canada; Daniele Luigi Pinti, University of Quebec at Montreal UQAM, Montreal, QC, Canada

Abstract Body: Radon is a radiogenic isotope derived from the disintegration of ^{238}U. Dramatic loss of ^{222}Rn is produced when groundwater is discharged into rivers, where it rapidly degasses to the atmosphere. By measuring ^{222}Rn in the aquifer and in the river, it is possible to simulate groundwater-river exchanges if the radon degassing rate (a function of river width, depth and turbulence). Argon is a noble gas which is present in rivers in equilibrium with the atmospheric concentration. Performing argon tracing in the river could provide an estimate of its degassing rate to be used as a proxy for the ^{222}Rn degassing rate. The objective of this work was to quantify exchanges between groundwater and small rivers using the noble gases argon and radon as tracers of groundwater discharge processes. ^{222}Rn activities in groundwater and river water was analyzed during the 2013 and 2014 summers in two watersheds from the Centre-du-Québec and Vaudreuil-Soulanges regions of southern Quebec (Canada), i.e. the upper Nicolet River and the Raquette River respectively. Sampling in 2013 was dedicated to collect 130 groundwater samples. In 2014, the sampling focused on measuring ^{222}Rn in the two rivers. Groundwater ^{222}Rn activities show a relation with the local geology. Groundwater from the metasedimentary rocks of the Appalachians and in Grenvillian age magmatic rocks of Mount Rigaud show ^{222}Rn activities between 40 and 400 Bq/L while groundwater from the St. Lawrence Platform shows ^{222}Rn activities from 3 to 30 Bq/L. In the river, concentrations in ^{222}Rn are between 0.1 and 4 Bq/L. Localized groundwater inflows to the two rivers are shown by peaks of ^{222}Rn activities but exchanged flowrates need to be confirmed with a field-measured estimate of degassing rates Tests are currently under way to perform a laboratory-scale continuous argon injection that will help identify the required conditions for field-scale injections to be performed next summer

Title: The Effect of Mine Dewatering and Peatland Form on the Pattern of Surface Recharge Around the Victor Diamond Mine, James Bay Lowlands

Presenter: Jonathan S Price, University of Waterloo, Waterloo, ON

Presenter Email: jsprice@uwaterloo.ca

First Author: Mazda Kompanizare, University of Waterloo, Waterloo,

Abstract Body: The Victor diamond mine requires substantial aquifer dewatering and depressurization of the limestone bedrock to keep the mine pit dry. Located in the James Bay Lowland, the dewatering has affected the pattern and rate of surface recharge through the peatlands that cover >90% of the area. The area is typified with domed bogs and fen water tracks; the fens act as the conveyors of water and connect with active stream. The surface recharge rate in the modelled watershed was simulated using HYDRUS 3D for the period of Jan 2005 to Dec 2012 (dewatering began Jan 2007), with two periods of two and six years in steady and unsteady state, respectively. The model was calibrated by using the daily water level in 20 observation wells, as well as observed total surface outflow and recharge of mine process water into the central quarry. The flow domain is 106 km² and extends to a depth of 300 m with 13 layers. The results shows that in pre-mining and mining conditions about 50,000 m3/day of water recharged through the surface mostly through the bogs that are the inter-fluvial areas between water tracks; the shallow peat along the fen water tracks conveyed most of this water out of the system as horizontal shallow surface and sub-surface flow. At the end of the simulated period for the mining condition (Dec 2012) when the dewatering rate approached 86,000 m3/day, ~ 25% of this water was derived from a 2-3 km radius around the mine. The model suggests recharge here was intensified because of a locally thinner or absent low permeability claystone layer (elsewhere ~50 m below the surface, separating upper and lower bedrock aquifers) and a thinner marine sediment layer. Simulation revealed that surface outflow along the fen water-tracks and dewatering of the mine are the two main components that control the surface recharge rates across the domain.

Title: Surface-subsurface flow analysis of the Raquette River watershed (Vaudreuil-Soulanges, Quebec, Canada)

Presenter/First Author: Félix Turgeon, University of Quebec at Montreal UQAM, Montréal,

Presenter/First Author Email: turgeon.fel@gmail.com

Co-authors: Marie Larocque, Univ du Quebec - Montreal, Dorval, QC, Canada; Sarah Dorner, Université de Montréal, Montréal, Canada

Abstract Body: Located 50 km west of Montreal (Quebec, Canada), the Raquette River watershed covers an area of 133 km² and its main river is 34 km long. Groundwater resources are under pressure in this region, notably due to an important population increase in the past decades. These changes are expected to impact the hydrology of the entire watershed. The main objective of this research was to evaluate the relative contribution of surface and subsurface flow to the Raquette River using field data and the fully-coupled MikeSHE model. Upstream, the river flows through an agricultural zone on a thick clay deposit, where drained soils cover a sandy aquifer in a major bedrock depression. Towards its center, the river flows over the bedrock between Mount Rigaud and the Sainte-Marthe Hill (in the Sainte-Marthe channel). The river flows downstream over clay deposits and then over fluvioglacial sandy deposits towards the Ottawa River. Groundwater recharge is limited to Mount Rigaud and the Sainte-Marthe Hill. Low-flow measurements have shown that the main groundwater contribution to the river takes place on a 3 km long segment located in the Sainte-Marthe channel, where the river gains 35% of the flow measured at the outlet. The fully-coupled model is built with 10 layers and 165 870 cells (100 m x 100 m) and is run with a daily time step over two hydrological years. The spatial distribution of geological units in the surface layer was used to represent the spatial heterogeneity of parameters, such as the Manning roughness coefficients and the infiltration fractions. The calibrated model simulates adequately the measured heads, as well as the spatially variable flow rates and river-aquifer exchanges. The model shows that the stratigraphy and hydrogeological parameters in the Sainte-Marthe channel, as well as recharge rates over the Sainte-Marthe Hill control groundwater inflows to the river. Results from this study are also used to estimate the impacts of land use changes on the watershed hydrology.

Title: The Hydrology of a “Spontaneously” Re-vegetated Vacuum-harvested Peatland, Eastern Manitoba

Presenter/First Author: Pete N Whittington, Brandon University, Brandon, ON

Presenter/First Author Email: whittington.pete@gmail.com

Abstract Body: Peatlands cover over 38% of Manitoba’s land area and represent an important component of the natural landscape. Nearly 13% of Canada’s horticultural peat is produced in Manitoba in the southeastern part of the province. Vacuum harvesting requires the removal of all surficial vegetation and ditches to drain the peatland, lowering the water table. A consequence is that vacuumed harvested sites do not re-vegetate themselves naturally; active restoration efforts in eastern Quebec have been largely successful, though with considerable trial and error to get the ecohydrological processes correct.

The Moss Spur peatland was a large (~3 km diameter) domed bog, harvested from the 1940s and was abandoned in the early 1990s. With little intervention, the natural re-vegetation of the site has been remarkable, with over 90% wetland vegetation coverage and Sphagnum hummocks in a few locations, something that has not occurred naturally in Quebec. Preliminarily results suggest that the success of the re-vegetation is due to groundwater discharge under the site, which contradicts the ombrogenous requirement of bog hydrology. In areas with regeneration indicative of bogs (e.g., Sphagnum), hydraulic gradients of groundwater discharge averaged 0.02; in areas with more fen vegetation hydraulic gradients averaged 0.002; and in areas with no re-vegetation, hydraulic gradients averaged -0.1 (groundwater recharge). It is speculated that these groundwater flow reversals are occurring due to the lowered hydraulic head in the now abandoned former bog. This has been observed in other Western Boreal Plain peatlands in times of extreme drought, and thus peat harvesting may act as a surrogate extreme drought which causes groundwater flow reversals in large peatlands. Supporting this as a mechanism that aids restoration is that Moss Spur’s hydrogeomorphic setting is quite different than Quebec sites, as eastern boreal shield peatlands are more typically situated on a thin veneer of sediment over bedrock, thus precluding regional groundwater exchanges.

Title: Quantifying the Increasing Impact of the Human Footprint on Water Quality in a Rural-Urban Kenyan Watershed: Can Upstream Stewards and Downstream Beneficiaries Find Common Ground?

Presenter/First Author: Kennedy Waweru Nganga, Consultative Group on International Agricultural Research (CGIAR), Nairobi,

Presenter/First Author Email: k.w.nganga@cgiar.org

Co-authors: Fred Kizito, , , ; Deborah Bossio, , , ; Justine Cordingley, , ,

Published Material: Findings from this work were submitted to the CGIAR Research Program on Water, Land and Ecosystems in a technical report from the International Center for Tropical Agriculture in 2014. Findings have also been presented at the Global Landscapes Forum in 2014. Various aspects of this work have also been reported in traditional and social media by various organizations in 2014 including Reuters AlertNet, Water Land and Ecosystems website, as well as the Global Landscapes Forum and CIAT websites.

Abstract Body: Watersheds in rural Africa are facing new challenges from population growth and urbanization. As the anthropogenic footprint expands over the landscape (with population growth rates projected to rise to 4%), factors such as land cover changes driven by human activities and infrastructural development are increasing the severity of erosion and river sedimentation. Of particular importance are quarries that supply the material demanded by the growing construction industry, and the earth roads that feed to them. These quarries, many of which are unregulated, do little to mitigate their impact on the streams and rivers they border. Our assessments indicate that quarries and earthen roads (point sources) contribute up to 25% (79T/Ha) of the total annual sediment load in the watershed with the other 75% (302 T/Ha) contributed by agriculture as a non-point source. Both point and non-point sources combined have been found to significantly alter watershed characteristics and have modified hydrological responses in ways that are poorly understood. Our study findings monitored, modeled and quantified the importance of these new point sources and conventional non-point sources in the agriculturally dominated watersheds. We present a method for using remote sensing based techniques and scenario modeling to disaggregate the pollution sources and also present viable management options for mitigating the sediment problem. Finally the study demonstrates win-win solutions (that may have global relevance) on how upstream stewards and downstream beneficiaries can find common ground in these vulnerable rural-urban connected watersheds.

Title: Temporal variability in phosphorus losses in tile drain effluent from agricultural fields

Presenter/First Author: Vito Lam, University of Waterloo, Waterloo,

Presenter/First Author Email: vito.lam@uwaterloo.ca

Co-authors: Merrin L Macrae, University of Waterloo, Waterloo, ON, Canada; Michael English, Wilfrid Laurier University, Waterloo, ON, Canada; Ivan O'Halloran, , , ; Yutao Wang, , ,

Abstract Body: Tile drains in agricultural fields have been identified as a significant source of phosphorus (P) to surface water bodies and have been identified as a potential contributor to algal blooms in Lake Erie. Tile-drains were monitored in two agricultural fields in southern Ontario (Lake Simcoe watershed) over approximately a 28-month period (year round sampling) to quantify runoff, P concentrations, mass and speciation, and, to determine if these varied with tillage practices. Discharge and P export were temporally variable and episodic in nature, with the majority of loss occurring in a relatively small number of events throughout the water year. Over the study period, 27 events were recorded. Events were highly responsive to precipitation events, snowmelt or a combination of both and were observed in every season. Tile drain hydrologic and biogeochemical responses did not vary with tillage practices. Rapid transmission of water from the surface into drainage tiles via macropores was not observed, and a threshold soil moisture was required to initiate runoff generation in tile drains. Consequently, antecedent moisture conditions, soil/crop conditions and seasonality led to differences between events, such as discharge magnitude, runoff-coefficients, and P concentrations and mass in tile drain effluent. As expected, tile drain responses were greatest following precipitation on bare, moist soils. Larger precipitation events and snowmelt events exported more runoff and P mass; however, the largest events did not always have the highest P concentrations in tile drain effluent, and, P supply limitation was apparent in the data set. Temporal variability in P mobilization in tile drain effluent is discussed and related to antecedent soil moisture conditions, event climate drivers and antecedent rainfall.

Title: Waterlogged: The Case for Participatory Science in Investigating Water Quality Impacts

Presenter/First Author: Ashlee J Jollymore, University of British Columbia, Vancouver, BC

Presenter/First Author Email: ashleejo@interchange.ubc.ca

Co-authors: Morgan Haines, University of British Columbia, Vancouver, BC, Canada; Mark S. Johnson, University of British Columbia, Vancouver, BC, Canada

Published Material: This project was briefly discussed in a Water Pop Up talk at the 2013 AGU. This talk was an overview of the project, and did not discuss the results and experience of the project, and thus represents a small percentage of the abstract presented here.

Abstract Body: The reference condition approach for investigating the impact of human activities in watersheds makes it necessary to study multiple sites that represent a range of disturbance. Gathering sufficient data to tease out human effects can be difficult due to the range of human disturbances and activities possible, as well as the variability in natural factors that contribute to water quality. Given this, we began a citizen science campaign to help investigate how land use change, like forest cover loss, affects the biogeochemical cycling of organic matter in stream and river ecosystems. We asked citizens to participate by collecting water samples in local watersheds around the Metro Vancouver area in British Columbia, Canada. Community-based samples augmented our sampling activity at sites chosen as either reference or disturbed sites. All researcher-collected and community-collected samples were analyzed for water quality parameters specifically related to organic matter, including dissolved organic carbon (DOC) concentration and quality through methods including high temperature combustion (DOC concentration) and UV-Vis absorbance and fluorescence spectrophotometry (DOC quality indices). Community-collected samples represented a high degree of variability in terms of disturbance, with the greatest number of samples collected from mixed-use watersheds surrounding Vancouver. All sample sites, and information related to water quality, were mapped in order to quantify types and severity of land uses upstream of sites, and these variables were evaluated relative to measured organic matter water quality parameters. Although not a replacement for sampling campaigns undertaken by researchers, participatory science can provide benefits beyond increased sample coverage and variability. Specifically within our experience, the presence of highly educated and active community groups within local watersheds presented an opportunity to augment the valuable environmental monitoring activities already occurring, and to draw from extensive knowledge regarding the histories of specific watersheds. Lastly, participatory science approaches serve as a means of directly engaging the community about the cumulative effects human activities have on environmental processes.

Abstract Body: The use of sediment color as a fingerprint property to determine sediment sources is an emerging technique that can provide a rapid and inexpensive means of investigating sediment sources. The present study aims to test the ability of color parameters to distinguish between potential sources of sediment and apportion their contributions within the South Tobacco Creek Watershed, MB, Canada (74 km^2). The results are compared with the findings from a conventional fingerprinting approach undertaken in the same watershed (i.e., geochemical and radionuclide fingerprints). Suspended sediment and potential source samples were collected at six sites along the main stem of the creek. Canonical discriminant analysis was used to determine the number of source groups. Sample color of sediments and source materials was quantified from diffuse reflectance spectrometry measurements and sixteen color coefficients were derived from several color space models (CIE XYZ, CIE xyY, CIE Lab, CIE Luv, CIE Lch, Landsat RGB, Redness Index). Experiments were undertaken to test the linearly-additive nature of the color coefficients and this was used to further refine the number of coefficients that were suitable for source apportionment. The discrimination power of the color coefficients was assessed using discriminant function analysis. The selected fingerprints were included in a Bayesian mixing model using Monte-Carlo simulation to apportion the contribution of the different sources to the sediment collected at each site. Consistent with the conventional fingerprinting approach, a switch in the dominant sediment source between the headwaters and the outlet of the watershed was observed. As the stream crosses and down-cuts through the Manitoba Escarpment, sediment is enriched with shale bedrock and stream bank materials from within and below the escarpment and depleted of topsoil and/or stream bank materials from above the escarpment.

Title: Evaluation of Paleo-Hydrologic Extremes and Their Uncertainties

Presenter/First Author: Saman Razavi, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: saman.razavi@usask.ca

Co-authors: Amin A Elshorbagy, University of Saskatchewan, Saskatoon, SK, Canada; Howard S. Wheater, University of Saskatchewan, Saskatoon, SK, Canada; Dave Sauchyn, University of Regina, Regina, SK, Canada; Gonzalo Sapriza, University of Saskatchewan, Saskatoon, SK, Canada; Kwok Pan Chun, University of Saskatchewan, Saskatoon, SK, Canada

Published Material: None of these have been previously published. Parts of the findings are currently under review in Water Resources Research for publication.

Abstract Body: Natural proxy records of hydroclimatic behaviour, such as tree-ring chronologies, are a rich source of information of past climate-driven changes and non-stationarities in hydrologic variables. They are typically directly related to available water in respective years, thereby providing a means to go beyond the limited observational records. In this study, we investigated the tree-ring chronologies that demonstrate significant correlations with streamflows, with the objective of identifying the spatiotemporal patterns and extents of changes and non-stationarities in climate and hydrology, which are essentially representations of past "climate changes". To this end, we developed a framework that also quantifies uncertainties around the reconstructions of paleo-hydrologic

extremes. The major headwater tributaries of the Saskatchewan River basin (SaskRB), the main source of surface water in the Canadian Prairie Provinces, are used as the case study. Results confirm that stationarity has never existed in the hydrology of the region, as the statistical properties of annual paleo-hydrologic proxy records across the basin, i.e., the mean and autocorrelation structure, have consistently undergone significant changes at different points in the history of the region. This study identified paleo-hydrologic extremes (e.g., severe droughts) in the past four centuries that are well beyond recorded hydrologic extremes in the observational period of this region. This presentation highlights the need to broaden the understanding of hydrologic extremes in the Saskatchewan River Basin beyond the limited observational records, as an improved understanding is essential for more reliable assessment and management of available water resources.

Title: Sources of Uncertainty in Replicating Hydro-climatic Extremes

Presenter/First Author: Arelia T Werner, Pacific Climate Impacts Consortium, University of Victoria, Victoria, BC

Presenter/First Author Email: wernera@uvic.ca

Co-authors: Alex J Cannon, University of Victoria, Victoria, BC, Canada; Markus Schnorbus, University of Victoria, Victoria, BC, Canada; Rajesh R Shrestha, Pacific Climate Impacts Consortium, University of Victoria, Victoria, BC, Canada

Abstract Body: Effective communication of projected hydrologic extremes starts with a discussion of uncertainty. We perform an analysis using 56 downscaled (2 x observations; 4 x reanalyses; 7 x downscaling methods) results to drive the Variable Infiltration Capacity hydrologic model. Performance of each method is tested for timing and distribution of 3-day peak flow, 7-day low flow and 26 ClimDEX indices. Downscaling methods include bias corrected constructed analogues (BCCA), double BCCA (DBCCA), climate imprint (CI), bias corrected climate imprint (BCCI), bias correction spatial disaggregation based on mean temperature (BCSD), BCSD based on minimum and maximum temperature (BCSDX), and BCCA bias corrected with BCCI (BCCAQ). NCEP1, ERA40, ERAInt and 20CR are the reanalyses downscaled and two separate observational datasets are used as the downscaling target. The ability to replicate the timing and distribution of ClimDEX indices depended on downscaling technique, reanalyses and gridded-observation in order of importance. The strongest method was DBCCA, while the weakest was BCSDX. 3-day peak flow performance was more dependent on reanalysis than downscaling technique. ERA40 results were strongest and NCEP1 weakest. In the case of 7-day low flow, results depended most strongly on downscaling method, CI failed to replicate the distribution, while BCSD and BCSDX failed to replicate the timing regardless of reanalyses; these poorly performing methods over estimated low flow volumes. BCCI and BCCAQ tied for best combined performance for 7-day low flow and 3-day peak flow. Uncertainty can be reduced by careful selection of downscaling methods for those metrics most sensitive to downscaling (7-day low flow), but can't be reduced where global climate model uncertainty plays a more important role (3-day peak flow).

Title: Risk of Exceeding Extreme Design Storm Events under Possible Impact of Climate Change

Presenter/First Author: Chun-Chao Kuo, University of Alberta, Edmonton, AB

Presenter/First Author Email: chunchao.kuo@gmail.com

Co-authors: Thian Yew Gan, University of Alberta, Edmonton, AB, Canada

Published Material: Kuo, C.C. and T.Y. Gan, 2015. Risk of Exceeding Extreme Design Storm Events under Possible Impact of Climate Change. *Journal of Hydrologic Engineering-ASCE*. (Under Review)

Abstract Body: In order to evaluate how the risk of intensive storms, which is the probability of exceeding certain storm intensity one or more times within a given number of years, is expected to change in central Alberta in the future. We proposed a new Risk Chart which represents the nonlinear relationship between storm intensity, design project life, and the risk of intensive storms being exceeded within the project life. First, a comparison between estimated Risk Charts of the past (1914–1995) and the present (1984–2010) for central Alberta shows that the risk of intensive storms occurring has increased for all storm durations in recent years, and the risk had been higher for storms of large return periods (≥ 50-yr). Given a design project life of 50-yr, the average increase in risk is 9 percentage points (pp). Second, the uncertainty associated with projecting the risk of intensive storms occurring in 2011–2100 was assessed by considering three Special Report on Emissions Scenarios (SRES) of four Global Climate Models (GCMs) of IPCC (2007) dynamically downscaled by a Regional Climate Model, MM5. Based on storms simulated by MM5 for central Alberta forced by SRES climate scenarios of IPCC for 2011–2100, the median risk for short-duration storms (≤ 1-h) of a design project life of 25-yr and 50-yr is projected to increase up to 37 pp and 38 pp, respectively. In other words, climate change impact could increase the vulnerability of central Alberta to the hazards of flooding by intensive storms in future. The proposed Risk Chart present the risk in a straightforward and meaningful way which will be useful for the long-term planning and engineering design of municipal infrastructure.

Title: Renewal and Update of MTO IDF Curves: Defining the Uncertainty

Presenter/First Author: Eric D Soulis, University of Waterloo, Waterloo, ON

Presenter/First Author Email: rsoulis@uwaterloo.ca

Co-authors: Daniel G. Princz, University of Waterloo, Saskatoon, SK, Canada; John Wong, , ,

Published Material: Accepted, but not yet published, for journal publication by the Journal of *Water Managment Modeling*. Parts presented at the Ontario Climate Advisory Committee (OCAC) meeting #45. Preliminary finding were presented at CMOS 2012 and 2013.

Abstract Body: The University of Waterloo has been commissioned by the Design and Contract Standards Office of the Ministry of Transportation of Ontario (MTO) to update the intensity–duration–frequency (IDF) curves that are used to estimate design storms for drainage infrastructure. Environment Canada provides analyzed rainfall data for weather stations in Ontario. Project engineers determine the design storm parameters using a variety of methods. Thus, there is a need for a consistent interpolation procedure that can deal with the sparseness and unevenness of the Ontario station network. This presentation describes the procedures that form the basis for the MTO IDF Curve Lookup system. Confidence limits assist in the design process and allow comparison with other results. These were used to assess the spatial bias in the error fields. There appears to be none, but there is room for improvement where there are sharp changes in geography, such as the highlands west of Thunder Bay. Validation curves are presented for several Canadian stations and one American station.

Title: Scaling Laws for Extreme Precipitations: Assessing the Impacts of Datasets Characteristics on Extreme Distribution Estimation.

Presenter/First Author: Silvia Innocenti, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Québec,

Presenter/First Author Email: silvia.innocenti@ete.inrs.ca

Co-authors: Alain Mailhot, Institut National de la Recherche Scientifique, Québec, QC, Canada; Anne Frigon, Ouranos, Montreal, QC, Canada

Abstract Body: Characterizing extreme precipitations at small spatial and temporal scales is crucial in order to evaluate and predict the impacts of natural hazards on regional ecosystems. Available datasets, including climate model simulations and reanalysis products, still have many deficiencies related to their temporal and spatial resolution. Biases and uncertainties are also important, especially when considering extreme precipitations.

The present study aims at validating the use of scaling models for the description of the spatio-temporal structure of extreme precipitations in North-America. By means of scaling models, the statistical distribution of the extremes estimated at specific spatial and temporal scales is related to the distribution at other scales. It is therefore possible to assess extreme precipitation distribution at temporal and spatial scales which are only partially or not sampled. Hence, a consistent and parsimonious construction of IDF curves is possible.

The influence of datasets characteristics (e.g., their temporal and spatial resolution, or spatial coverage) on the scaling properties of sub-daily and daily precipitations is investigated through the comparison of different available datasets (station network series, NCEP Stage IV dataset, and reanalysis series). The range of validity, the magnitude, and the variability of the estimated scaling laws are compared among observed datasets and reanalysis having different spatial resolutions. The spatial distribution of scaling estimates is presented. The influence of climatic and geographic characteristics of Canadian region on scaling estimates is also evaluated. The objective is to validate the use of scaling models to estimate IDF curves for precipitation extremes over Canada. Preliminary results will be presented.

Title: Coupling System Dynamics and SWAT Models for Participatory Water Quality Management in the Du Chêne basin, Québec

Presenter/First Author: Jerome Boisvert-Chouinard, McGill University, Montreal, QC

Presenter/First Author Email: jerome.boisvert-chouinard@mail.mcgill.ca

Co-authors: Azhar Inam Baig, McGill University, Sainte-Anne-De-Bellevue, QC, Canada; Jan F Adamowski, McGill University, Montreal, QC, Canada

Published Material: Partial results presented at the ASABE 2014 Annual International Meeting.

Abstract Body: The Québec Water Policy outlines the importance of stakeholder participation in water management processes, but in practice, there is a lack of meaningful engagement in water planning and implementation, and participation is often limited to public consultation and education. When models are used to support water planning, stakeholders are usually not involved in their development and use, and the models commonly fail to represent important feedbacks between socio-economic and physical processes.

This paper presents the development of a holistic model of the Du Chêne basin that simulates socio-economic and physical processes related to water quality management, and feedbacks between them. The model consists of two sub-components: a System Dynamics (SD) model, and a Soil and Water Assessment Tool (SWAT) model. The SD component was developed in collaboration with key stakeholders in the watershed. The coupled SD-SWAT model was used to assess the environmental and socio-economic impacts of different management scenarios proposed by stakeholders. The scenarios included different combinations of water quality improvement strategies such as planting buffer strips, replacing obsolete septic tanks, and putting in place economic incentives for sustainable agricultural management practices.

Our results indicate that a coupled SD-hydrologic model can be used as an effective tool for participatory water planning and implementation. The participatory modeling process provides a structure for meaningful stakeholder engagement, and the model itself can be used to transparently and coherently assess and compare different management options. In this case, the SD model was coupled with SWAT to address water quality, but a similar approach could be used to couple SD models with other physically based models to address different problems, such as water scarcity or soil salinity.

Title: PARAMETERIZATION AND VALIDATION OF SWAT MODEL FOR WHEAT YIELD AND CROP WATER PRODUCTIVITY UNDER RAINFED CONDITIONS

Presenter/First Author: Mukhtar Ahmed, Organization Not Listed, Rawalpindi,

Presenter/First Author Email: ahmadmukhtar@uaar.edu.pk

Co-authors: Atif Mehmood, PMAS Arid Agriculture University, Rawalpindi, Pakistan; Fayyaz ul Hassan, Comsats Institute of Science and Technology, Islamabad, Pakistan; Muhammad Aqeel Aslam, , , ; Muhammad Akmal, , , ; Muhammad Aslam, , ,

Abstract Body: The greatest challenge faced by the agriculture sector now days is production of more food from less available water. Increasing water productivity of the crops can help in facing this challenge. For understanding the relationship between water and food, a sound knowledge of crop water productivity (CWP) is important. Therefore, to achieve higher CWP under changing climatic conditions, increasing WUE (water use efficiency) could be an option by adopting mitigation strategies. These measures might be, adopting good management practices like optimizing the sowing date on long-term basis using simulation modeling as decision support tool. In the present study, Soil and Water Assessment Tool (SWAT) model was parameterized and validated to study the relationship between yield and crop water productivity of rainfed wheat. For this study, field experiment was conducted at three locations (Islamabad, University Research Farm, Chakwal Road and Talagang) with three wheat Cultivars (PAK-13, Chakwal-50 and Dharabi) and two sowing dates (20-30 October and 10-30 November). Data regarding soil moisture and grain yield were recorded from the field experiments. Crop water productivity was calculated by dividing the grain yield by evapotranspiration during crop growth cycle and was used for studying the relationship between available water, rainfed wheat yield and water productivity. Satellite based parameterization of study area for GIS mapping, topographic analysis, vegetation dynamics, land use, and soil

mapping was done by using different software packages like ArcGIS 10.1, Erdas Imagine, QGIS, and Swat-CUP. The SWAT model was used to simulate the processes related to the soil-crop-atmosphere interaction in the present study. Simulated results were compared with the observed values. Present study revealed that the changing climatic conditions significantly affect the rainfed wheat growth, yield and productivity. The simulated values for grain yield were close to the observed values with validation skill score of R^2 (0.827). Similarly, simulated values for crop water productivity were close to the observed values with validation skill score of R^2 (0.88).

Title: Assessment of SPEI as a Tool for Representing Drought in the Agricultural Landscapes of the Southern Canadian Prairies

Presenter/First Author: Sunil Gurrapu, University of Regina, Regina, SK

Presenter/First Author Email: gurrapus@gmail.com

Co-authors: Aston Chipanshi, , , ; David Sauchyn, Prairie Adaptation Research Collaborative (PARC), Regina, SK, Canada; Allan Howard, , ,

Abstract Body: Droughts have had a significant impact on the agricultural yield across the southern Canadian Prairies. This region is home for the majority of the agricultural land in Canada and therefore, any negative impact on the crops has a significant influence on the agricultural economy of Canada. Moreover, increasing economic activity and growing population in this region is increasing the demand for water resources and therefore influencing the vulnerability to drought. The future projections of increased climate variability resulting from climate change suggest an increasing likelihood of droughts in this region. Due to the complex interrelation between climate, hydrology and water demand, a comprehensive index to represent drought has been difficult to find. Measured meteorological and hydrological quantities are primary indicators of drought and various drought indices were derived by assimilating these measured quantities. The Standardized Precipitation Index (SPI) has been used to assess drought conditions in Canada however the Standardized Precipitation Evapotranspiration Index (SPEI) may better capture the evaporative stress associated with drought conditions. In this study, we compared the SPI and SPEI to understand which of the two indices best represent drought conditions across the southern Canadian Prairies. The initial results indicate no significant difference between the indices in assessing drought under observed climatic conditions. However, drought severity as projected by the future climatic projections from GCMs are captured best by the SPEI, which accounts for the loss of moisture through Potential Evapotranspiration. Our results indicate that SPEI would be a better measure of drought in this region with the projected increases in temperature.

Title: A hydrologic-based lumped method for stochastic internal dose calculation and the time evolution of the probability density distribution of radioactivity in the human body

Presenter/First Author: Syota Sasaki, Chuo University, Tokyo,

Presenter/First Author Email: s-sasaki@civil.chuo-u.ac.jp

Co-authors: Tadashi Yamada, Chuo University, Bunkyo-ku, Japan; Tomohito Yamada, Hokkaido University, Sapporo, Japan

Abstract Body: In this report, we calculate the probability density function of the internal dose based on a hydrologic lumped method. The authors have been studied readily-understandable hydrologic-based lumped method to calculate the internal dose by treating the human body as a single vessel. In our previous research, the internal dose is calculated deterministically. However, radioactivity in the human body actually distributes by individuals stochastically. It is shown by the investigation of radiocesium by using whole-body counting [1]. The distribution emerges from some uncertain factors regarding the intake and excretion of radioactivity. Therefore, we suggest that the probability density distribution of the internal dose is appropriate to be discussed from the viewpoint of radiological protection of the public. The ingestion flux of radioactivity is including Gaussian white-noise fluctuations. Then, the continuity equation of radioactivity in the human body is formulated as the stochastic differential equation including the standard Wiener process. The stochastic formulation gives the time evolution of the probability density function of the internal dose as shown in the figure.

Title: Effects of time series lengths on the design of hydrometric networks using Dual Entropy and Multiobjective Optimization

Presenter/First Author: Jongho Keum, Utah State University, Logan, UT

Presenter/First Author Email: hydrokeum@gmail.com

Co-authors: Paulin DL Coulibaly, McMaster University, Hamilton, ON, Canada

Abstract Body: Recently, Dual Entropy Multiobjective Optimization (DEMO) has been developed and applied to design optimal networks for streamflow, precipitation, and soil moisture monitoring. While the previous applications to various hydrologic variables have shown versatility of DEMO application, it is still not clear how the length of input time series affects the optimization results and network designs. In this study, various time series lengths were applied to find the optimal streamflow and precipitation network designs. The study area is Hamilton, Halton and Credit Valley in southern Ontario, Canada. Numbers of the currently active streamflow and precipitation stations are 23 and 20, and the potential stations are 137 and 61, respectively. Three objective criteria were used in DEMO applications, including maximizing joint entropy, minimizing total correlation, and minimizing total costs. Five, ten, fifteen, and twenty-year of streamflow and precipitation data were used as input time series, respectively. The strong "hot- spots" (or high probability areas) were relatively constant for all four time series lengths. However, some areas with lower probabilities show some sensitivity to the length of the time series used. In summary, few years of time series (about 5-year daily series) can be used to determine "hot-spots" where additional monitoring stations are highly required.

Title: A Critical Look at Sensitivity Analysis of Hydrologic Systems Models: A New Framework for Global Sensitivity Analysis

Presenter/First Author: Saman Razavi, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: saman.razavi@usask.ca

Co-authors: Hoshin Vijai Gupta, University of Arizona, Tucson, AZ

Published Material: A part of it (mainly introduction and motivation part) was presented in AGU general meeting 2014 and is in review in Water Resources Research. This abstract is the next step of our work and contains significant additional materials.

Abstract Body: Sensitivity analysis (SA) is an important paradigm for effective understanding and modelling of hydrologic systems. Example essential functions of SA include (1) Uncertainty Apportionment - attribution of total uncertainty to different uncertainty sources, (2) Assessment of Similarity - diagnostic testing and evaluation of similarities between the functioning of the model and the real system, (3) Factor and Model Reduction - identification of non-influential factors and/or insensitive components of model structure, and (4) Factor Interdependence - investigation of the nature and strength of interactions between parameters/factors, and the degree to which factors intensify, cancel, or compensate for the effects of each other. However, despite the availability of a large body of literature on the development and application of various SA approaches, two issues continue to pose major challenges: (1) Ambiguous definition of sensitivity – Different SA methods are based in different philosophies and theoretical definitions of sensitivity, and can result in different, even conflicting, assessments of the underlying sensitivities for a given problem, (2) Computational cost – The cost of carrying out SA can be large, even excessive, for high-dimensional problems and/or computationally intensive models.

In this presentation, we first revisit the fundamental basis for sensitivity analysis and critically evaluate the existing approaches so as to demonstrate their flaws and shortcomings. Then we propose a new framework for 'global' sensitivity analysis that characterizes a range of important properties of metric 'response surfaces' encountered when performing SA on hydrologic models. We show how this framework embraces, and is consistent with, a spectrum of different concepts regarding 'sensitivity', and that commonly-used SA approaches (e.g., Sobol, Morris, etc.) are actually limiting cases of our approach under specific conditions. We show, through multiple hydrologic modelling case studies, that the new framework provides a fundamental understanding of the underlying sensitivities of hydrologic models, while requiring orders of magnitude fewer model runs.

Title: Revealing Multi-Variate And Multi-Scale Controls Of Soil Water

Presenter/First Author: Bing Si, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: bing.si@usask.ca

Co-authors: Wei Hu, University of Saskatchewan, Saskatoon, SK, Canada; Asim Biswas, McGill University, Montreal, QC, Canada

Published Material: Part of the presentation was given at Soil Science Society of America Annual meeting in 2014 and some material was submitted to WRR.

Abstract Body: Soil water varies spatially and temporally within the landscape. The variability is controlled by a complex suite of environmental factors and processes acting in different intensities over a variety of scales. While modeling approach has made progresses in this aspect, but its application has been hindered by the lack of detailed measurement of soil hydraulic properties and biophysical properties of land surface. There is a need for developing new statistical methods for revealing this multivariate, nonstationary, potentially nonlinear variability and its dominant controls at multiple scales in the landscapes. The objective of this study is to summarize recent progresses in methodology and a few recent applications of the methods on understanding of the soil water dynamics and the underlying processes causing the variability. Soil water storage (SWS) was measured down to 1.4 m (0.2 m depth interval) at 128 regularly spaced locations along a transect over five years from the Hummocky landscape of central Canada. The locations and the scales of the most persistent spatial patterns over time and depth were quantified using the wavelet coherency. The variability in SWS spatial patterns was controlled by different factors at different scales. Scale specific dominant controls were identified after using the Hilbert-Huang transform, structural equation model and multivariate wavelet coherency. The large scale macro-topographical control and medium scale landform control were much stronger than very large scale soil textural control on SWS. The scale-specific relationship with controlling factors improved the prediction of SWS.

Title: Joint multifractal analysis for three variables: Characterizing the effect of topography and soil texture on soil water storage

Presenter/First Author: Asim Biswas, McGill University, Montreal, QC

Presenter/First Author Email: asim.biswas@mcgill.ca

Abstract Body: Multifractal analysis describes the variability and heterogeneity in the distribution of a variable by characterizing and summarizing the variability across scales. Joint multifractal analysis has been widely employed to characterize scale relationships between two variables co-existing along a single geometric support. In this study, the joint multifractal analysis was carried out for three variables coexisting in the same geometric support in order to describe the influence of topography (relative elevation) and soil texture (sand content) on water storage within the soil profile. Soil water storage was measured down to 1.4 m depth along a transect of 576 m long from the hummocky landscape of central Saskatchewan, Canada along with sand content and relative elevation. Joint multifractal analysis was conducted considering both the strange attractor formalism and the method of moments. The variability in soil water storage, sand content and relative elevation were scale dependent. The spatial variability in relative elevation was strongly reflected on water storage across analyzed spatial scales but the joint multifractal spectrum for sand content and water storage suggested a lower degree of correlation. The change in multifractality was also observed when both relative elevation and texture varied highly. This clearly demonstrated the capability of joint multifractal analysis to completely characterize the scaling behavior among three variables.

Title: Spatio-temporal Change Assessment Using Normalize Difference Vegetative Index and Spectral analysis techniques for vegetation cover on Wadi Auranah

Presenter/First Author: Gohar A Mahar, Federal Urdu University of Arts, Sciences and Technology, Karachi,

Presenter/First Author Email: goharmahar@gmail.com

Co-authors: Nassir Al Aamri, , , ; Omar Siraj Aburizaiza, King Abdulaziz University, Jeddah, Saudi Arabia

Published Material: the article has been published in Global Nest journal in December 2014.

Abstract Body: Abstract

Wadi Auranah is one of the potential wadis located on the western shield (Hijaz escarpment) of Saudi Arabia. A spatio-temporal change assessment of the wadi was conducted with the help of landsat data. The results of the spectral analysis and NDVI for vegetation changes assessment reveals a continuous increasing trend of land cover biomass in specific parts of the wadi. Geological review by enhancing geological map and field assessment of the study area showed this trend. About 73 km^2 of vegetation land cover has been created in the last 20 years. Treated wastewater is the main source of water supply that is used for afforestation and cultivation purpose.

Title: Multi-scale heterogeneous movement on hillslope solute transport toward surface water

Presenter/First Author: Suzanne Edith Allaire, Organization Not Listed, Quebec,

Presenter/First Author Email: suzanne.allaire@fsaa.ulaval.ca

Published Material: Some information submitted to the Plos One journal

Abstract Body: Surface water quality is controlled at the hillslope scale through a variety of processes occurring at different scales. Modeling efforts have significantly advanced but additional real field data over entire hillslopes is needed for studying relationship between these processes in time and space. The objective of this study concerns a field description of several preferential flow and matrix flow processes at different locations in a catena using different tracers. Tracer concentration was studied over two years in all three soils of the catena, in the buffer strip and in the creek of an agricultural site. The results indicate that each scale influenced solute transport toward surface water, but the connectivity between these vertical and lateral processes was most important. The processes occurring upslope were just as important on surface water quality as those close to the creek. Bypass of the buffer strip occurred due to different preferential flow processes within the buffer strip and uphill.

Title: Hillslope-Scale Spatial Variability of Snowmelt Runoff via Interflow in a Minnesota Forest

Presenter/First Author: Carl P J Mitchell, University of Toronto, Toronto, ON

Presenter/First Author Email: carl.mitchell@utoronto.ca

Abstract Body: In humid temperate catchments with permeable surface soils underlain by confining soil horizons, lateral interflow is an important runoff mechanism, particularly during the spring snowmelt period. Numerous physical and biological factors affect the spatial variability of interflow runoff. From a hydro-biogeochemical perspective, flow path (e.g. soil contact), residence time (affecting soil-water partitioning of chemicals), and magnitude of flow (controlling how much water or solute is delivered to a particular area) are important, but spatially-variable factors controlling downstream or down-gradient biogeochemical processing. To characterize the spatial variability of interflow across a north-facing forested hillslope, three separate 10 m wide interflow collecting trenches were dug to the confining layer across an approximate 75 m wide hillslope area. Continuous measurements of runoff, and spatially distributed perched water table elevations, soil moisture, and snowmelt rates were made through the spring snowmelt period. Stable isotope-based hydrograph separation was also applied to each of the hillslope plots to assess variability in event vs. pre-event water signatures. The runoff response to a rain-on-snow event (112 mm total input) varied from 40 to 72 mm. While hydrograph shapes and inter-site runoff amounts differed considerably during the rising limb, broad characteristics such as peak flow lag times were similar (45-47 hours). Hydrograph recession analysis revealed three distinct drainage periods; an early, relatively rapid draining of nearer-surface, high conductivity soils over a period of 15-30 hours, a middle recession ranging from 45 to 110 hours that was distinctively longest at the hillslope plot where toe slope soils were comparably deepest, and a longer draining component that is too ephemeral to be characterized as baseflow. Variability in the contribution of event water across the hillslope was high during the rising limb, but relatively low (~60 ± 20%) after peak flow. Overall, this work provides a needed baseline from which the uncertainty of future impacts can be quantitatively assessed and demonstrates the likelihood that small-scale differences in soil depth, particularly at the toe slope, are important to runoff response at this scale.

Title: *Field scale flow processes and soil water dynamics in seasonal wetlands of the Canadian Prairies*

Presenter/First Author: Dawn Keim, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: dawn.keim@usask.ca

Co-authors: Melkamu Ali, University of Saskatchewan, Saskatoon, SK, Canada; Andrew M Ireson, University of Saskatchewan, Saskatoon, SK, Canada

Abstract Body: *The Canadian Prairies are characterized by hummocky terrain containing numerous depressions and wetlands with complex hydrological systems. Quantifying hydrological processes is challenging as a result of the intricate relationships between surface flow, interflow and groundwater flow. Northern hydrology is further complicated by a seasonal freezing component that can lead to large variations of near surface and surface fluxes which dominate soil water redistribution in the unsaturated zone. We couple intensive field monitoring and numerical modeling to investigate the seasonal dynamics of soil water variability and groundwater flow direction at a wetland field site in the Saskatchewan Canadian Prairies. Soil water content, matric potential and soil temperature are monitored continuously within the top three meters of the unsaturated zone along a transect located between two terminal monitoring ponds. Water levels are monitored via nested piezometers located at the center of each of the terminal ponds and along the monitoring transect. We have used field observations to develop a numerical flow model based on Richards' equation coupled with a frozen soil infiltration algorithm to simulate unsaturated-saturated flow and examine the contribution of snowmelt infiltration in the spring. The interaction of subsurface flow and terminal wetland ponds along with observed water table responses is presented. This study provides valuable insights into field scale flow processes and soil water dynamics within the Canadian Prairies unsaturated zone.*

Title: A new impacts-driven approach to understanding climate vulnerabilities

Presenter/First Author: Julie A Vano, University of Washington, Seattle, WA

Presenter/First Author Email: jvano@coas.oregonstate.edu

Abstract Body: Extreme weather events have the biggest impact on society, yet are often the climate phenomena we understand least, especially in GCMs. Even though these understandings are limited, there are opportunities from a hydrologic perspective to use past weather events to better quantify conditions (e.g. extent, duration, and intensity of precipitation, snow pack, soil moisture) that caused those events. This will help identify how the character of simulated future events, as they continue to evolve, differs from those of the past. To explore this, this research works to develop an impacts-driven method that uses the same modeling framework as past climate change studies (global climate models, hydrological models, and impact assessment tools), but reverses the typical direction of information flow: first, resource managers identify a metric of concern, e.g., flow above X cfs at a certain gauge, then hydrologic factors that lead to the metric are diagnosed, and finally connections to climate drivers are quantified. This presentation will discuss the opportunities and challenges of this new approach in the Pacific Northwest region of North America. Floods in the Skagit River in western Washington, selected after numerous meetings with stakeholders throughout the region, will be highlighted as a test case for this impacts-driven approach.

Title: Ecological Flows for a Large Hydroelectric Reservoir Regulated River System: Will Projected Climate Change Bring About Beneficial Opportunities?

Presenter/First Author: Daniel L Peters, Environment Canada, Victoria, BC

Presenter/First Author Email: daniel.peters@ec.gc.ca

Co-authors: Rajesh R Shrestha, Pacific Climate Impacts Consortium, University of Victoria, Victoria, BC, Canada; Markus Schnorbus, University of Victoria, Victoria, BC, Canada; Wendy A Monk, Canadian Rivers Institute, University of New Brunswick, Fredericton, NB, Canada; Donald J Baird, Enivironment Canada @ Canadian Rivers Institute, University of New Brunswick, Fredericton, NB, Canada

Abstract Body: The Peace River in Western Canada has been regulated since 1968 with a large dam and storage reservoir for the production of hydroelectricity. The reservoir releases feed a run-of-the-river facility, and there are plans to add two more run-of-the-river dams downstream. Previous studies have found that flows emanating from the mountain headwaters have increased by ca. 250% during the winter low flow period and peak summer flows have decreased by ca. 35% - both associated with the introduction of hydroelectric operations. Although reduced by tributary inflow, this alteration in the flow regime was transferred more than a thousand kilometers downstream to the internationally important Peace-Athabasca Delta (PAD). The PAD ecosystem is influenced by occasional ice-jam and open-water flood events that recharge lake and wetland basins with varying degrees of connectivity to the main flow system. Reservoir spillage is a rare occurrence on this reservoir system. For instance, additional reservoir flow was released in the spring of 1996 to enhance natural hydro-climatological conditions in the lower watershed, conducive to the formation of ice-jams, and associated overland flooding in the Peace Delta. The Williston Reservoir was lowered by ~3m during the summer of 1996 in response to a sink-hole in the earth dam, generating near natural summer flows on the lower Peace River that helped raise the connected lake system into contiguous wetlands. Most recently, additional flow was released from the reservoir over the summer of 2012 in response to above average snowpack/rainfall and runoff in mountain headwaters. The objective of this presentation is twofold: i) examine the hydroclimatic drivers of these atypical historical flow releases; and (ii) examine the projected impacts of climate change on the timing and quantity of water available for hydropower generation. Based on our understanding of historical flow release events and projected climate change effects on streamflow into the Williston Reservoir, the goal of this study is to develop ecologically-relevant flow release recommendations that will contribute to the maintenance/sustainability of downstream deltaic ecosystem.

Kildare, Ireland; Philippe Crochet, Icelandic Meteorological Office, Reykjavik, Iceland; Donna Wilson, Norwegian Water Resources and Energy Directorate, Oslo, Norway

Published Material: Status and partial results from this project have been presented on posters at past AGU and EGU meetings. The project team is currently working on revisions based on journal review. We will resubmit to that journal after updates are complete. Resubmission will likely take place prior to the May Joint Assembly.

Abstract Body: We present an intercontinental assessment of historical climate-driven trends in major-flood occurrence—floods exceeding 25, 50, and 100 year return-period thresholds—using many diverse but minimally altered catchments. It is important to understand historical changes in major floods to help inform how floods may change in the future. To date there is very limited evidence of past changes in major-flood magnitude and occurrence. Many studies have analyzed annual-maximum flood trends (which primarily represent minor floods) and they have often not differentiated between trends influenced by human catchment alterations and those caused by climatic changes. Based on our results, there is no compelling evidence for consistent changes over time in major-flood occurrence across North America and Europe. Flood occurrence based on all 1206 gauges in our study increased from 1961 to 2010 but not significantly ($p<0.05$), driven primarily by European increases; there was no change overall in the occurrence of major floods in North America. Flood occurrence based on all 322 longer-record gauges increased from 1931 to 2010 but not significantly, this time driven primarily by North American increases. There were a few significant flood-occurrence increases and decreases for subgroups of gauges for both time periods, differentiated by catchment size, type of climate, flood threshold, and period of record. Significant increases from 1931-2010 in the occurrence of 25-year floods in North America appear to be driven by a relatively low occurrence of floods in the 1930s and 1940s. Past changes in major-flood occurrence are complex and future changes are also expected to be complex. International hydrologic networks containing minimally altered catchments will play an important role in understanding these complexities for both historical and future climatic conditions.

Title: Hydrologic Impacts of Projected Climate in the Athabasca Watershed: Implication on Water Availability in the Region

Presenter/First Author: Yonas B Dibike, Environment Canada, Victoria, BC

Presenter/First Author Email: yonas.dibike@ec.gc.ca

Co-authors: Hyung-Il Eum, , , ; Terry D Prowse, University of Victoria, Vancouver, BC, Canada

Abstract Body: The potential impact of projected climate change on the hydrologic regime of the Athabasca watershed in Alberta, Canada, is examined using the process based and distributed hydrologic modelling system, MIKE-SHE. High resolution climate data statistically downscaled from the latest Coupled Model Inter comparison Project phase 5 (CMIP5) global climate projections was used as climate forcings to the hydrologic model. Analysis of the multiple climate change projections derived from six GCMs, two statistical downscaling techniques and two emission scenarios, showed an overall increase in projected temperature and precipitation in the region for all seasons except the summer that has shown both increases and decreases in temperature and precipitation, depending on the specific climate model and scenario considered. The watershed's response to these climate change scenarios is also assessed by computing hydrologic indicators that represent the magnitudes and timings of the hydrologic regime from the simulated discharges, to identify possible alterations between the baseline (1971-2000) and the two future periods (2050s, and 2080s). The results show overall projected decreases in mean monthly and annual maximum snow water equivalent (SWE) over the basin, with the biggest decreases in the upper reaches; and an overall increase in the actual evapotranspiration (AET) with the highest increases in the middle and lower reaches. The results also show future increases in winter and spring flows at most hydrometric stations considered within the basin, with relatively higher increases being projected for the stations located at the upper reach. On the contrary, summer flows are projected to decrease at most of the stations because of earlier snow-melt, increased evapotranspiration and no significant increase in summer precipitation. Implications of the projected changes in the hydrologic regime on water availability in the region are also identified.

Title: Climate Change Impacts on Extreme Wet and Dry Events for Southern California Water Resources

Presenter/First Author: Brianna Rita Pagan, Loyola Marymount University, Los Angeles, CA

Presenter/First Author Email: bpagan1@lion.lmu.edu

Co-authors: Jeremy S Pal, Loyola Marymount University, Los Angeles, CA; Moetasim Ashfaq, Oak Ridge National Laboratory, Oak Ridge, TN; Donald R Kendall, Loyola Marymount University, Los Angeles, CA

Published Material: To be presented at:2015 WateReuse California Annual Conference Los Angeles, CA March 15-17, 2015America Water Resources Associaton's 2015 Spring Specialty Conference *"Water for Urban Areas: Managing Risks and Building Resiliency,"* Los Angeles, CA March 30-April 1, 2015

Abstract Body: Southern California's lack of local water supplies has caused the region to extensively rely on imported sources originating from snowpack in the Sierra Nevada and Rocky mountains. This study evaluates how climate change will impact the interannual variability of runoff primarily generated from snowpack across all imported supplies of water to Southern California including 1) the Sacramento River basin, 2) the San-Joaquin River basin, 2) the Tulare Lake basin, 3) Mono Lake and Owens Valley basin and 4) the Colorado River basin. A 10-member ensemble of coupled global climate models are dynamically downscaled forcing one regional and one hydrological model resulting in a high-resolution 4.6-km output for the region. Greenhouse gas concentrations are prescribed according to the IPCC Representative Concentration Pathway 8.5 using the present-day period of 1966-2005 and future period of 2011-2050. Projected changes in average annual runoff across all basins are minimal. However, the likelihood of experiencing above or below average annual runoff increases. Supplies of water are further constrained under extreme dry conditions. Yet extreme wet years do not necessarily equate to an increase in water supply availability as the majority of precipitation occurs in the winter months and water must be released for flood control purposes. Significant water management problems can arise as the region currently does not possess enough surface water storage facilities to capture rising quantities of runoff.

Title: Projecting climate change impacts on streamflow extremes using nonstationary generalized extreme value analysis

Presenter/First Author: Rajesh R Shrestha, Pacific Climate Impacts Consortium, University of Victoria, Victoria, BC

Presenter/First Author Email: rshresth@uvic.ca

Co-authors: Markus Schnorbus, University of Victoria, Victoria, BC, Canada; Alex J Cannon, University of Victoria, Victoria, BC, Canada

Abstract Body: Projecting nonstationarity of the streamflow extremes is crucial for managing river flooding in a changing climate. The objective of this study is to develop a statistical modelling framework for relating climate variables (i.e., precipitation and temperature) with streamflow extremes. The non-stationarity in streamflow extremes is represented by the variable parameter Generalized Extreme Value (GEV) distribution, with the Conditional Density Network (CDN) model used to evaluate the GEV parameters as a function of seasonal precipitation and temperature. The model was set up using an ensemble of 23 CMIP3 climate models derived precipitation and temperature, and simulated annual maximum streamflow from the Variable Infiltration Capacity (VIC) hydrologic model for the Fraser River Basin, Canada. Based on the model setup for the CMIP3 generation of GCMs, the CMIP5 precipitation and temperature will be used to derive the GEV distribution of annual maximum streamflow under CMIP5 climate change scenarios. Preliminary results indicate the flexibility of the GEV-CDN model to describe the non-stationarity of streamflow extremes. Future changes in streamflow extremes indicate increasing magnitude for a given return period. Such changes in the return periods could have major implications on flood risk, such as adequacy of the existing dikes in the lower Fraser region to offer long-term flood protection.

Title: A Novel Method for Extraction and Characterization of Porewater Chemistry in Low-Permeability Sedimentary Rocks

Presenter: Tom Anthony Al, University of New Brunswick, Fredericton, NB

Presenter Email: tal@unb.ca

First Author: Magda Celejewski, University of New Brunswick, Fredericton, NB

First Author Email: m.celejewski@unb.ca

First Author Student?: Yes

Co-authors: Ian Douglas Clark, University of Ottawa, Ottawa, ON, Canada

Published Material: The method has been published in Applied Geochemistry. Some of the results will be presented at the 2015 Clay Conference.

Abstract Body: Measurements of spatial variability of naturally-occurring tracers in porewater from low-permeability rocks can provide insight into porewater residence time and the nature of solute transport. These system characteristics are required to assess the long-term stability of geologic systems for waste management. However, the measurement of porewater chemistry in low-permeability rocks is challenging because of small fluid volumes and the difficulty of extracting representative samples. Several techniques for porewater characterization are available, but the results they provide can be affected by ion exchange and mineral dissolution.

The objectives of this work are to develop and test a method of extracting representative samples of *in-situ* porewater from low-permeability rocks, and to accurately quantify solute concentrations in the extracted porewater. The method involves extraction of porewater by absorption into hydrophilic cellulosic membranes. *In-situ* porewater solute concentrations are obtained by normalizing solute mass, quantified by inductively coupled plasma - mass spectrometry (ICP-MS), to water mass, quantified by near infrared (NIR) spectrometry. Laboratory experiments confirm that the method is capable of providing porewater solute concentrations with precision and accuracy that are within the limits suggested by USEPA Method 6020A for analysis of saline water samples by ICP-MS.

A detailed description of the absorption method will be provided, followed by the results of porewater extractions from two field trials. The first trial was conducted on samples of low-permeability ($K < 10^{-12}$ m/s, porosity < 10 %) shale drill cores from the Michigan Basin in Kincardine. The second trial will examine porewater extracts from Opalinus Clay ($K < 10^{-12}$ m/s, porosity < 22 %) obtained from a deep borehole at the Mont Terri Laboratory, Switzerland. Concentrations of major ions (Na^+, K^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Cl^-, Br^-) will be quantified and compared to results from other methods.

Title: Transient electromagnetic investigations in the Ahmedabad region,central Cambay basin, Gujara, INDIA

Presenter/First Author: Yashavant Singh, Institute of Seismological Research, Gandhinagar,

Presenter/First Author Email: yashavant_s@yahoo.in

Co-authors: Pavankumar Gayatri, Institute of Seismological Research, Gandhinagar, India; Virender Choudhary, , , ; Mahender E, Institute of Seismological Research, Gandhinagar, India; Damodar K, Institute of Seismological Research, Gandhinagar, India; Rastogi B K, Institute of Seismological Research, Gandhinagar, India

Abstract Body: We present the preliminary results of a time domain electromagnetic (TDEM) surveycarried out in the Bhavla region of the Ahmadabad district located in the central part of the Cambay basin to delineate shallow subsurface resistivity image of the region. Fixed in-loop TDEM soundings were made at 15 selected locations along N-S and E-Wlineswith 100 m sided transmitter loop. For each loop, the transmitter is operated for a sequence of data repetition frequencies ranging from 32 Hz to 1 Hz. Rate of change of secondary magnetic field produced due to the induced eddy current in the subsurface has been measured at every TDEM sounding site using a receiver coil. The data were processed to get apparent resistivity as a function of decay time.The subsurface electrical resistivity image obtained by combining the results of 1-D smooth inversion for 15 locations along a 10 km long N-S line indicates ingeneral at three-layered structure upto 160m. A 20-30m thick conductive channel of resistivity ~10 Ω.mat a depth of 20-25m, interpreted as saturated/unconsolidated rock, is overlain on another saturated rock (with possible content of sulfides, clay etc.) of comparably low resistivity. A fractured resistivity zone (20-25Ω.m) at a depth of 20m extending to entire depth section is observed at the north central part of the line. The results could be integrated with hydrogeophysical information for further characterization of the aquifer and the fractured zones observed in region.

Title: Spatiotemporal variability of heavy metals contamination of surface water: a case study in the Cordillera Blanca, Peru

Presenter: Alexandre Guittard, Ecole de Technologie Superieur, Montreal, QC

Presenter Email: Alexandre.guittard@gmail.com

First Author: Michel Baraer, Ecole de Technologie Superieur, Montreal, QC

First Author Email: michel.baraer@etsmtl.ca

First Author Student?: No

Co-authors: Jeffrey M McKenzie, McGill University, Montreal, QC, Canada; Bryan G Mark, OSU-Byrd Polar Rsrch Ctr, Columbus, OH; Oliver Henry Wigmore, The Ohio State University, Columbus, OH; Alfonso Fernandez, The Ohio State University, Columbus, OH

Abstract Body: The Rio Santa, Peru, drains the western slopes of the glacierized Cordillera Blanca and provides water resources at almost all levels of the watershed. As it flows away from the valleys of the Cordillera Blanca, the Rio Santa takes out pollution from numerous sources, including acid mine drainage and natural sulfide oxidation by-products. The Rio Santa dry season discharge decline that is projected to be a consequence of glaciers retreat will probably have implications for the evolution of water pollution. This threat makes the characterization of the actual contamination mechanisms of primary importance.

The present study focuses on the spatiotemporal variability of the heavy metal contamination across the entire Rio Santa Watershed. During the summer 2013, 36 points of the Rio Santa watershed were sampled for filtered water, suspended sediments and riverbed sediments and analyzed for heavy metals. In addition, 30 water samples were taken from a point next to the city of Huaraz at a frequency of once every 2 weeks and analyzed for trace metals. Results show clear spatial and temporal variability in metal concentrations in water and sediments. Elements like iron exhibit an increase in concentration in the liquid phase during the wet season when others like zinc or manganese show the opposite behavior. During the dry season, water in tributaries in the upper part of the watershed is contaminated with arsenic, zinc and aluminium. In that area, concentrations up to 360 ppb of arsenic were measured in tributaries situated downstream of mines while The Rio Santa water showed a decreasing concentration of 15 ppb to less than 6 ppb from south to north. This reduction in liquid phase concentration being simultaneous to an increase concentration in river sediments suggests that, during the dry season, a large part of the arsenic that reaches the Santa in an aqueous phase does not make it to the outlet but remains trapped in the riverbed.

Title: Water coverage and quality fluctuations of the Aral Lake tributary reservoir in Kazakhstan

Presenter/First Author: Ongarbek Alipbeki, National Academy of Science of the Republic of Kazakhstan, Astana,

Presenter/First Author Email: o.alipbeki@gharysh.kz

Co-authors: Jay Sagin, Saskatchewan Polytechnic, Saskatoon, SK, Canada; Nurgul Kazangapova, National Academy of Science of the Republic of Kazakhstan, Astana, Kazakhstan

Abstract Body: Koksaray reservoir is one of the tributary reservoirs located on the Sur Darya River upstream of the Aral Lake in Kazakhstan. Sur Darya River has big seasonal fluctuations with a high amount of water release and flooding in the yearly spring and extreme shallow levels during the summer. Water coverage and quality fluctuations were studied over Koksaray by applying a combination of the Earth Observation Satellites (EOS) and field works in 2010-2014 years. High resolution German satellite RapidEye, Russians Recourse P and Meteor M satellite data were applied for this study. The water coverage fluctuations changes were traced from 457 to 44 km^2, or 10 times difference. Water pollution areas were also traced during these years. The future research work is planned with the data applications from EOS KazEOSat-1 and -2. The KazEOSat-1 is a high-resolution observation satellite, which was built by Astrium for the Space Company Garysh Sapary of the Republic of Kazakhstan. KazEOSat-1 satellite was launched in the first quarter of 2014 (KazEOSat-1 on 30 April 2014 and KazEOSat-2 is planned to be launched on 20 June 2015). KazEOSat-1 satellite provides high-quality panchromatic, 1 m, and four multispectral channels, 4 m, for a wide range of applications. KazEOSat-2 satellite provides medium-quality five multispectral channels, 6.5 m, for a wide range of applications. The current stage of the satellite's data applications for geomorphological research work is also to be discussed.

Abstract Body: Schuchinsk-Borovoye natural reserve is one of the most popular resort area and national park in North-East Kazakhstan. Flora and fauna is has been impacted from the increasing numbers of tourists in the park in the last decade. Lakes are under anthropogenic pressure with increasing pollution and deterioration of aquatic ecosystems. Over the past 35 years, the water level of lakes of Burabay resort area has decreased to 1.5-2 meters. The new islands have appeared on lakes Shchuchye and Ainakol. The water receded from the shore in some places up to 100 meters. These reservoirs are still not subjected to the proper support as the national park zones, as recommended by the UNESCO Biosphere Reserve Sustainable Development (http://www.unesco.org/new/en/natural-sciences/environment/ecological-sciences/biosphere-reserves/asia-and-the-pacific/kazakhstan/). We have studied surface and groundwater of the catchment area and the hydro-chemical changes in Lake Schuchye of the Shuchinsk-Burabaynatural reserve (SCHBKZ) over the past five years on the basis of an accredited chemical laboratory for the lakes environmental monitoring. The organic, oil pollution, and non-organic, heavy metal (Cи, Zn, Hg, Cd, Pb, Sn, Fe, Mn, Ag, CrCo, Ni, As, Al) and their salts were analyzed. The maximum permissible concentrations of petroleum products for the spring of the year 2009-2013 has exceeded by 4.6 time. Results of the Hydro-chemical studies of the Schuchinsk-Borovoye natural reserve will be presented during the conference. The future research work is planned with the data applications from EOS KazEOSat-1 and -2. The KazEOSat-1 is a high-resolution observation satellite, which was built by Astrium for the Space Company GaryshSapary of the Republic of Kazakhstan. KazEOSat-1 satellite was launched in the first quarter of 2014 (KazEOSat-1 on 30 April 2014 and KazEOSat-2 is planned to be launched on 20 June 2015). KazEOSat-1 satellite provides high-quality panchromatic, 1 m, and four multispectral channels, 4 m, for a wide range of applications. KazEOSat-2 satellite provides medium-quality five multispectral channels, 6.5 m, for a wide range of applications. The current stage of the satellite's data applications for the Schuchinsk-Borovoye natural reserve also will be discussed.

Title: The Influence of Glacial Landforms on Subsurface and Surface Hydrology and Chemistry Across a Heterogeneous Boreal Plain Landscape

Presenter/First Author: Kelly J Hokanson, University of Alberta, Edmonton,

Presenter/First Author Email: hokanson@ualberta.ca

Co-authors: Jaime J Carrera-Hernandez, Universidad Nacional Autonoma de Mexico, Mexico City, Mexico; Kevin J Devito, University of Alberta, Edmonton, AB, Canada; Craig Thompson, , , ; Carl A Mendoza, University of Alberta, Edmonton, AB, Canada

Abstract Body: The Boreal Plains (BP) region of Canada is experiencing high levels of anthropogenic activity and is highly susceptible to climate change. The BP is characterized by heterogeneous glacial landforms with large contrasts in storage and transmissivity, which when coupled with a sub-humid climate, results in complex groundwater-surface water interactions. Predicting the impacts of land use change, climate change, and the future performance of constructed landscapes is currently not possible due to our limited knowledge regarding the natural variability of water table fluctuations, geochemistry, and salinity across the various glacial landforms in the BP. In this study, we test the influences of the interactions between landform, geology, and climate on local and regional groundwater flow, recharge, and storage as well as address the variation in landscape connectivity and overall salinity distribution. We have collected hydrogeological, geochemical, and isotopic data that spans from 1998 to present, which includes both wet and dry climate cycles. Data were collected from surface waters to a depth of 40m, along a 50 km transect encompassing pond-wetland-forestland sequences across the major glacial depositional types typical of the BP (coarse textured glaciofluvial outwash, fine textured stagnant ice moraine, and lacustrine clay plain). Within each landform, sites range from isolated headwater complexes to large regional discharge complexes. High spatial variability of water table fluctuations and salinity illustrate the strong regional controls that geology exerts over scales of groundwater flow between landforms and surface water bodies across the BP. Fifteen years of isotopic data delineate 'isotopic landscapes' with characteristic water storage and transmission properties.

Title: Regional nutrient export modeling of the South Saskatchewan River catchment using SPARROW

Presenter/First Author: Luis Alejandro Morales-Marin, University of Saskatchewan, Saskatoon,

Presenter/First Author Email: luis.marin@usask.ca

Co-authors: Howard S. Wheater, University of Saskatchewan, Saskatoon, SK, Canada; Karl-Erich Lindenschmidt, Global Institute for Water Security, University of Saskatchewan, Saskatoon, Canada

Abstract Body: The South Saskatchewan River (SSKR) and the North Saskatchewan River forms the largest river system in western Canada. The SSKR catchment extension facilitates a variety of climates, topographies, soil types and land uses that form a highly heterogeneous environment. In the last years changes in the land use and new industrial developments in the South Saskatchewan River area have brought serious concerns about the future of water quality in the catchment and downstream waters. Agricultural activities have increased the supply of manure and fertilizer for cropping. Oil and gas exploitation has also increased the risk of surface water and groundwater contamination. The rapid population growth not only leads to increments in water consumption and wastewater, but in the construction of roads, railways and the expansion of new urban developments that impose hydraulics controls that affect the catchment hydrology and therefore the sediment and nutrient transport. Consequences of the actual anthropogenic changes have impacted Lake Diefenbaker aquatic ecosystem, where around 1229 tons yr^{-1} of nutrient are sequestrated. Although environmental agencies are constantly improving the mechanisms to reduce nutrient export into the river and ensure safe water quality standards, further research is needed in order to identify major nutrient sources and quantify nutrient export and also, with the aim of improve water quality sampling programs. The SPAtially Referenced Regression On Watershed (SPARROW) model is therefore implemented to assess water quality regionally, in order to describe spatial and temporal patterns to identify those factors and processes that affect water quality. The model is a suitable method to interpret monitoring data sets that suffer from network sparseness, bias and basin heterogeneity. Ultimately, the model will provide environmental agencies improved information for future water quality management practices and policies.

Title: Water Resource Futures Under Climate Change - Framing Uncertainty Within the Context of Vulnerability to Identify Risk

Presenter/First Author: Howard S. Wheater, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: howard.wheater@usask.ca

Co-authors: Ali Nazemi, University of Saskatchewan, Saskatoon, SK, Canada

Published Material: Mention can be found in the following three publications: (1) Nazemi, A. and H. S. Wheater (2014), Assessing the vulnerability of water supply to changing streamflow conditions, *Eos Transactions of American Geophysical Union,* 95(32), 288, doi: 10.1002/2014EOS320007. *(2)* Nazemi, A. and H. S. Wheater (2014), How can the uncertainty in the natural inflow regime propagate into the assessment of water resource systems? *Advances in Water Resources*, 63, 131-142, doi: 10.1016/j.advwatres.2013.11.009. (3) Nazemi, A., H. S. Wheater, K. P. Chun, and A. Elshorbagy (2013), A stochastic reconstruction framework for analysis of water resource system vulnerability to climate-induced changes in river flow regime, *Water Resources Research*, 49, doi:10.1029/2012WR012755.

Abstract Body: Estimation of potential impacts of climate change on water resources is of high societal importance, but conventional scenario-based estimation is subject to a cascade of models, each with high uncertainty. Uncertain socio-economic scenarios are used to drive uncertain global climate models, which are then downscaled to provide uncertain climate outputs at the scales of relevance for uncertain hydrological models, which can then be input to uncertain water resource systems models. Communication of the resulting overall uncertainty to water managers and other stakeholders is challenging; it is not unusual for not only the magnitude but also the sign of change in future resources to be uncertain. We present an alternative, and complementary, approach to the communication of risk. Analysis of the vulnerability of water resource systems to potential change is illustrated for a relatively complex, fully allocated water resource system in Alberta, Canada. Using a simple two-dimensional representation of potential changes in hydrology, water resource system vulnerability can be mapped onto a two-dimensional space, which clearly illustrates potential scenarios of concern. Conventional scenario-based estimates can be superimposed on the vulnerability map, to provide important insight into potential areas of future risk of system failure.

Title: Suppressed Convective Rainfall by Agricultural Expansion in southeastern Burkina Faso

Presenter/First Author: Marc B Parlange, Swiss Federal Institute of Technology Lausanne, Lausanne,

Presenter/First Author Email: marc.parlange@ubc.ca

Co-authors: Theophile Mande, Swiss Federal Institute of Technology Lausanne, Lausanne, Switzerland; Gabriel George Katul, Duke University, Durham, NC; Natalie C Ceperley, Swiss Federal Institute of Technology Lausanne, Lausanne, Switzerland; Scott W Tyler, University of Nevada, Reno, NV

Abstract Body: With the 'green economy' being promoted as a path to sustainable development and food security within the African continent, the conversion to agricultural land is proliferating at a rapid pace often replacing natural savannah forests. Where agriculture is primarily rain-fed, the possible adverse impacts of agricultural land influx on rainfall occurrences in water- limited areas such as West Africa are investigated. . Using field observations complemented by model calculations in southeastern Burkina Faso, the observation of a 10-30% suppressed rainfall recorded over agricultural fields when referenced to natural savannah forests are explained. Measurements and simulations reveal that the crossing of the mixed layer height and lifting condensation levels, a necessary condition for cloud formation and subsequent rainfall occurrence, was 30% more frequent above the natural savannah forest. This increase in crossing statistics was primarily explained by a larger sensible heat flux above the savannah forest rather than differences in lifting condensation heights.

Title: Examining why trends in extreme precipitation should not be mistaken for trends in extreme discharge

Presenter/First Author: Timothy Ivancic, SUNY College of Environmental Science and Forestry, Syracuse, NY

Presenter/First Author Email: tji11@case.edu

Co-authors: Stephen B Shaw, SUNY College of Environmental Science and Forestry, Ithaca, NY

Abstract Body: It is firmly established in the hydrologic literature that flooding is dependent on both antecedent moisture and precipitation. One could possibly phrase this relationship even more directly as "heavy precipitation does not necessarily lead to high stream discharge", but studies are rarely formulated in such a way as to directly affirm this statement. However, we have observed a number of non-hydrologists mistake trends in heavy precipitation as a proxy for trends in flooding. If indeed the relationship between heavy precipitation and high discharge (or lack thereof) was more often explicitly presented, heavy precipitation would possibly be less often misinterpreted as a direct proxy for discharge. We undertake such an analysis by directly evaluating the frequency in which 99th percentile precipitation events result in 99th percentile discharge events for 300 watersheds spread across the contiguous U.S. We found that 99th percentile precipitation only results in 99th percentage discharge 30% of the time. However - not unexpectedly - when conditioned on soil moisture, 99th percentile precipitation results in 99th percentage discharge 51% of the time during wet periods and 8% of the time during dry periods. This study suggests that especially when one is interested in relating trends in heavy precipitation to hydrologic response, precipitation data should be segregated based on concurrent soil moisture. Taking such an approach for future climate predictions, we found that CMIP-5 GCM projections forecast an increase in concurrence of greater than median soil wetness and extreme precipitation in the northern half of the United States and a decrease in the southern half. This suggests that northern regions may see an increase in very high discharges while southern regions may see a decrease despite both regions having predicted increases in extreme precipitation.

Title: Novel Supervised Nonlinear Dimensionality Reduction Techniques for Improvement of Statistical Downscaling Processes

Presenter/First Author: Ali Sarhadi, University of Waterloo, Waterloo,

Presenter/First Author Email: alisarhadi2005@gmail.com

Co-authors: Donald H Burn, Professor, Waterloo, ON, Canada; Chad William Thackeray, , ,

Abstract Body: Statistical downscaling approaches relying on developing a statistical and quantitative relationship between large-scale atmospheric variables and fine scale hydro-climate variables at particular sites have gained popularity for predicting climate change impacts on hydro-climate variables. Due to the complexity of climate-associated processes, one of the main challenges in development of the statistical downscaling approaches for climate change projection is identification of predictor variables from high dimensional atmospheric variables conveying climate change information with respect to the hydro-climate variable of interest. Due to the inherent complexity, nonlinearity, and interdependency among explanatory large-scale atmospheric parameters, using conventional unsupervised linear dimensionality reduction methods leads to unsatisfactory predictive performance of data-driven models in statistical downscaling. To improve the performance of the machine learning-based models, the present paper proposes a new approach to supervised dimensionality reduction, which is called "Supervised Principal Component Analysis (Supervised PCA)" for regression-based statistical downscaling with high-dimensional input data. This method is a generalization of PCA, extracting the principal components of atmospheric variables along which the dependency between target hydro-climate variable and projectors is maximized. Moreover, a dual formulation is derived for supervised PCA, which significantly reduces the high computational complexity of iterative optimization procedures. To capture the nonlinear variability between hydro-climatic response variables and projectors, a kernelized version of supervised PCA is also proposed for nonlinear dimensionality reduction. The effectiveness of the proposed supervised PCA method in comparison with some state-of-the-art algorithms for dimensionality reduction is evaluated for precipitation under a statistical downscaling process using two soft computing nonlinear machine learning methods, Support Vector Regression (SVR) and Relevance Vector Machine (RVM). The results indicate a significant improvement over supervised PCA methods in terms of performance and computational efficiency.

Title: Subsurface hydrological processes and surface irrigation management

Presenter/First Author: Jean Caron, Laval University, Quebec, QC

Presenter/First Author Email: jean.caron@fsaa.ulaval.ca

Co-authors: Vincent Pelletier, Laval University, Quebec, QC, Canada; Yann Periard, Laval University, Quebec, QC, Canada; Jonathan A Lafond, Laval

University, Quebec, QC, Canada; Silvio Gumiere, Laval University, Québec, QC, Canada

Abstract Body: Increasing world food demand will result in a higher proportion of agricultural production surfaces to be irrigated. With an increasing risk of water scarcity, irrigation water use efficiency need to be continuously improved. Subsurface hydrological processes and pedological features influencing them (drainage, leaching, presence of a compacted layer, root development) act at different spatial scales and are generally neglected in managing irrigation at the whole field scale, in absence of adequate identification and quantification of their influence. Real time GPS equipped monitoring tools now allow us to identify the effect of capillary rise, compacted zones or differential crop water uptake on the surface water potential and the consequent irrigation needs acting at different spatial scales. Ongoing research taken from surface and subsurface irrigated crops (lettuce and cranberry) indicates that important water savings (30 to 80%) and gain in water and crop productivity (50%) can be achieved by implementing procedures that take into account subsurface processes in managing surface irrigation of crops. Given these results, long-term efforts should be put to implement such approaches at the farm scale.

Title: Characterization of Field-Scale Water Balance Components at A Heterogeneous Prairie Field Site

Presenter/First Author: Xicai Pan, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: xicai.pan@usask.ca

Co-authors: Warren Helgason, University of Saskatchewan, Saskatoon, SK, Canada; Andrew M Ireson, University of Saskatchewan, Saskatoon, SK, Canada

Abstract Body: Understanding hydrological processes at different scales is essential for hydrological modeling, particularly in heterogeneous environments, such as the internally drained prairie basins, with high spatial variability in the snowpack and soil properties. A soil-weather monitoring system was installed at a pasture site in the Brightwater Creek sub-basin, near Saskatoon, Saskatchewan, Canada, to characterize field-scale water balance components during two continuous years with contrasting weather. In addition to traditional meteorological measurements, intensive transect surveys of snowpack, vadose zone soil water content and groundwater were conducted within the footprint of a flux tower (around 500 m). Through quantifying the field-scale water balance, some interesting results were found. During the snow accumulation period, snow redistribution happened at sub-field-scale and over-field-scale due to overcatch of patterned vegetation compared to surrounding stubble field. During the melt period, snowmelt and rainfall leads to surprisingly high infiltration into the vadose zone of glacial till. The features of spatiotemporal storage dynamics indicate existence of unique flow paths at the study site. These would of great interests for prairie hydrological modeling.

Title: Scale-classification of water table response in a low-gradient Prairie watershed

Presenter/First Author: Genevieve Ali, University of Manitoba, Winnipeg, MB

Presenter/First Author Email: Genevieve.Ali@ad.umanitoba.ca

Co-authors: Halya Petzold, University of Manitoba, Winnipeg, MB, Canada; Amber R Penner, University of Manitoba, Winnipeg, MB, Canada

Abstract Body: While shallow subsurface stormflow has been found a major contributor to runoff generation in many temperate, moderate to high-relief catchments, its importance in low-gradient environments remains unclear. Our objective was therefore to characterize the water table-runoff relationship in low-gradient, Canadian Prairie landscapes by (1) deriving a range of metrics of water table response, and (2) inferring the presence of various runoff processes from those metrics. The focus was on the Catfish Creek Watershed (Manitoba, Canada), which drains 642 km^2 of forest and agricultural land. Nine different riparian areas were selected to illustrate a range of land use conditions (e.g., forest, shrub or bare land cover), upslope accumulated areas and human landscape features (e.g., dykes). Each riparian area was equipped with three, 1.5 m deep water-table wells and paired with a stilling well in the adjacent stream, recording data every 15 minutes in 2013 and 2014. For each site, hydrological events were delineated and the stream response compared with the water table response. Specifically, several metrics of event-scale water table response were computed, notably the pre-event water table depth, the maximum water table rise, the rates of water table rise and recession, the time lag from the initiation of precipitation to the maximum well response, and an hysteresis index quantifying the delay in response between the water table and the stream. Preliminary analyses show that the metrics were highly variable among sites. The metrics also suggest different event conditions leading to either saturation-excess overland flow, local subsurface flow or more widespread translatory flow as the dominant runoff process in the riparian areas. Some of the metrics portraying hysteresis or recession characteristics were markedly different between short and longer events, thus reflecting a scale-dependence effect on soil hydrology.

Title: Recent Advances in Monitoring of the Unfrozen Soil Water in the Source Area of the Yellow River, China

Presenter/First Author: Dongliang Luo, Cold and Arid Regions Environmental and Engineering Research Institute, Chinese Academy of Sciences, Lanzhou,

Presenter/First Author Email: luodongliang@lzb.ac.cn

Co-authors: Huijun Jin, Cold and Arid Regions Environmental and Engineering Research Institute, Chinese Academy of Sciences, Lanzhou, China; Lanzhi Lv, , ,

Abstract Body: Recent permafrost degradation in the Source Area of the Yellow River (SAYR) is obviously manifested by reduction in areal extent from continuous and discontinuous to sporadic and patchy, thinning of permafrost, and expansion of taliks. On this account, substantial transformation of surface and subsurface hydrological cycles have occurred. Therefore, the water yielding and runoff mechanism caused by ground ice-water phase change in permafrost is needed to be clarified. To investigate the trends in changes of climate, permafrost, and water resources in the SAYR, we built a monitoring network of permafrost-hydrology in the SAYR. This monitoring network includes three automatic meteorological stations, and ten active layer profiles. It is set up in consideration of elevation, landscape, and hydrology and vegetation conditions. The elevation of these sites range from 4320 m to 4720 m. The monitoring elements including the air temperature, air humidity, precipitation, radiation, and unfrozen soil moisture content, and soil temperature, and so on. Sensors with accuracy of 0.05 °C made and calibrated by the State Key Laboratory of Frozen Soil Engineering, Chinese Academy of Sciences, were set up to monitor the thermal regimes of the active layer at depths of 5 cm, 20 cm, 40 (50) cm, 80 cm, 100 cm, 120 cm, 160 cm, 200 cm, 250 cm, respectively. The CS616, with resolution of 0.1% v/v and accuracy of 3.0% v/v, were set up at comparable depths of soil temperature to monitor the unfrozen soil moisture content. All these observation elements were collected and recorded hourly or half-hourly by the CR3000 data loggers made by the Campell Scientific Inc. Additional field work including testing soil texture and measuring soil dry bulk density were carried out during the excavation of the profiles. Preliminary results demonstrate that yearly dynamics of unfrozen soil moisture content in the active layer strongly depending on the freezing and thawing processes of the soils, as well as infiltration of rainfalls and melting snow, particularly during the onset and finishing of the thawing and freezing periods. The content of soil moisture varied greatly with the diversity of ground surface condition and soil textures. These data could facilitate the research on evolutions of environments and response of permafrost to climate change in the SAYR.

Title: Groundwater Flow System in a Permafrost Area in the Upper Reaches of Heihe River

Presenter/First Author: Yalu Hu, China University of Geosciences Wuhan, Wuhan,

Presenter/First Author Email: yaluhu1990@hotmail.com

Co-authors: Wenle Xing, China University of Geosciences Wuhan, Wuhan Shi, China; Rui Ma, China University of Geosciences Wuhan, Wuhan, China; Ziyong Sun, China University of Geosciences, Wuhan, China

Abstract Body: Heihe River is the second largest inland river in China, and the permafrost zone in the upper reaches is a main water flow producing region for Heihe River. However, few hydrogeological investigations were conducted and understanding about groundwater flow system in the source areas of major rivers reminds almost blank. This study aims to characterize the groundwater flow system in a typical permafrost zone at Hulugou catchment in the upper reaches of Heihe basin. A hydrogeological approach was used based on the integration of hydrogeological survey, field drilling, groundwater level and temperature data monitoring. In the summer of 2014, 21 boreholes were drilled at four sites, separately located at seasonally frozen zone and permafrost zone. At each site, 5 to 7 boreholes with different depth were drilled and the deepest one was as deep as 30m. Taking this method of drilling is to monitor subsurface ground temperature and take groundwater samples at different depth. Data shows that seasonally freezing zone mainly distributed in the piedmont plain of the catchment, where the altitude is below 3,400 meters above sea level. From June to October, groundwater flow system is mainly affected by the porosity and permeability of sediment layers at this area. Water within 2 meters below ground surface has become frozen in the winter and functioned as impermeable layer for infiltration recharge. Permafrost is mainly distributed in the mountainous area above 3,400 m above sea level. The temperature-log data shows that the depth between 2m and 17m below the surface is freezing layer and the depth between 0m to 2m is active layer, which leads to a weak hydraulic relationship between supra- and sub- permafrost water. The supra-permafrost water table in active layer is near ground surface in summer. During and after the precipitation events, the water table increases and reaches to the ground surface, and is likely to produce surface runoff. Unfrozen layer under the base of permafrost is with low soil moisture. More hydrogeochemical and isotopic data has been collected to further identify the origin of the sub-permafrost water, and groundwater and surface water interaction. The seasonal freezing and thawing process has significant impacts on groundwater flow and its contribution to Heihe River.

Title: Modeling the Impacts of Soil, Vegetation and Climate on Evapotranspiration and Groundwater Recharge during 2001-2010 on the Chinese Loess Plateau

Presenter/First Author: Wei Hu, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: huweihw@gmail.com

Co-authors: Bing Si, University of Saskatchewan, Saskatoon, SK, Canada

Abstract Body: Knowledge of spatio-temporal soil water balance over the Chinese Loess Plateau (CLP) is crucial to optimizing land uses for sustainable development. Daily evapotranspiration (ET) and groundwater recharge (GR) at 58 sites on the CLP during 1981-2010 was simulated using the HYDRUS-1D model. The impacts of soil, climate, and vegetation on annual ET and GR during 2001-2010 were explored. Both the annual ET and GR generally decreased from the southeast to the northwest, with annual ET ranging from 14.3 cm (105% of precipitation (P)) to 59.5 cm (82% of P) and annual GR from 0.0 cm to 14.3 cm (18% of P), respectively. The average simulated annual ET and GR were 39.0 cm and 2.4 cm over the CLP, contributing to 95.6% and 4.7% of annual P, respectively. Annual evaporation (E) was twice greater than annual transpiration (T) due to the sparse vegetation in most areas of the CLP. Spatial distribution of ET was dominated by P followed by leaf area index (LAI) and potential evapotranspiration (ETp). Specifically, LAI played an equivalent control on T as P did. Groundwater recharge was also dominated by P, while it was not affected by the ETp and LAI at the region scale. Soil hydraulic properties also influenced the distribution of ET and GR, but their effects were much smaller compared to the climatic forcings. This work highlights the dominance of P on water flux at the regional scale on the CLP, providing a basis for eco-restoration and groundwater use scheduling.

Title: Abundance of earthworm species is influenced by the proximity to the tile drainage

Presenter/First Author: Habib Diop, Kansas State university, Manhattan, KS

Presenter/First Author Email: hdiop@ksu.edu

Co-authors: Joann K Whalen, , , ; Chandra Madramootoo, , , ; Aubert Michaud, , ,

Abstract Body: Earthworm burrowing affects water movement and nutrient transport in soil layers to a depth of more than 1 m, which is where subsurface tile drains are found. Subsurface tile drainage changes the soil moisture regime and is expected to alter the abundance as well as the composition of earthworm populations. The impact of tile drainage on earthworms will depend on soil properties, land use (cropping systems) and management. The objective of this study was to evaluate how earthworm abundance and composition was affected by the presence of subsurface tile drainage, and how the relationship was modulated by soil type and cropping systems at two farms in Southern Quebec. The spatial distribution of earthworms was considered in two 3m triangles located on top and between tile drain lines, which were the sampling points for earthworm collection by formalin extraction and hand sorting. We expect that earthworm species will respond differently to the presence of tile drain lines and anticipate an increase in earthworm populations above the tile drain lines, particularly of anecic species. The modulating effect of soil and land use on earthworm abundance and distribution gives us the opportunity to explain the spatial distribution pattern of earthworm species in this context. Knowledge about the number and distribution of earthworm species in relationship to tile drain lines permits us to draw conclusions about the potential contribution of earthworms to soil

porosity and solute movement in tile-drained fields, which could be important to avoid nutrient loss from agroecosystems with tile drainage.

Title: Quantifying the Impacts of 23-years of Warming and Drying Trends on Peatland/Upland Succession in Central Alberta

Presenter/First Author: Laura Chasmer, Wilfrid Laurier University, Waterloo, ON

Presenter/First Author Email: laura.chasmer@gmail.com

Co-authors: Chris Hopkinson, University of Lethbridge, Lethbridge, AB, Canada; Richard M Petrone, University of Waterloo, Waterloo, ON, Canada

Abstract Body: In this study we compare peatland ecosystem resilience (stability following climatic perturbations) using an index of evapotranspiration (ET) (EI) (actual ET/ precipitation) vs. dryness index (DI) (potential ET / precipitation)) and water yield within six heterogeneous upland/lowland catchments in the increasingly arid Central Boreal Plains (CBP) region of north-central Alberta from 1986-2009. The impacts of increased atmospheric drying over time within energy limited (DI < 1) and water limited (DI > 1) ecosystems and their resilience (or elasticity) is quantified using time series slope and residual analysis of the Normalize Difference Vegetation Index (NDVI) from Landsat TM combined with SRTM (Shuttle Radar) topographic positioning. This allows us to determine if ecosystems are experiencing long-term browning (declining NDVI trends), greening (increasing NDVI trends), resilience (recovery) or threshold (tipping point) change in boreal regions where NDVI is used as a spatio-temporal proxy indicator of ecosystem trajectory following annual atmospheric drying and catchment runoff. We find that catchments with low (detrended) topographic variability containing mostly peatland land cover types are highly resilient due to abundant water supply. Despite their resiliency, these catchments are characterised by declining water yield over the period of study and increased greening via succession of woody shrub and tree biomass into ~76% of peatlands. This indicates rapid loss and conversion to riparian/forest land cover types as peatlands dry. Meanwhile, catchments containing greater topographic variability have experienced increased water yields and declining NDVI trends during the same period. These catchments are typically water limited, highly sensitive to atmospheric warming and as such, have experienced significant browning (loss of chlorophyll, leaf cover) within 74% of upland treed and shrub peatlands with lagged recovery. A likely explanation for increased catchment yield coincident with reduced green foliage cover is a reduction in ET losses from upland land covers. The results of this study indicate that wide-spread browning trends observed in parts of the central boreal forest are complicated by energy-/water-limited systems, spatio-temporal lags and underlying geology.

Title: Hydroclimatic Controls on Peatland CO_2 Exchange Following Adjacent Forest Harvesting on the Western Boreal Plain

Presenter/First Author: Janina Plach, University of Waterloo, Waterloo, ON

Presenter/First Author Email: janinaplach@gmail.com

Co-authors: Kevin J Devito, University of Alberta, Edmonton, AB, Canada; Richard M Petrone, University of Waterloo, Waterloo, ON, Canada

Abstract Body: The Boreal forest of the Western Boreal Plains (WBP) is experiencing extensive land use changes from industrial expansion and deforestation. Potential alterations to surrounding hydrology and microclimate as a result of upland forest harvesting may threaten the ecosystem function of hydrologically connected-peatlands that are ubiquitous across the region, including the sequestration of greenhouse gases i.e. carbon dioxide (CO_2). Predicting the potential impact of deforestation on adjacent peatland CO_2 source/sink functionality requires comparison of peatland hydrology, microclimate and carbon exchange dynamics following tree removal relative to undisturbed ecosystems under natural climate variability. As such, the objectives of this study were to investigate: (1) Net Ecosystem Exchange (NEE) (i.e. CO_2) of undisturbed peatlands during the snow-free period; (2) the relative impact of upland forest harvesting on adjacent peatland NEE, including the hydrologic and microclimatological controls on this exchange; and (3) estimate the sustainability of WBP peatlands' functionality as a CO_2 source/sink in context of periodic land use disturbances. Growing season peatland CO_2 exchange was modelled in two neighbouring forest upland-peatland complexes over a four-year period (2005-2008) in the Utikuma Region Study Area of Alberta within the WBP. The forested upland area of one complex was harvested between 2007 and 2008, and the adjacent peatland was evaluated for potential shifts in NEE relative to the peatland in the undisturbed complex. These results, linked to changes in peatland hydrology (e.g. water table, soil moisture) and microclimate (e.g. wind speed, vapour pressure deficit, evaporation), as well as the implications for future forest harvesting in the region will be discussed.

Title: Trembling Aspen (*Populus tremuloides*) Transpiration and Recovery Post-fire Disturbance in the Western Boreal Plains of Alberta

Presenter/First Author: Midori Depante, University of Waterloo, Mississauga,

Presenter/First Author Email: mdepante@uwaterloo.ca

Co-authors: Richard M Petrone, University of Waterloo, Waterloo, ON, Canada; Kevin J Devito, University of Alberta, Edmonton, AB, Canada; Nicholas Kettridge, University of Birmingham, Birmingham, United Kingdom; James Michael Waddington, McMaster University, Hamilton, ON, Canada

Abstract Body: The Western Boreal Plains of Canada (WBP) is characterized by a sub-humid climate where evapotranspiration often exceeds precipitation, highlighting the importance of the interactions between peatlands that hydrologically feed uplands. The connectivity between both land units can also be attributed to trembling aspen (*Populus tremuloides*) clones and rooting systems that aid in hydraulic redistribution, though this process has not been linked to aspen roots found in peatlands. The objectives of this study are: 1) to understand why aspen, an upland tree species, exist in peatlands post-fire, and 2) to determine the contribution of aspen roots in peatlands to the early recovery of burned sites in the WBP. Aspen leaf stomatal conductance was measured daily across a burned upland-peatland gradient in the Utikuma Research Study Area (URSA) in north central Alberta two years post-fire. Aspen transpiration (mm s^{-1}) in peatlands was particularly of interest since they are not known to establish in peat after disturbance. In the same plots, plant tissue and soil was also collected and analyzed for 18-oxygen ($\delta^{18}O$) and deuterium (δ^2H) composition to determine the water source for regenerating aspen. While usually stressed in waterlogged soils, the results showed that aspen transpiration did not significantly differ across each land unit regardless of differences in leaf area and soil moisture. Furthermore, $\delta^{18}O$/ δ^2H signatures of pore water and plant tissue of aspen found in peatlands indicate the uptake of peat water through aspen rooting systems and hydraulic redistribution to the adjacent land units. Although the long-term effect of aspen transpiration and water usage in peatlands remains unknown, this study demonstrates that aspen can

withstand wetland soils which aids in the hydrologic connectivity between peatlands and uplands needed during the early recovery of naturally and anthropogenically disturbed sites.

Title: Assessment of the evaporation rates of pools, strings and lawns of a boreal patterned fen

Presenter/First Author: Alain N Rousseau, INRS-ETE, Neuville, QC

Presenter/First Author Email: alain.rousseau@ete.inrs.ca

Co-authors: Gwenael Carrer, , , ; Daniel F Nadeau, INRS - ETE, Quebec City, QC, Canada; Silvio Gumiere, Laval University, Québec, QC, Canada; Sylvain Jutras, , , ; André St-Hilaire, Institut National de la Recherche Scientifique - centre Eau, Terre et Environnement, Quebec city, QC, Canada

Abstract Body: In northern landscapes, the hydrological budget is largely influenced by evaporation (*E*), particularly in boreal watersheds where peatland is a predominant land cover. To improve the hydrological modelling of boreal watersheds, a better estimation of this term is required. The summer *E* variability of pools, strings and lawns of a patterned fen (3.6 ha) was assessed using 26 small lysimeters. To investigate the impact of water table depth on *E*, direct (weighing lysimeters) and indirect (automated lysimeter) methods were used during the snow-free period (June to October). Results indicated that *E* rates from pools, strings and lawns did not vary significantly throughout the fen. At the peatland scale, atmospheric conditions seemed to govern *E* more than the type of land cover. These results suggest that discriminating each land cover in the *E* budgets is not required and a mean value may be sufficient. A significant impact of water table depth on *E* was observed in *Sphagnum* lawn. Indeed, a rapid decline in *E* was monitored in the first 100 mm of peat. This decline was in all likelihood due to limited upward fluxes of water from saturated layers, which was limited by the low unsaturated hydraulic conductivity of the peat layers. The monitored *E* was consistent with previous values and a depth-dependent *E* relationship could be used in future hydrological modelling. The findings of this field work further validated the use of the classical Priestley-Taylor equation for patterned fens and demonstrated the potential of using an automated lysimeter in remote locations.

Title: The Transport and Hydrological Response of Simulated Wastewater from a Continuous Point Source in a Northern Ribbed Fen

Presenter/First Author: Colin Patrick Ross McCarter, University of Waterloo, Waterloo,

Presenter/First Author Email: cmccarte@uwaterloo.ca

Co-authors: Jonathan S Price, University of Waterloo, Waterloo, ON, Canada

Abstract Body: To minimize the discharge of wastewater contaminants from remote northern communities and mining operations, fen peatlands in sub-arctic regions are used for tertiary wastewater treatment to detain, transform, and remove these contaminants. However, there is a limited understanding of contaminant transport in fen peatlands, particularly in sub-arctic Canada. To better characterize contaminant transport in these systems, approximately 44 m^3 day^{-1} of simulated wastewater (concentrated custom-blend fertilizer and Cl^- diluted with water) was pumped into a small 0.5 ha sub-arctic northern ribbed fen continuously for 47 days (July 15th – August 31st 2015). Electrical conductivity (EC) of 3 similar northern ribbed fens varied between 15 (min) and 88 (max) µm cm^{-1} over the study period (May – September 2015). Water table quickly increased (~0.16 m in 6 days) nearest the point source (8 m down-gradient), resulting in rapid solute transport, as measured by electrical conductivity (EC) (20 to140 µm cm^{-1} in 11 days). This rapid transport was due to the large increase of hydraulic conductivity (~2 to180 m day^{-1}) as the water table rose. More gradual increases in water table (0.18 m in 13 days) and EC (140 µm cm^{-1} in 15 days) were observed farther (~50 m) from the point source; this delay was likely due to increased total storage capacity rather than differences in hydraulic conductivity. After 34 days the water table had risen on average 0.16 m across the site, but EC (113 µm cm^{-1} in 25 days) was limited to a final distance of 119 m. Northern ribbed fens have a large capacity to detain wastewater as illustrated by the conservative solute plume only travelling 49 % of the total site length (notwithstanding the large increase in hydraulic conductivity as the water table rose) and have the potential to significantly decrease wastewater contamination in northern aquatic environments.

Title: Analyzing the Impacts of Road Construction on the Successional Trajectory of a Poor Fen in Northern Alberta.

Presenter/First Author: Emma Bocking, University of Waterloo, Toronto,

Presenter/First Author Email: ecbockin@uwaterloo.ca

Co-authors: Jonathan S Price, University of Waterloo, Waterloo, ON, Canada; David J Cooper, Colorado State University, Fort Collins, CO

Abstract Body: Roads that bisect wetlands can alter their hydrologic connectivity on a local or landscape scale. These impacts were studied in a poor fen located 45 km south of Fort McMurray, Alberta, where a raised road was built across the northern fringe of the fen in 1977. Examination of the fen's response to this impoundment provided insight into post-disturbance vegetation succession patterns and peatland development. The objectives of this study are to quantify the impacts of the road on fen vegetation composition and microtopography, and to predict its successional trajectory based on current vegetation and hydrology. To quantify the impact of the fen, vegetation cover along with several abiotic variables were measured in 281 1 m^2 plots. In sixteen 50 m^2 transects, recent moss growth was calculated by measuring the depth to the root crown of black spruce trees, as the root crown's position represents the original ground level at time of germination. Density and age of saplings were also measured in these transects. Analysis of vegetation reveals dominance of non-hummock forming species (such as *Carex aquatilis*) closest to the culvert (located in the NW corner). The average depth of recent moss growth was greater immediately up-gradient of the road (36.2 cm) compared with undisturbed areas (19.7 cm). There were no saplings near the culvert, very few within 220 m up-gradient of the road (12% of total trees), and many saplings in the transects furthest from the road (57%). These data suggests that periodic blockage of the culvert leads to flooding in the immediate area that encourages non-hummock forming species of sedge and moss, making an unfavourable environment for black spruce germination. This cycle of hydrologic disturbance may be preventing some areas of the fen from regaining the original vegetation structure, with implications for the system's development.

Abstract Body: Twelve significant Ni-Cu-PGE occurrences are recognized in the Nancy magmatic feeder and subconcordant sills of the LKU. Mineralization occurs as disseminated to net-textured to massive sulfides hosted in ultramafic rocks and within the adjacent country rocks. The high metal tenors (>20% Ni and 20 g/t PGE) combined with the presence of MgO-rich komatiites that exhibit evidences of interaction and contamination with surrounding S-rich country rocks testify the potential of the VGB to host additional Ni-Cu-PGE mineralizations.

First Author Student?: No

Published Material: Aspects of this work were presented as part of an invited review talk at the Geological Society of America Annual Meeting in Vancouver (Canada) in October 2014.

Abstract Body: Mafic layered intrusions preserve stunning rock records of the processes by which magma evolves in crustal magma chambers. They host major resources of Cr-Ni-Cu-V and platinum group elements (PGE), including the two world-class PGE reef-type deposits, the Merensky Reef in the Paleoproterozoic Bushveld Complex and the J-M Reef in the Neoarchean Stillwater Complex. Accurate and precise dates are needed to establish how different parts of layered intrusions are related to each other, including defining genetic relations with their contained ore bodies. Surprisingly, the classic layered intrusions in petrology (e.g., Stillwater, Bushveld, Muskox, Skaergaard) do not yet possess robust geochronological frameworks. Dateable accessory minerals, predominantly zircon, are typically present in minute quantities (10s to 100s of grains per 10-20 kg of sample), which is sufficient to provide high-precision geochronologic results. Heterogeneous textures and macroscopic evidence for interstitial minerals that crystallized from evolved interstitial melt at near-solidus temperatures are key criteria for selecting prospective samples. As part of larger chronostratigraphic studies of the Bushveld and Stillwater complexes, we have successfully determined the ages of a wide range of mineralized samples, including basal Ni-sulphide mineralization, chromitite horizons, and the PGE reefs. Our U-Pb geochronological results indicate that (1) these two major layered intrusions formed incrementally over millions of years, (2) distinct time gaps or magmatic hiatuses are recorded in their respective stratigraphic successions of cumulates, and (3) ages do not systematically decrease with increasing relative stratigraphic position (i.e., some older units are bounded by younger rocks). These extended magmatic time spans for large mafic-ultramafic layered intrusion and their associated ore deposits are remarkably similar to those recognized in intermediate to felsic plutonic and volcanic systems.

Title: Extreme Variations in ɣOs, on the Thin Section Scale in Laurites from Chromite Layers from Stillwater Complex: Implications for the Origin of Laurite and the Representativeness of Whole Rock ɣOs.

Presenter/First Author: Laurene Wavrant, Sciences de la Terre, Université du Québec à Chicoutimi (UQAC), Chicoutimi,

Presenter/First Author Email: laurenemariewavrant@gmail.com

Co-authors: Sarah-Jane Barnes, Université du Québec à Chicoutimi, Saguenay, QC, Canada; Philippe Pagé, Sciences de la Terre, Université du Québec à Chicoutimi (UQAC), Chicoutimi, Canada; Norman Pearson, Macquarie University, Sydney, Australia; William L Griffin, Macquarie University, Sydney, Australia

Abstract Body: The origin of massive chromite layers in large layered intrusions and their role in collecting Platinium-Group Element (PGE) is poorly understood. There have been a number of studies based on whole rock geochemistry and whole rock isotopic systems, including Re-Os, which conclude that contamination of a primary magmas with crustal component played a key role in the formation of the chromite layers.

The Re-Os isotopic system is particularly appropriate for examining the origin of PGE enrichment because Os is a PGE and is enriched in chromite layers. In the case of Stillwater Complex (Montana, U.S.A) chromite layers, the host of the Os is laurite which is generally enclosed in chromite. In order to eliminate contributions of alteration and metamorphism from interstitial phases, we applied a new approach based on Os isotopes in-situ analyses on laurite by LA-MC-ICP-MS. The ɣOs obtained are variable, from sub-chondritic to radiogenic, and are surprisingly variable at the thin section scale (ɣOs = -2 to 7) and raise question about the representativeness of ɣOs from whole rock studies. These results imply mixing between at least two components. The first is chondritic to subchondritic and indicates a mantle derived source. The second is supra chondritic and implies a crustal component.

Three models may explain these results: the laurites represent i) transported residual mantle xenocrysts, ii) phenocrysts that have crystallized from magma variably contaminated “en route” to emplacement, iii) the products of Os and Ru diffusion from chromite into base metal sulfides. In this latter case unradiogenic composition may reflect chromite-derived signature whereas radiogenic composition could represent a sulfide-dominated component.

Title: Sulfide Distribution and Oxygen Isotopic Variation Within the J-M Reef, Stillwater Complex, Montana

Presenter/First Author: Matthew Lilley, Indiana University Bloomington, Bloomington, IN

Presenter/First Author Email: mlilley@indiana.edu

Co-authors: Edward Ripley, Indiana University, Bloomington, IN; Chusi Li, Indiana University, Bloomington, IN

Abstract Body: The Stillwater Complex of Montana is host to one of the world's premier platinum-group element (PGE) deposits, the J-M Reef. The J-M Reef is found in what is known as olivine-bearing zone I (OB I) of the Lower Banded Series of the Complex. The Reef averages 1 to 3 m in thickness and occurs over 40 km of strike length (Todd et al. 1982). Rock types present within the Reef include dunite, troctolite, norite, and anorthosite. PGE concentrations strongly correlate with sulfide abundance. The origin of the J-M Reef remains controversial, and theories are broadly divided between those which favor downward collection of PGE-bearing immiscible sulfide liquids (e.g. Campbell et al., 1983) and those that favor an upward accumulation of PGEs controlled by magmatic hydrothermal fluids (e.g., Boudreau and McCallum, 1992). In addition to the very high concentration of Pd in the Reef, the distribution of PGE-rich sulfides remains enigmatic. We have examined interfaces between sulfide-bearing units of the J-M Reef and sulfide-poor units above, below, and within the Reef itself. PGE-rich and sulfide-rich lenses show vertical separation as well as horizontal discontinuities. The downward extent of the mineralization is defined by the presence of sulfide minerals and is not controlled by variations in host lithologies. Neither downward drainage of immiscible sulfide liquid through a fractionation/differentiation sequence nor upward fluid infiltration can readily explain these features.

Some of the distribution of sulfide minerals in the Reef and associated ballrooms may be a function of low-T hydrothermal fluid mobilization (e.g. Godel and Barnes, 2008). Oxygen and hydrogen isotopic studies show that the J-M Reef behaved as a horizon of relatively high permeability compared to other stratigraphic units in the Complex. The presence of plagioclase with $\delta^{18}O$ values as low as 4.0 ‰ and olivine with normal mantle values of 5.4 ‰ suppressed to 4.8 ‰ when partially serpentinized are indicative of kinetically controlled oxygen isotopic exchange between minerals and a low-temperature and low-^{18}O fluid. The elevated concentrations of Pd in pentlandite (5.6 to 9.8 wt. %) associated with the desulfurization of braggite and cooperite to isoferroplatinum-sulfide intergrowths indicates that Pd was transported within late-stage fluids.

Title: Multiple Sulfur Isotope Studies of the Stillwater Complex, Montana

Presenter/First Author: Anne Michelle Ayre, Indiana University Bloomington, Billings, MT

Presenter/First Author Email: anne.ayre1@gmail.com

Co-authors: Edward Ripley, Indiana University, Bloomington, IN; Chusi Li, Indiana University, Bloomington, IN

Published Material: I presented a portion of my data at the 11th International Platinum Symposium.

Abstract Body: Models for the genesis of the J-M Reef of the Stillwater Complex include magma mixing and the attainment of high R-factors to produce PGE-rich immiscible sulfide droplets (e.g., Campbell et al., 1983), leaching of trace sulfides in the Ultramafic Series and concentration at the level of the Reef by magmatic fluids (e.g., Boudreau and McCallum, 1992; Boudreau and Meurer, 1999), and the emplacement of PGE-rich magmas that had been upgraded via sulfide dissolution at depth (e.g., Keays and Lightfoot, 2013). In order to better evaluate the extent to which crustal sulfur was key for PGE enrichment we have initiated a multiple sulfur isotope study of the Complex. The work compliments the early S isotope studies of the Complex by Zientek and Ripley (1990), but the utilization of both ^{33}S and ^{34}S permits the detection of deviation from the terrestrial fractionation line that may be due to assimilation of S from Archean country rocks and was previously undetectable.

We have measured $\Delta^{33}S$ values for samples of country rocks and sulfides within country rocks, as well as rocks of the Reef Package in the area of the Stillwater Mine. $\Delta^{33}S$ values for both massive sulfides in country rocks and pyroxene-hornfels below the Basal Series range from 0 to 0.25 ‰. $\delta^{34}S$ values generally range from -1.3 to +1.3 ‰, with one massive sulfide sample having a value of 3.9 ‰ Samples of sulfides from the J-M Reef have $\delta^{34}S$ values from -1 to +1.5 ‰. J-M Reef samples have $\Delta^{33}S$ values from 0.005 to 0.05 ‰. The $\Delta^{33}S$ values of sulfides so far measured from the J-M Reef are not considered to be anomalous, however the range of sulfur isotopic values found in the metasedimentary country rocks does not preclude a contribution of country rock sulfur to the magmas that produced the Stillwater Complex. The relative uniformity of $\Delta^{33}S$ values in the igneous rocks of the Reef is consistent with no country rock contribution of sulfur, and exclusive incorporation of mantle S or, alternatively, contribution of country rock S characterized by similar $\Delta^{33}S$ values. A multi-component mixing process involving sulfur from various country rocks and that of mantle derivation remains feasible. Samples of Archean gneisses and other intrusive rock types are being analyzed to further constrain the involvement of country rock S in the formation of the J-M Reef.

Title: Setting and Style of VMS Mineralization in the Eastern Goldfields Superterrane, Western Australia: Insights from the Ag-Zn-(Au) Nimbus Deposit

Presenter/First Author: Steven Philip Hollis, CSIRO Earth Science and Resource Engineering Perth, Perth, WA

Presenter/First Author Email: steven.hollis@csiro.au

Co-authors: Paul Gillespie, , , ; David Robert Mole, University of Western Australa, Perth, WA, Australia; Andrew Pumphrey, , , ; Stephen J Barnes, CSIRO, Perth, Australia; Alicia Verbeeten, , , ; Svetlana Tessalina, Curtin University, Perth, WA, Australia; Stephen Wyche, , , ; Christopher J Yeats, , ,

Abstract Body: Economic VMS mineralization in the Archean Yilgarn Craton of Western Australia is largely restricted to two main zones of juvenile crust as revealed through regional (Nd, Pb) isotope variations (Huston et al. 2014). Interpreted as Archean paleo-rift zones, one of these runs N-S through the central Eastern Goldfields Superterrane and is associated with the high-grade Teutonic Bore, Jaguar and Bentley deposits, plus sub-economic VMS mineralization further south at Anaconda and Erayinia. The Nimbus Ag-Zn deposit (4.9 Mt at 149 g/t Ag-eq) is located approximately 265 km south of Teutonic Bore, near the margin of this paleo-rift zone and 17km ESE of Kalgoorlie. The local stratigraphy comprises a NW-trending and steeply-dipping bimodal-felsic package of volcanic rocks (i.e. FI affinity quartz-feldspar porphyritic dacite and lesser basalt, plus their autoclastic equivalents) with subordinate carbonaceous black shale, chert and polymict conglomerates. Primary sulfide mineralization occurs as a series of stacked plunging lenses which parallel a mineral elongation lineation. Early well-developed massive pyrite is underlain by 1) semi-massive, stringer and breccia-type Ag-Zn±Pb(Cu-Au) sulfides (including: pyrite, sphalerite, galena, pyrargyrite, marrite, boulangerite, arsenopyrite, chalcopyrite and tetrahedrite) associated with the autoclastic top of a thick unit of dacite; and 2) stringer and disseminated sulfides (dominated by pyrite and sphalerite) in largely coherent pseudo-brecciated dacite at depth. Hydrothermal alteration is characterized by extensive and pervasive quartz-sericite-carbonate which becomes more intense towards mineralization. Compared to other VMS occurrences in the Yilgarn Craton, the Nimbus deposit is unusual in terms of its tectono-stratigraphic position, the geochemistry of its host sequence (i.e. FI affinity felsic volcanic rocks, ocean-plateau like low-Th basalts), mineralogy (e.g. low Cu-Au through most of the deposit, abundance of Ag & Sb sulfosalts) and alteration assemblages (e.g. lack of chlorite, presence of kaolinite at depth). Classification of Nimbus as a shallow-water and low-temperature VMS deposit with epithermal characteristics (i.e. a hybrid bimodal-felsic deposit), is consistent with its position near the margin of this paleo-rift zone.

Title: AURIFEROUS VOLCANOGENIC MASSIVE SULPHIDE, A NEW TYPE OF GOLD DEPOSIT IN THE GUIANA SHIELD?

Presenter/First Author: Guiraud James, University of Quebec at Montreal, Montreal, QC

Presenter/First Author Email: guiraud.james@courrier.uqam.ca

Co-authors: Alain Tremblay, GEOTOP, Montréal, QC, Canada; Michel Jebrak, UQAM, Montreal, QC, Canada; Pierre-Simon Ross, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, Canada; Lefrançois Rock, , ,

Abstract Body: In French Guiana, the “Montagne d’Or” gold mineralization (4.3 Moz Au at 1 g/t), property of Columbus Gold Corp., is hosted by the northern branch of the Proterozoic Paramaca Greenstone Belt (PGB). The PGB represents the remnant of a volcanic island-arc sequence formed between 2.18 to 2.13 Ga, during the Transamazonian orogeny. The main tectonic event has structured the two branches of the PGB, merging together along an E-W orientation, which there are surrounded by diverse intrusions and metamorphic complexes. The geological characteristics of the “Montagne d’Or” deposit contrast with those of other gold deposits of the area which comprise clastic-hosted, porphyry systems, shear zones, and lateritic enrichments.

The “Montagne d’Or” deposit is hosted by a bimodal volcanic and volcaniclastic sequence bounded to the south by a major E-W shear zone. These volcanic rocks are affected by a penetrative E-W trending and south-dipping regional schistosity. The rock sequence is facing south and is dominated by calc-alkaline felsic lithologies interbedded and interdigitated with tholeiitic mafic rocks cross-cut by transitional to calc-alkaline intrusives. Some mafic flows are pillowed and few graded felsic volcaniclastic sequences were found, indicating a submarine environment. The Au mineralization is associated with pyrite, pyrrhotite and chalcopyrite with minor sphalerite, magnetite and arsenopyrite. The sulphides show three distinct aspects, (1) stratiform disseminations, (2) stockworks or veinlets, and (3) structurally-transposed layers of semi-massive sulphides. Visible gold occurs within chlorite-sericite-rich zones and is spatially related to sulphides.

Based on these characteristics, the “Montagne d’Or” mineralization is thought to have a syn-genetic origin and is currently interpreted as the first occurrence of auriferous VMS in the PGB. However, remobilisation of sulphides may have occurred during metamorphism and tectonic deformation.

Title: CONSONORM_LG: a new method of norm and alteration indexes calculation for low grade metamorphic rocks altered by VMS related hydrothermal systems

Presenter/First Author: Lucie Mathieu, University of Quebec at Chicoutimi UQAC, Chicoutimi,

Presenter/First Author Email: mathiel@tcd.ie

Co-authors: Sylvain Trépanier, Mines Virginia, 300 Saint-Paul, suite 200, Québec, QC, Canada; Réal Daigneault, Centre d'études sur les Ressources minérales (CERM), Chicoutimi, QC, Canada

Abstract Body: The CONSONORM_LG provides a standardised solution to approximate metamorphic parageneses as well as indexes for estimating chemical and/or mineralogical changes induced by hydrothermal alteration. These indexes are particularly performant for identifying and quantifying the Fe-Mg, K and CO2 alterations common in VMS systems (Volcanogenic Massif Sulphides).

The CONSONORM_LG is designed for silicate, Fe-Ti oxides and/or carbonate-dominated rocks that may contain sulphides, and it approximates the main parageneses of metamorphic rocks for three temperature-pressure conditions of the green schist and lower amphibolite facies (cf. 2SV350, 2SV450 and 2AMP575 facies of the norm). For each of the facies modelled, the norm calculates silicate assemblages using an Al-Ca-FeMg-NaK tetrahedron that is a convenient way to represent a large amount of silicate assemblages. In addition to silicates, the CONSONORM_LG calculates several accessory minerals from minor elements, Fe-Ti oxides, sulphides from analysed sulphur and/or from analysed metals and carbonates from analysed CO2 or from normative CO2 estimated from the LOI using the NORMAT method. The CONSONORM_LG also calculates several alteration indexes to estimate Fe-Mg (cf. chloritization), Ca (cf. propylitic alteration), Na and K alterations (cf. sericitization, phyllic alterations) and Al relative gains (cf. argilization for example). Carbonatation indexes are also calculated using the amount of normative minerals formed by this type of alteration, i.e. carbonates, chlorite and muscovite.

During this presentation, the calculation sequence of the CONSONORM_LG will be presented and validated using published whole rock analyses and petrographic descriptions. Then, the alteration indexes provided by this normative method will be tested using several natural samples of alteration halos associated with VMS-type deposits.

Title: Geochemical Classification of Archean Volcanic Rocks in the Blake River Group, Abitibi Greenstone Belt, Québec

Presenter/First Author: Sarane Sterckx, Institut national de la recherche scientifique, Quebec City, QC

Presenter/First Author Email: sarane.sterckx@ete.inrs.ca

Co-authors: Pierre-Simon Ross, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, Canada; Jean Goutier, Géologie Québec, Rouyn-Noranda, QC, Canada

Abstract Body: The Archean Abitibi Greenstone Belt is one of the best places in the world to explore for volcanogenic massive sulphide deposits (VMS), with 810 Mt of ore known so far. The Blake River Group (BRG) in the Rouyn-Noranda area includes two important mining camps, Noranda and Doyon-Bousquet-LaRonde, representing together about 374 Mt. VMS deposits are partially controlled by stratigraphy and, for the BRG, few regional marker horizons are known. Therefore, an improved knowledge of the volcanic stratigraphy would be valuable, and a chemo-stratigraphic

approach could help, especially if combined with the large high-precision U-Pb geochronology dataset now available.

We have compiled more than 2000 complete geochemical analyses (major and trace elements) for the Québec side of the BRG. With such a large database, multivariate statistical analysis is needed to utilize the data to its full potential. The BRG has been divided into a number of volcanic formations. We have so far focussed on two of these, the Noranda formation (hosting many VMS deposits of the Noranda camp) and the Reneault-Dufresnoy. For each formation we first split the data into mafic-intermediate and felsic samples, and discard a few outliers. Then we use hierarchical clustering analysis to place samples into groups. Examination of spidergrams and extensive tests leads us to use the elements Th, Nb, La, Ti, and Yb for the hierarchical clustering analysis. These elements (except La) are known to be largely immobile during hydrothermal alteration and metamorphism. The dendrograms shows the hierarchy of clusters, and we decide on the optimal number of groups based on (1) geological/geographical consistency of the groups; (2) maximizing the differences between groups; (3) maximizing the similarity within groups. We interpret those groups as volcanic units having different geochemical signatures, an interpretation consistent with the stratigraphic polarity and the U-Pb data.

Title: Reconstruction and evolution of Archean intracaldera facies: the Rouyn-Pelletier Caldera Complex, Abitibi greenstone belt, Canada.

Presenter/First Author: Lyndsay Moore, University of Quebec at Chicoutimi UQAC, Chicoutimi, QC

Presenter/First Author Email: lyndsay.moore@uqac.ca

Co-authors: Réal Daigneault, Centre d'études sur les Ressources minérales (CERM), Chicoutimi, QC, Canada; Hannah M Aird, Duke University, Durham, NC; Neil Banerjee, Western University, London (Ontario), ON, Canada; Wulf U Mueller, Universite Quebec A Chicoutimi, Chicoutimi, QC, Canada

Published Material: This presentation is a summary of a paper that is currently under revision by the Canadian Journal of Earth Sciences.

Abstract Body: The internal architecture of modern subaqueous volcanic edifices is rarely exposed and when visible, is difficult to access. Vertically-dipping Archean strata allow for the study of synvolcanic structures and the internal organization of subaqueous volcanic complexes. The Abitibi greenstone belt in Canada, and specifically the Blake River Group, hosts numerous subaqueous volcanic centres including the Blake River megacaldera complex (BRMCC). Within the BRMCC are three previously identified caldera complexes: the host Misema Caldera and the nested and overlapping New Senator and Noranda Calderas. Of particular interest is the southern sector of the New Senator Caldera (SNSC) and its close association with the 54 Mt Horne Au-rich volcanogenic massive sulfide (VMS) deposit.

Detailed mapping of volcanic and intrusive facies, along with site-specific geochemical and geochronological analysis at selected outcrop localities throughout the SNSC show that the stratigraphy of the sector is composed of mostly subaqueous effusive mafic volcanic sequences with intermittent felsic events. With the use of available structural data and the geometry of synvolcanic faults and dykes, volcanic and intrusive facies are grouped into facies assemblages. These facies assemblages compose a volcanic complex known as the Rouyn-Pelletier Caldera Complex. This study predominantly focuses on the Basal and Central Intracaldera Facies Assemblages (BIFA and CIFA respsectively) but also characterizes the other facies assemblages and places the Horne deposit within the context of the complex.

Facies of the BIFA represent the terminal stages of seamount construction and compose the first caldera floor. Following emplacement of those facies, a trapdoor collapse event occurred, allowing for the emplacement of the ponded lavas in the western CIFA. Piecemeal-type faulting follows this event and permits the extrusion and intrusion of facies of the eastern CIFA; forming yet another caldera floor. The caldera complex continues to build and shallows and a shift to more explosive activity occurs. This shift is interpreted to be one of the final phases of activity and is represented by the volcanic facies of the Horne deposit.

Title: Volcanic Reconstruction of the Powderhouse Dacite in the Paleoproterozoic VMS Hosting Chisel Sequence, Snow Lake, Manitoba

Presenter/First Author: Vanessa Christine Friesen, Laurentian University, Sudbury, ON

Presenter/First Author Email: vfriesen@laurentian.ca

Co-authors: Margaret Engelbert, Laurentian University, Sudbury, ON, Canada; Michelle DeWolfe, Mount Royal University, Calgary, AB, Canada; Harold Lorne Gibson, MERC, Department of Earth Sciences, The Goodman School of Mines, Laurentian University, Sudbury, ON, Canada

Abstract Body: The Chisel sequence is a 3 -5 km thick succession of voluminous felsic volcaniclastic rocks that hosts six known volcanogenic massive sulfide deposits (VMS) in the 1.89-1.88 Ga Snow Lake arc assemblage. The VMS deposits occur at the boundary between the upper and lower Chisel sequences. The Powderhouse dacite is the uppermost unit of the lower Chisel sequence and constitutes the stratigraphic footwall to the Chisel, Chisel North, Lost, Ghost, and Lalor VMS deposits. The Powderhouse dacite is laterally discontinuous and is localized to the extent of the overlying VMS deposits.

The stratigraphy and structure of the Powderhouse has been established through detailed surficial mapping (1:25 to 1:1000), core logging, lithogeochemistry, and petrographic analyses. The most distinctive lithofacies is a massive, feldspar crystal-phyric felsic tuff containing 5 -10 % lithic dacitic clasts and 10 -20% tectonically flattened dark lapilli, interpreted to be juvenile vitric clasts. The juvenile lapilli, voluminous clastic material, and massive to poorly graded bedforms suggests that the Powderhouse was emplaced subaqueously as a mass flow. Subsidence occurred during the emplacement of the Powderhouse dacite as indicate by abrupt truncation (restriction) of facies and localized heterolithic breccia beds intercalated with these massive tuffs. The uppermost lithofacies of Powderhouse dacite is a unit that consists of well stratified, heterolithic, block-rich breccia intercalated with beds of fine tuff or siliceous finely laminated tuffs without breccia. The stratified sub-unit represents a hiatus in voluminous massive flow deposition that is contemporaneous with the emplacement of rhyolite domes and formation of the VMS deposits. The Powderhouse dacite is interpreted to be a product of voluminous pyroclastic eruptions, which along with concomitant subsidence, preceded the formation of VMS deposits.

Title: The Lower Lemoine Member of the Waconichi Formation, Abitibi Greenstone Belt, Chibougamau, Quebec: Implications for VMS Exploration

Presenter/First Author: Alexandre Richard Boulerice, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec,

Presenter/First Author Email: ABoulerice4817@Gmail.com

Co-authors: Pierre-Simon Ross, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, Canada; Patrick Mercier-Langevin, Geological Survey of Canada, Québec, Canada; Sylvain Lépine, Cogiter Resources Inc., Rouyn-Noranda, QC, Canada; Francois Leclerc, Ministry of Natural Resources and Wildlife, Val-d'Or, Canada

Abstract Body: The Abitibi greenstone belt (AGB) is host to some of the richest volcanogenic massive sulphide (VMS) deposits in Canada. Only one VMS deposit, Lemoine, has been mined in the Chibougamau district thus far with 0.76 Mt of ore averaging 4.2 wt % Cu, 9.5 wt % Zn, 4.6 g/t Au and 83 g/t Ag. It is hosted in the Waconichi Formation (Roy Group). This MSc study aims at better constraining subunits within the Lemoine Member of the Waconichi Formation, identify emplacement processes and reconstruct its volcanic architecture through field mapping, core logging, petrography and geochemistry.

The study area encompasses the eastern sector of the NE-trending Lower Lemoine Member, where it comprises the intrusive Marelle QFP, the intrusive to extrusive Alpha Rhyolite, the extrusive Lemoine Rhyolite, the intrusive Coco Lake Rhyolite, and the extrusive Lemoine Dacite, Lemoine Andesite and Hangingwall QFP. The Lemoine deposit, 4 km SW of the study area, was located on top of the Lemoine Rhyolite and was overlain by the Hangingwall QFP.

Observations made in the 2014 field season have provided further evidence for the complexity of the volcanic architecture in the study area. For example, the the Alpha Rhyolite was emplaced in two pulses, a first effusive phase on the seafloor quickly overlain by the Lemoine Rhyolite, and a second phase intruding the Lemoine Rhyolite. The early, effusive (lobe-hyaloclastite flow) portion of the Alpha Rhyolite is characterized by a strong chlorite-sericite alteration whereas the intrusive portion is unaltered, showing the strong control of volcanic facies on alteration distribution. Facies mapping and thickness variations provide evidence for the location of possible volcanic vents in the study area,. The location of volcanic vents coupled with the spatial distribution of the hydrothermal alteration help better understand VMS systems and define new vectors for exploration in the eastern sector of the Lower Lemoine Member.

Title: Contrasting the settings of seafloor massive sulfide deposits on the South Central Indian Mid-Ocean Ridge: Results of the Bundesanstalt für Geowissenschaften und Rohstoffe (BGR) INDEX 2013 cruise

Presenter/First Author: Harold Lorne Gibson, MERC, Department of Earth Sciences, The Goodman School of Mines, Laurentian University, Sudbury, ON

Presenter/First Author Email: hgibson@laurentian.ca

Co-authors: Ulrich Schwarz-Schampera, BGR Federal Institute for Geosciences and Natural Resources, Hannover, Germany; Michelle DeWolfe, Mount Royal University, Calgary, AB, Canada; Margaret Engelbert, Laurentian University, Sudbury, ON, Canada; Ralf Freitag, BGR Federal Institute for Geosciences and Natural Resources, Hanover, Germany

Abstract Body: The INDEX 2013 cruise mapped, in detail, four polymetallic seafloor massive sulfide (SMS) deposits located on the western (Sonne) and eastern flanks (Kairei, Edmond, Gauss) of the active, South Central Indian Mid-Ocean Ridge at water depths ranging from 2,440 to 3,300m; a fifth deposit (Score) was discovered along the latter. Altered sediments, hydrothermal crust, sulfide chimney debris and basalt talus cover the mound-like SMS deposits. Actively venting (up to 418˚C at Edmond) and extinct sulfide chimneys define “fields” on the mound surface; the deposits are typically copper-rich. Delicate, bladed Fe-Mn precipitates occur between pillows peripheral to the SMS deposits.

The active Kairei and Edmond, and inactive Gauss and Score SMS deposits occur on rift-parallel, fault-controlled ridges. The deposits formed on and are partly covered by deposits of coarse, blocky talus comprising blocks of fine-grained to aphanitic, olivine and plagioclase porphyritic basalt, typically mantled by centimetres of fine sediment; massive and pillowed basaltic lava are only exposed in fault scarp windows. There is no evidence of recent volcanism. The location of the SMS deposits along the flanks of structural ridges and their association with talus breccia devoid of glassy pillow components indicate that long-lived, ongoing tectonic unroofing of oceanic lithosphere along steep, ridge-parallel (and perpendicular) faults was accompanied by high-temperature hydrothermal activity, and that the faults acted as fluid conduits. In contrast, the hydrothermally inactive Sonne deposit occurs along the crest of an intact rift-parallel, pillow volcano. Variations in topography and bathymetry define two eruptive centres that attain their maximum height where they overlap immediately below the SMS deposit. Pillow lavas and glassy pillow-fragment talus without sediment cover indicate that the volcano is tectonically (volcanically?) active. The spatial coincidence of volcanic and hydrothermal vents at the Sonne SMS deposit is typical of ancient VMS deposits.

Title: *Importance of sample preparation, representivity, and reporting methologies for quantitative evaluation of precious metal mineralogy*

Presenter/First Author: Louis J Cabri, Cabri Consulting Inc., Ottawa, ON

Presenter/First Author Email: lcabri@sympatico.ca

Abstract Body: It is essential to use quantitative methods in evaluation of precious metal minerals and determining precious metal deportment, well-known to process and applied mineralogist, but this approach is under-appreciated by many, especially for those unfamiliar with study of crushed and sized representative samples. The majority of economic geology publications are still only based on study of metallic minerals in polished thin sections (PTS) that cannot be representative of the ore being described, but are then used in conjunction with bulk chemical assays to arrive at so-called mass balances and metal deportment. Precious metal mineral abundances are still being reported in terms of frequency percent or volume percent based on approximate length x width measurements. The increased access to automated SEM-based imaging systems give a false sense of reliability unless these are used by knowledgeable operators based on careful sample preparation and representivity, as well as evaluated by reconciling to chemical assays. Sample preparation, measuring techniques, and reporting of data, has been the subject of continual improvement over the last few decades. The presentation will focus on platinum-group minerals (PGM) and platinum-group elements (PGE), such as occur in mafic-ultramafic magmatic deposits.

Title: Experimental confirmation of high temperature silicate liquid immiscibility in multicomponent ferrobasaltic systems

Presenter/First Author: Tong Hou, China University of Geosciences Beijing, Beijing,

Presenter/First Author Email: thou@cugb.edu.cn

Co-authors: Ilya V Veksler, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam, Germany

Published Material: These findings are still under review by American Mineralogist (Minor Revision).

Abstract Body: Here we report the results of an experimental study aimed at testing the existence of stable, super-liquidus immiscibility between silica-rich and Fe-rich multicomponent melts at temperatures above 1100 °C. Four pairs of the potentially immiscible compositions were tested in a one-atmosphere gas-mixing furnace (Ar/H_2-CO_2 gas mixture) at 1150 and 1200 °C and at the oxygen fugacity corresponding to that of the QFM buffer. Pre-synthesized pairs of the silica-rich and Fe-rich starting compositions were loaded in Pt wire loops, fused separately at 1300 °C, then brought in contact and kept at constant experimental temperature for more than 24 hours. Three pairs of compositions out of four used in this study did not mix. Some temperature-dependent chemical re-equilibration was observed in the Fe-rich liquid phase but, in the cases of immiscibility, the two liquids remained compositionally distinct and showed sharp compositional gradients at contacts. One pair of liquids crystallized some tridymite, whereas the other compositions were clearly above the liquidus. Overall, the results of the experiments are in good agreement with the earlier centrifuge study and confirm the existence of stable, super-liquidus immiscibility in some Fe-rich basaltic-andesitic compositions at temperatures up to 1200 °C.

Published Material: All findings were reported during a seminar for Undergraduate thesis presentations, hosted at the University of Toronto in March of 2014.

Abstract Body: Given the evidence in nature for a strong Pt-As association in magmas, we evaluated the effect of arsenic on platinum solubility in molten silicate. Two different approaches were employed. In the first, vacuum-sealed quartz tubes contained a synthetic basalt analogue with Pt metal +/- arsenide melt encapsulated in a natural chromite crucible. Oxygen fugacity (fO_2) was fixed using solid oxide buffers, corresponding to log fO_2 of -11.65, -7.72 and -4.10, respectively. Experiments were done at 0.1 MPa, 1200º C for 1 to 4 days, then quenched in water. It was found that As was volatilized from samples and began to contaminate the oxygen buffer, leading to a systematic decrease in Pt and As solubility with time. To mitigate this problem, a second series of experiments (type 2) first equilibrated the basalt sample with (initially) pure Pt in a gas-mixing furnace, with the sample then sealed in a silica ampoule along with arsenide melt, but without the solid oxide buffer. The fO_2 in these experiments was checked using partitioning of vanadium between chromite and melt. All experiments contained Pt-Fe alloy + Pt-arsenide melt, except some type 2 runs in which the Pt-Fe alloy was absent. The dissolved As content of the silicate melt increased significantly with fO_2, varying from 10 to 10,000 ppm, over the fO_2 range investigated. The average Pt content of the As-bearing glasses produced at log fO_2 of -7.72 and -4.10 are 0.16 ppm and 0.18 ppm, respectively, compared to 0.02 ppm and 0.14 ppm Pt in As-free glasses. At log fO_2 of -7.72, the As content of the silicate melt is ~400 ppm, in which the Pt solubility is enhanced by 8-fold. Hence, the molar As/Pt required to affect this "excess" Pt solubility is ~7400. The As content of typical primitive basalts is ~0.1 ppm, compared to 1-10 ppb Pt, resulting in molar As/Pt of ~300-30; this suggests the solubility enhancement by As complexing will be insignificant in natural systems. Importantly, despite high levels of As in two experiments which were saturated in Pt-arsenide melt (60-80 at% Pt), but not Pt metal, each contained Pt contents of <0.01 ppm. Results therefore imply that the Pt level required for Pt-arsenide saturation in molten silicate is low, possibly leading to crystallization of such phases as sperrylite ($PtAs_2$) in sulfur-poor, As-bearing magmas.

Title: Characterizing the mineralogy of orthomagmatic Fe–Ti–V (± P) oxide mineralization hosted in Paleoproterozoic anorthosite in the Cape Caribou River Allochthon, Grenville Province, Southeast Labrador

Presenter/First Author: Anthony Valvasori, Memorial University of Newfoundland, St. John's, NL

Presenter/First Author Email: avalvasori@mun.ca

Co-authors: Merline L.D. Fonkwe, Labrador Institute of Memorial University of Newfoundland, Happy Valley-Goose Bay, NF, Canada; Stephen J Piercey, Memorial University, St. John''S, Canada; James Conliffe, , ,

Abstract Body: The Cape Caribou River Allochthon (CCRA) is a thick lobate thrust slab located in the Grenville Province of south-eastern Labrador. It consists mainly of Paleoproterozoic anorthosite-mangerite-charnockite-granitoid rocks. The uppermost unit of the CCRA is the North-West River Anorthosite (~1625 Ma), a heterogeneous unit containing rocks ranging from anorthosite to gabbronorite, which are host to Fe–Ti–V (± P) oxide mineralization. Exploration activity in the CCRA has been sparse, despite several known mineralized areas. Ongoing research is investigating the mineralogy, geochemistry, and mineral chemistry of oxide mineralization to understand the origin of mineralization, and to provide insights into exploration potential of the CCRA and similar geological settings; amenability of oxides to beneficiation is also explored. Preliminary results are presented herein.

Fe–Ti–V (± P) oxide mineralization in the CCRA is abundant and widespread, and has four modes of occurrence: (1) pods of semi-massive to massive oxide (apatite-poor and -rich); (2) oxide veins (with straight or irregular contacts with host rocks); (3) disseminated oxide (mineralization occurring on its own or associated with orthopyroxene); and (4) alternating oxide bands having sharp contact with host rocks. All mineralization occurrences consist of spinel series (ulvospinel-magnetite solid solution) and trigonal series (ilmenite-hematite solid solution) Fe-Ti oxides, and are associated with pyrrhotite, chalcopyrite and pyrite. The mineralization exhibits complex mineral associations between oxides, apatite, silicates and sulfides, and within each mineral group; complex and variable exsolution textures within oxide minerals (magnetite, ilmenite, hematite and hercynite) are abundant. These mineral relationships will be used to determine the oxide mineral paragenesis, the partitioning and residence of Ti and V, the physiochemical conditions of oxide formation, and the processing route for oxide concentrate.

Title: Genesis of Co-Ni mineralizations during serpentinisation process in Bou Azzer ore deposits, the Neoproterozoic ophiolite of Bou Azzer El Graara (Central Anti-Atlas, Morocco)

Presenter/First Author: Bhilisse Mohamed, Cadi Ayyad University, Marrakesh,

Presenter/First Author Email: mohamed.bhilisse@edu.uca.ma

Co-authors: Wafik Amina, Cadi Ayyad University, Marrakech, Morocco; Admou Hassan, , , ; Maacha Lhou, Managem Group, Casablanca, Morocco; Haemyeong Jung, Seoul National University, Seoul, South Korea

Abstract Body: The neoproterozoic Bou Azzer inlier central Anti Atlas Mountains, southern Morocco represents a geological window into the Precambrian basement. It's surrounded by a discordant Phanerozoic cover. It is interpreted as the boundary between the northern margin of West African Craton (WAC) and dismembered parts of the Anti-Atlas Pan-African orogenic belt commonly known as Bou Azzer ophilite. In Bou Azzer two main phases of serpentinization at Bou Azzer was pointed out (Wafik, 2001) : i) an oceanic syn-rifting pseudomorphic serpentinisation stage with antigorite and two continental tectonic serpentinzation stages during tectonic setting of ophiolite with ii) syn-collision extensional stage lizardite and iii) post-collision extensional stage chrysotile filling veins and faults. After this author, Serpentinite is initial reserve of Ni-Co mineralization in Bou Azzer, where is reconcentrated by tectono-magmatic events that took place later.

The genesis of Co-Ni arsenides resulted from hydrothermal and tectono-magmatic processes. A primary paragenesis of magmatic origin with pentlandite, chromospinelle, and cobaltiferous and nickeliferous magnetite has been highlighted in Ambed massive where the serpentinization of ultramafic rocks is partial, and it is probably associated with Fe sulphides. However, the mineralogical assemblages identified in Aghbar and Bou Azzer East massive where serpentinization is total are composed on secondary minerals of polydymite cobaltiferous, millerite cobaltiferous, orcelite and magnetite cobalti-nickeleferous. These mineralizations could come during serpentinization from mutation of a primary mineral pargenesis formed on olivine and pentlandite+pyrrhotite aggregates. The genesis of cobaltiferous hydrothermal mineralizations is basically related to the serpentinization process. In tectonical term, serpentinization modify serpentine plasticity and provide doming phenomenon and has important contribution on genesis and structural context of Bou Azzer mineralized corps. In chemical level, serpentinization control the mobility of nickel and cobalt exist in primary ultramafic minerals which marked in arsenides, sulfides and iron oxides.

Co-authors: Joel E Gagnon, University of Windsor, Windsor, ON, Canada; Robert Linnen, University of Western Ontario, London, Canada; David John Good, University of Western Ontario, London, ON, Canada; Graham D Layne, Memorial University of Newfoundland, St John's, NF, Canada; Boswell A Wing, McGill University, Montreal, QC, Canada

Abstract Body: The Marathon and Geordie Lake Cu-PGE deposits are hosted by the Two Duck Lake (TDLG) and Geordie Lake (GLG) gabbros of the Coldwell alkaline complex, respectively. The TDLG intruded Archean metavolcanic rocks and the GLG occurs within syenite of the Coldwell Complex. The role of sulphur contamination from country rocks in the genesis of these two deposits is a point of debate.

All sulphide $\delta^{34}S$ (V-CDT) values for both Marathon and Geordie Lake mineralization fall between -2.0 and +2.0 ‰. There are no significant or consistent differences between different minerals at Marathon, although slight differences exist between some textural variants. Py from the country rocks at Marathon exhibits a wide range of $\delta^{34}S$ with an average of 0.2 ‰. At Geordie Lake, Po exhibits a distinctly lower range of $\delta^{34}S$ values (<-1 ‰) than other sulphides. At Marathon, there is no systematic variation in $\delta^{34}S$ with distance from the Archean country rocks, however, $\delta^{34}S$ values of Cpy from mineralized samples at Geordie Lake decrease with increasing distance from the syenite.

Analyses of multiple sulfur isotopes of representative samples from mineralized zones in the Marathon deposit show evidence of mass-independent fractionation, with negative $\Delta^{33}S$ values for most samples (total range = -0.91 to 0.0 ‰). There is a negative correlation between $\Delta^{33}S$ and $\Delta^{36}S$ with a slope of ≈ -1, which is characteristic of Archean surficial sulphur. In addition, $\Delta^{33}S$ values approach magmatic values of ≈0 systematically with increasing distance from the country rocks.

These results support genetic models that involve locally derived sulphur for both deposits. In the case of Marathon, this likely reflects crustal contamination and assimilation of during emplacement of the TDLG, whereas at Geordie Lake, sulphur was likely added to the gabbros through subsolidus volatile transport.

Title: Stratigraphy and distribution of chromite in the Black Label deposit, McFaulds Lake greenstone belt, Superior Province, Ontario, Canada

Presenter/First Author: Kaveh Mehrmanesh, Laurentian University, Sudbury,

Presenter/First Author Email: kaveh59mehr@gmail.com

Co-authors: C.Michael Lesher, Laurentian University, Sudbury, ON, Canada; Michel Houle, Geological Survey of Canada, Québec, QC, Canada

Abstract Body: The Black Thor Intrusive Complex (BTIC) is a semi-conformable sill-shaped intrusion that can be subdivided into: 1) a *lower ultramafic series* of basal olivine websterites and lherzolites, interlayered dunites and lherzolites with minor interstitial chromite, and overlying websterites, 2) a *middle ultramafic series* characterized by a lower chromitite horizon (Black Label), olivine websterites, lherzolites and dunites, and an upper chromitite horizon (Black Thor), and 3) an *upper ultramafic to mafic series* of websterites, mela/meso/leucogabbros and lesser anorthosites. A late pyroxenite composed primarily of websterite intruded the lower and middle ultramafic series and locally brecciated Black Label chromitites. Unbrecciated chromite-bearing rocks in Black Label have been divided into 6 textural facies: 1) massive, 2) semi-massive, 3) matrix-textured, 4) net-textured, 5) heavily-disseminated, and 6) lightly-

disseminated. Lithologies, textures, contacts, and bedding are similar within the unbrecciated SSW and NNE parts of the horizon, but distinct within the central brecciated part. Massive and semi-massive textures are more abundant near the feeder zone, whereas disseminated and net-textured are more abundant away from the feeder zone (NNE and SSW parts), and disseminated textures are more abundant in the NNE than in the SSW parts. It is possible to confidently make correlations of massive chromitites within the SSW parts over distances of up to 300m, and possibly up to 900m, but correlations are difficult in the NNE part as the chromite layers are very thin. The total amounts of chromite (integrated massive chromite equivalent) are greatest near the feeder, decrease away from the feeder, and are lowest in the NNE part. Mineralogical and geochemical investigations are in progress to establish whether the concentration near the feeder is attributable to mechanical sorting from a slurry or preferential in-situ crystallization.

Title: Platinum-Group Minerals in the Black Thor Mafic-Ultramafic Intrusive Complex, McFaulds Lake Greenstone Belt, Ontario

Presenter/First Author: Naghmeh Farhangi, Laurentian University, Sudbury,

Presenter/First Author Email: farhang8361@gmail.com

Co-authors: C Michael Lesher, Laurentian University, Sudbury, ON, Canada; Michel G Houlé, Laurentian University, Sudbury, ON, Canada

Abstract Body: Several styles of Ni-Cu-PGE mineralization occur within the Black Thor Intrusive Complex and

PGMs have been characterized in 20 samples from 7 zones containing sulfide mineralization: 2 basal contact zones (AT-12 extension, basal contact), 3 magmatic breccia zones (NW breccia, Unnamed, F2), and 2 stratiform chromite horizons (Black Label, Black Thor). Host rocks include dunite, peridotite, chromitite, and granodiorite (footwall). The PGMs in contact zones are froodite with lesser michenerite, sperrylite, and unidentified Pd-Bi telluride, Pd-Bi-Sb, Rh-Ru-Ir sulfarsenide, Pt-Ir arsenide, and Rh-Ir sulfarsenide. Most PGMs are enclosed within pyrrhotite-pentlandite-chalcopyrite-cubanite, but are also associated with amphibole-chlorite-serpentine and occur along sulfide-silicate boundaries. Euhedral shapes, large grain sizes (>20µm), and the strong association with sulfides suggest a magmatic origin. The PGMs in the brecciated zones are paolovite, sperrylite, michenerite, and Hollingworthite with lesser unidentified Pt-Rh-Os sulfarsenide, Rh-Pt-Pd-Os sulfarsenide, and Rh-Pt-Ir arsenide. Most of the PGM occur within sulfides, some along sulfide-silicate boundaries, and only minor amounts within silicate phases. The associations suggest that they are magmatic, but anhedral habits and occurrences in high strain zones suggest post-magmatic mobilization. The PGMs in Black Label are paolovite associated with chalcopyrite with lesser froodite, michenerite, sperrylite, hollingworthite, and telluropalladinite in both sulfides and silicates. The PGMs in Black Thor are stibiopalladinite, arsenopalladinite, isomertieite, palladoarsenide, and majakite, with lesser sperrylite and polkanovite, all of which are enclosed in silicate phases. Many Pd-bearing PGMs in Black Thor occur in carbonate veins, suggesting that Pd was mobile during carbonate alteration, but the low but uniform abundances of PGEs in both stratiform zones suggest that they were also originally magmatic.

Title: Hybridized Ultramafic Rocks in the Black Label Hybrid Zone of the 2.7 Ga Black Thor Intrusive Complex, McFaulds Lake Greenstone Belt, Ontario, Canada

Presenter/First Author: Charles S Spath, Laurentian University, Sudbury,

Presenter/First Author Email: cjspath@gmail.com

Co-authors: C Michael Lesher, Laurentian University, Sudbury, ON, Canada; Michel Houle, Geological Survey of Canada, Québec, QC, Canada

Published Material: Geology section at SEG Keystone 2014

Abstract Body: The Black Thor Intrusive Complex (BTIC) is a sill-shaped, semi-conformable, layered intrusion that is composed primarily of dunite, lherzolite, Ol websterite, websterite, and chromitite overlain by lesser mela- to leucogabbro, and anorthosite. After emplacement but before complete crystallization, a Late Websterite Intrusion (LWI) reactivated the feeder conduit and transected the basal part of the BTIC, including the Black Label chromitite horizon. Detailed core logging shows that the injection of LWI magma leads to the incorporation of inclusions and production of a 1-10m thick marginal zone of heterogeneous, interfingering brecciation defined as the Black Label Hybrid Zone (BLHZ). The BLHZ contains dunite/lherzolite/chromitite enclaves of variable sizes (1-50 cm) with subangular to amoeboidal geometries, sharp to diffuse contacts, and significant amounts of disseminated to patchy net-textured Fe-Ni-Cu-(PGE) sulfide mineralization. The core of LWI is typically an inclusion-free, medium-grained, Opx-rich adcumulate with accessory Chr or Ol, however, inclusion-rich intervals of the LWI contain more Ol and Chr produced by disaggregation and partial assimilation of ultramafic units. There are two types of interclastic hybrid groundmass, one containing xenocrystic Ol and one containing xenocrystic Chr+Ol of varying proportions. Geochemical signatures of the hybrid rocks reflect the partial assimilation and brecciation of dunite/lherzolite/ chromitite sequences and addition of Ol+Chr in hybrid rocks. Similar Th-U-Nb-Ta-LREE patterns suggest that the LWI is related to the remainder of the BTIC, presumably representing a more fractionated magma from deeper in the system. Further characterization of the hybrid rocks and inclusion variability is in progress and will help to establish the range and variability of processes involved within the BLHZ, and their influence on the nature and distribution of brecciated chromitite and associated Fe-Ni-Cu-(PGE) sulfide mineralization.

Title: Base Metal Sulphide Minerals in the Upper Critical Zone (UCZ) of the Bushveld Igneous Complex (BIC)

Presenter/First Author: Volodymyr Andrienko, University of Toronto, Toronto,

Presenter/First Author Email: volodymyr.andrienko@mail.utoronto.ca

Co-authors: James Mungall, Univ Toronto, Toronto, ON, Canada

Abstract Body: We report on the distribution and textures of base metal sulphide minerals in mafic cumulates of the Upper Critical Zone of the western Bushveld Complex. Samples from a 828 m section of a single exploration borehole on Turffontein Farm 34 km east of Rustenburg were examined in the petrographic microscope and with scanning electron microscopy (SEM) with energy dispersive X-ray fluorescence spectroscopy for point analysis and mapping. Primary sulfide melt inclusions hosted by silicate primocrysts were not observed in any samples, but pockets of sulfide minerals associated with late-crystallizing interstitial phases including quartz, albite, biotite, rutile, and apatite are common. The samples include orthocumulate textured pyroxenite and chromitite, and

meso- to adcumulate textured norite, gabbronorite, and anorthosite. Two principal generations of sulfide minerals are recognized, based in part on the identities of the associated silicate minerals. In those instances where sulfide minerals occupy positions apparently interstitial to the magmatic silicate minerals with pristine textures, the sulfide mineral assemblage is pyrrhotite + chalcopyrite + pentlandite mainly associated with anhydrous minerals (quartz, pyroxene, albite, plagioclase). However most occurrences show hydrothermal overprints, being associated with pyrite, millerite, galena and commonly showing disseminated halos of chalcopyrite within zones of hydrous alteration (actinolite/tremolite, chlorite) of the host silicate minerals. Rare platinum group minerals (sperrylite, cooperite) were observed in samples from the Merensky Reef and the UG2, UG3, and MG4 chromitite layers. Other occurrences of sulfide minerals were hosted by grain boundaries and cleavage fractures of silicate minerals, indicating local transport and redeposition of sulfur and base metals during alteration. A possible interpretation of the observations is that later hydrothermal fluids may have potentially affected the origin of sulphide mineral inclusions.

Title: Geological Setting of the Marbridge Mine: Komatiite Hosted Ni-Cu Ore Deposit

Presenter/First Author: Véronique Lafrance, University of Quebec at Chicoutimi, Chicoutimi, QC

Presenter/First Author Email: veronique.lafrance1@uqac.ca

Co-authors: Pierre Pilote, Ministère des Ressources Naturelles, Boucherville, Canada; Philippe Pagé, Sciences de la Terre, Université du Québec à Chicoutimi (UQAC), Chicoutimi, Canada; Réal Daigneault, Centre d'études sur les Ressources minérales (CERM), Chicoutimi, QC, Canada

Abstract Body: The Marbridge Mine is located in the southeastern part of the Abitibi Sub-province, at the base of the Malartic Group within the La Motte-Vassan Formation (2714 Ma). The mine was in operation from 1962 to 1968 with a production of 700,000 tonnes of ore at 2.28% Ni and 0.17% Cu, from four lenses associated with komatiites. The study area is surrounded by various plutonic rocks (Preissac pluton; 2681-2660 Ma; La Corne pluton; 2680-2642 Ma and La Motte pluton; 2647 Ma). Regional metamorphism reaches the amphibolite grade and surrounding rocks are part of an intense deformation zone which is characterized by L-tectonites. The main schistosity (S1) is commonly oriented NW-SE and is overprinted by a subvertical crenulation cleavage (S2) generally EW associated with Z-shaped P2 folds. The lithogeochemical analyses of the various units has allowed to recognize two distinct suites: (1) a calc-alkaline suite consisting of andesitic, dacitic, rhyolitic units and various associated volcanic rocks; and (2) a tholeiitic suite, consisting mainly of komatiitic flows, basalts and ultramafic intrusions. The presence of intense sericitic and chloritic alteration in felsic volcanic units and strong epidote alteration in mafic volcanic units is compatible with an early “VMS” hydrothermal system in this sector. Finally, these data will be used to reconstruct the sequence of geological events that have affected the Marbridge mine area. This reconstruction will allow the definition of exploration tools in such metamorphosed ultramafic-mafic environments.

Title: Platinum Group Element Enrichment and Mobilization in the Mesamax and Expo Ni-Cu-PGE Magmatic Sulfide Deposits, Cape Smith Fold Belt, New Quebec

Presenter/First Author: Julien Mailloux, University of Toronto, York,

Presenter/First Author Email: julien.mailloux@mail.utoronto.ca

Co-authors: James E. Mungall, University of Toronto, Toronto, ON, Canada

Abstract Body: The Expo and Mesamax Ni-Cu-PGE magmatic sulfide deposits are hosted within the Expo Intrusive Suite (EIS). The EIS consists of rocks of dunite to gabbronorite composition which have been metamorphosed by the Trans-Hudson orogen to the greenschist facies dominated by tremolite-actinolite, serpentine and chlorite. Both deposits consist of lenses of massive sulfides mainly composed of pyrrhotite-chalcopyrite-pentlandite-magnetite overlain by net-textured and disseminated sulfides. Palladium and platinum are significantly enriched at the vicinity of the contact between the net texture and the massive sulfide (Pt content as high as 236.1 ppm) and also in association with late talc-carbonate alterations. The scope of this study is to investigate PGE enrichment and mobilization mechanisms occurring in both deposits. Samples from the inner and outer zone of Mesamax and Expo were selected for geochemical assays at the onsite lab (Au, Pt, Pd, Ag, Rh, Cr, Cu, Fe, Mg, Ni, Co). A second selection was made for petrography, SEM, X-Ray mapping and LA-ICP-MS, based on the texture (massive sulfide, net texture, veins or alteration zones) and the PGE/ Cu+Ni ratio. From the preliminary results, there is an association between PGEs and carbonate alteration which suggests that CO2-bearing fluids mobilized PGEs during later events.

Title: Study of multiparameter data on exploration drill core from the McLeod VMS deposit, Matagami mining district, Quebec

Presenter/First Author: Nathalie Schnitzler, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Québec,

Presenter/First Author Email: nathalie.schnitzler@ete.inrs.ca

Co-authors: Pierre-Simon Ross, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, Canada; Alexandre Bourke, INRS-ETE, Quebec City, QC, Canada; Erwan Gloaguen, Institut national de la recherche scientifique, Quebec City, QC, Canada; Bastien Fresia, Glencore, Matagami, QC, Canada; Robert Boucher, , ,

Abstract Body: The INRS mobile laboratory for the physical, chemical and mineralogical characterization of rocks acquires multiparameter data on exploration drill cores. The laboratory can measure nearly simultaneously and non-destructively the density, magnetic susceptibility, geochemistry and mineralogy of drill core, directly on their storage sites. This data supplements the visual core description made by the geologist and helps to discriminate spatially the lithologies and alterations related to the emplacement of VMS (or other) deposits.

The Bracemac-McLeod mine is located in the Matagami VMS district, in the northern part of the Abitibi Subprovince, Quebec. Three exploration drill cores were analyzed in summer 2014 and seven more are planned for summer 2015, for a total of over 6000 m spread over the McLeod deposit and up to 1 km to the east. Measurements are taken at 20-30 cm intervals, at specific spots determined by the geologist.

The large amount of data (several thousand measurement spots, over 20 variables) requires the use of statistical multivariate analysis methods to simultaneously interpret all data. In previous studies at Matagami (Fresia, Ross, Gloaguen & Bourke), cluster analysis was used to group the data point into classes (corresponding to the various lithologies defined by the geologist), on the basis of their physical and geochemical signatures. Also, Principal Component Analysis (PCA) helped determine the alteration zonation along the drill core and spatially between the studied drill cores. As part of the new MSc project, we will propose other multivariate

methods, and attempt to develop exploration vectors using the composition or concentration of some mineral groups derived from near-infrared spectrometry.

Title: Metamorphosed Hydrothermal Alterations of the Auriferous Lalor VMS Deposit and Relations with Ore Styles

Presenter/First Author: Antoine Caté, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Québec,

Presenter/First Author Email: antoine.cate@ete.inrs.ca

Co-authors: Patrick Mercier-Langevin, Geological Survey of Canada, Québec, Canada; Pierre-Simon Ross, Institut National de la Recherche Scientifique-Eau Terre Environnement INRS-ETE, Quebec City, Canada; Shamus Duff, , , ; Mark D Hannington, University of Ottawa, Ottawa, ON, Canada; Benoît Dubé, Geological Survey of Canada, Québec, Canada; Simon Gagné, , ,

Abstract Body: The Paleoproterozoic Lalor auriferous volcanogenic massive sulphide deposit in Snow Lake, Manitoba, is hosted in a complex volcanic succession referred to as the Lalor volcanic succession. The deposit consists of stratigraphically and structurally stacked Zn-rich, Au-rich and Cu-Au-rich ore lenses. The volcanic rocks that host the deposit were affected by intense and laterally extensive ore-related synvolcanic hydrothermal alteration. These altered rocks were subsequently subjected to syn-deformation amphibolite-grade metamorphism that resulted in the development of distinct minerals and metamorphic mineral assemblages of varying composition in response to variably altered precursors. Five distinct alteration- and metasomatism-related chemical associations (K, K-Mg-Fe, Mg-Fe, Mg-Ca and Ca) were defined based on the mineralogy (mineral assemblages) and geochemistry of the altered zones. Mapping of the host volcanic rocks and ore-related mineral assemblages and chemical associations at Lalor indicate that: 1) the bulk geochemistry of the ore-related alterations has largely been preserved despite metamorphic processes, and the primary alteration styles can be inferred, 2) the Zn-rich massive sulphide lenses are preferentially associated with the low- to high-temperature K and Mg-Ca alteration zones, 3) the Zn-rich massive sulphide lenses formed at two distinct stratigraphic positions as a result of protracted seafloor/sub-seafloor hydrothermal activity, 4) the Cu-Au-rich zones at depth are associated with transposed discordant high-temperature Mg-Fe altered rocks and presumably represent footwall feeders, and 5) the precious metals were in part locally remobilized into low-strain sites during the main deformation event and consequently are not currently spatially associated with one chemical association in particular.

Title: The Coulon volcanogenic massive sulphide deposit, Northern Quebec: context, structure, alteration and zonation

Presenter/First Author: Rose Anne Bouchard, Université du Québec à Chicoutimi, Chicoutimi, QC

Presenter/First Author Email: roseanne_8@hotmail.com

Co-authors: Vital Pearson, Mines Virginia Inc., Quebec, QC, Canada; Réal Daigneault, Centre d'études sur les Ressources minérales (CERM), Chicoutimi, QC, Canada

Abstract Body: The Coulon volcanogenic massive sulphides deposit (14 mt @ 1.3% Cu and 3.9% Zn), located in Northern Quebec, has been strongly deformed and metamorphosed in high grade conditions, and its primary characteristics have been modified. Within the study area near lenses 08, 9-25, 44 and 16-17, five lithological units have been recognized: amphibolite, and sillimanite-, cordierite-sillimanite-, cordierite- and cordierite-anthophyllite-bearing schists. The schist that contains porphyroblastic sillimanite corresponds to the main unit and is characterised by a well-developed planar fabric. However, proximal to the sulphide lenses, cordierite and anthophyllite porphyroblasts overprinting the structural fabrics are observed; and these minerals are likely the metamorphosed equivalent of minerals formed by chloritization (cf. Mg-alteration). Using the TiO2 vs Zr diagram to characterize the main groups of volcanic rocks, basaltic, andesitic and two types of rhyolite were discriminated. The area is characterized by a steeply dipping foliation associated to a D1 event overprinted by regional and local folds related to a D2 event. The main fabric (D1) strikes north-south in the northern part of the study area and is NE-SW trending in the southern portion. A steep stretching lineation is especially visible in the southern area, but is completely obliterated by metamorphic recrystallization in the northern portion. The massive sulphide lenses exhibit a pyrite-pyrrhotite-chalcopyrite-sphalerite-galena paragenesis. Generally of metric to decametric thickness, lenses extend up to 300 meters horizontally and to 700 meters vertically. The project investigate the geometrical and textural changes that the orebodies underwent as a result of metamorphism and deformations, with particular focus on the remobilisation problematics in the perspective of adjusting exploration guides.

Title: Deciphering the hydrothermal evolution of a VMS system using trace elements in pyrite by laser ablation ICP-MS: an example from the Bracemac-McLeod deposits, Abitibi, Canada and implications for exploration.

Presenter/First Author: Dominique Genna, Université du Québec à Chicoutimi, Chicoutimi, QC

Presenter/First Author Email: gennadomi@hotmail.com

Co-authors: Damien Gaboury, University of Quebec at Chicoutimi UQAC, Chicoutimi, QC, Canada

Abstract Body: Textural and chemical characterization of pyrite was used to reconstruct the hydrothermal evolution of the Bracemac-McLeod archean VMS deposits in the Matagami district, Abitibi, Canada. The mineralization is divided into a 1) zinc-rich zone, concordant to the Key Tuffite - a marker horizon at the district-scale, 2) a copper-rich zone and 3) some localized magnetite-rich zones replacing sphalerite and pyrite. Petrographic and LA-ICP-MS studies of whole pyrite grains from the Key Tuffite and from the different ore zones of the deposits provided the opportunity to investigate the distribution of trace elements in pyrite over a wide range of sulfide assemblages related to temperature. The study has revealed five pyrite types. Nodular pyrites (I) in the Key Tuffite and pyrites from the low temperature (250°C) zinc-rich zone (II) have the same chemical signature (significantly enriched in Sb and Tl) suggesting that both precipitated from similar physicochemical conditions. Pyrites from the copper-rich zone (III) have a different signature, enriched only in Se ± Co. These pyrites are related to later higher-temperature fluids (300°C). Pyrite preserved during a later magnetite-replacement (>350°C) stage (IV) are also characterized by enrichment in Se, but are depleted in all other elements. Similar signature is found in idiomorphic metamorphic pyrite (V), which occurs at the district-scale. During recrystallization of pyrite IV and V, only Ni, Co, As and Se are preserved whereas other base metals are expelled from the pyrite structure. Consequently, only Ni, Co, As, Se, Sb and Tl are useful to reconstruct the hydrothermal evolution of the VMS system and used to build a suite of discrimination diagrams. Specifically, the ratio Se/Tl can discriminate pyrites from mineralized Zn-rich zone

(Se/Tl<10), from pyrites associated with Cu-rich zone (10<Se/Tl<10000) and pyrites from non-economic parts of the deposit (replaced by magnetite or metamorphogenic; Se/Tl>10000).

Co-authors: Patrick Hooker, , , ; Roxanne Leblanc, , , ; Pamela Patraskovic, , ,

Abstract Body: Comprehensive physical rock property measurements provide the critical quantitative link between geology and geophysics, thereby improving 3-D geologic modelling.

Machine learning, cluster analysis, and classical statistics are used to classify the rock into petrophysical (physical rock properties) domains and benefits of this classification scheme are discussed. Traditional lithological classification schemes, i.e. visual core logging, are compared to the rock property domains and methods to link geology to geophysics are explored. In addition, establishing relationships between petrophysical data and geometallurgical, geochemical, and geotechnical parameters to create proxy relationships are investigated and select case studies presented.

Additionally, in-situ structural measurements combined with structural analysis can aid in the development of structural models. Understanding the distribution of fault zones and their relationship with mineralization, can lead to better exploration targeting, and decreased operational risk.

Title: INTEGRATING BOREHOLE GEOPHYSICAL, GEOLOGICAL AND GEOPHYSICAL DATA - PAST AND PRESENT

Presenter: Philip Hawke, Wireline Services Group, Perth,

Presenter Email: philhawke@wirelineservices.com.au

First Author: Greg Maxim Hollyer, Organization Not Listed, Toronto,

First Author Email: greghollyer@wirelineservices.com.au

First Author Student?: No

Abstract Body: In the past twenty five years, integration of surficial geological, geochemical and geophysical data has led to new mineral finds. Final success, however, is driven by drill results which provide key information used to define and delineate deposits. But integration of borehole geological, geochemical, and geophysical data is not routine. Here, we look at a case history including integrated results acquired at a strategic copper-cobalt deposit in Central Montana, U.S.A. Basic methods for working with different data are presented. We then advance forward to today's exploration environment and examine some of the developments in technologies that can now add even more to key drilling investments.

Geological, geochemical and geophysical logs were made available by BHP and under the supervision of a geologist and a consulting geochemist. One challenge was to find a means of handling this huge volume of data – one approach which is presented here. Geophysical logs were lightly filtered and integrated with geological logs, and a cross-section was derived totalling 700 m in length. Results concurred with the geologist's interpretation of stacked sulphide plates in a complex framework of thrust faults. Next, the geochemical data were brought into play by integrating irregularly sampled geochemical data with regular geophysical logs. Geophysical and geochemical data were then combined in a Factor Analysis study which derived factors to evaluate and map trends across the deposit.

Today, these tasks are easier with enhanced computing power and other evolutions. Now, new geophysical tools are available, including borehole radar and televiewers which map structure in situ. New processing techniques now enable high-end calibration of gamma logs in uranium exploration. And, logging is now possible past the end of drill rods, for faster and more economic results.

In summary, we provide a detailed look at how integrated borehole geology, geochemistry, and geophysics can provide a fresh look at deeper geology such as is being encountered more routinely today. With an enhanced look at the 3rd and most important dimension in mineral exploration, namely the drill hole, we can learn from the lessons of the past while thinking ahead to the next discoveries and the new technologies and approaches that can drive them.

Title: Borehole Geophysical Logging During or just after Drilling : The developing technology of downhole Shuttle Probe survey systems

Presenter/First Author: Alan Robert King, Geoscience North, Sudbury, ON

Presenter/First Author Email: king.alan77@gmail.com

Abstract Body: A shuttle type borehole (BH) probe is a downhole geophysical logging system with sensor(s), on board memory, and battery power supply all together in the downhole tool. This configuration permits operation of the tool in a drill hole with no electrical or data connection to surface. Data is measured and stored downhole and is dumped from memory when the tool is returned to the surface.

This method of deployment inside the drill rods has a number of significant advantages including: -

- Elimination of loss of borehole probes. This is especially critical for expensive probes like BH televiewers or tools with small nuclear sources such as density probes.

- No more blocked holes. This is a problem in any area of unstable rock, but particularly in tropical environments where deep weathering often makes for an unstable interface between the drillhole casing through the overburden and the open hole in bedrock.

A number of groups around the world are working on a new generation of shuttle tools including:

DMT GmbH & Co. KG in Germany

- The Australian Deep Exploration Technologies Commonwealth Research Consortium (DET CRC)

- other industry groups

The available BH shuttle tools and current developments in the field will be reviewed with the goal of alerting potential users to the value of these systems as well as encouraging the development of practical, multi-sensor tools so that multiple key surveys can be done in a single pass on completion of every drillhole. Also potential applications to BH sensing systems other than those currently under development will be discussed.

BH Shuttle technology has the potential to provide most geophysical logs in most drill holes at little additional cost in money or time. The full development and deployment of these systems would be a tremendous step forward in our exploration and mine development process as well as in other geoscience fields including groundwater, petroleum and general earth imaging

Title: A New Logging-While-Drilling Approach for Natural Gamma Spectroscopy with Diamond Drilling

Presenter/First Author: Ida Hooshyari Far, Curtin University, Perth,

Presenter/First Author Email: ida.hooshyarifar@postgrad.curtin.edu.au

Co-authors: Anton Kepic, CURTIN UNIVERSITY, Perth, Australia; Andrew Greenwood, , , ; Anna Podolska, , ,

Abstract Body: Spectral gamma ray logging has been desired, but not been adopted in slim-hole drilling, especially in hard-rock environments. The common drawbacks of conventional wireline approaches are either a lack of natural gamma radiation verses wireline pull-rate, or the use of a radioactive source, in order to develop an adequate gamma ray spectrum. Using a radioactive source allows measurements such a rock density or heavy mineral concentration. However, the isotopic radioactive source used in such measurements is undesirable due the possibility of losing the source.

This issue encouraged Researchers at Curtin University within the Deep Exploration Technology Commonwealth Research Centre to develop “Shuttle”, a novel approach to logging while coring, in diamond drilling. This new tool can measure natural gamma ray activity during drilling process. The data is retrieved when the rock core is pulled out periodically. Thus, the spectral data is retrieved every 1.5-3 m of drilling. Since drilling is a long process it provides adequate time for the Shuttle to collect data. Thus, high quality natural gamma ray spectroscopy can be performed as the spectrum for a 1m segment typically results from millions of gamma rays analysed. Obtaining a high quality gamma ray spectrum is highly important; since analysis is based upon the different types of gamma scattering can lead to better identification of rock types and underground formations.

We have used a prototype spectral gamma sensor using BGO crystal on a wireline to simulate the data that will be collected by a shuttle system to demonstrate the data quality anticipated as well as laboratory tests on concrete blocks with different materials to test data analysis techniques. Our preliminary results indicate that spectral data collected by the Shuttle will allow us to reliably measure K, U and Th concentrations plus indicate the presence of heavy minerals. The high quality spectra obtained opens the possibility of identifying other lithological properties just with natural radioactivity.

Title: Decomposing the Electromagnetic Response of Magnetic Dipoles to Determine the Geometrical Parameters of a Dipole Conductor

Presenter/First Author: Jacques Kontak Desmarais, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: jk_desmarais@laurentian.ca

Co-authors: Richard Stuart Smith, University of North Carolina at Chapel Hill, Chapel Hill, NC

Published Material: This presentation deals with two papers that were submitted to Exploration Geophysics. Both papers are currently under review.

Abstract Body: Interpretation of airborne electromagnetic (AEM) data is hampered by effects of system and survey configuration, and is often a challenge for experienced interpreters, particularly in situations when the conductor is off-line or not striking perpendicular to the flight line. Consequently, it is often difficult for explorationists to define the position and orientation of conductors and hence correctly locate and orient drill holes from AEM measurements. These difficulties associated with geophysical data interpretation may be surmounted using automatic data transformation or interpretation algorithms. These algorithms convert measurements of geophysical fields into physical properties of the ground through the application of simplifying assumptions. This study presents a novel automatic data interpretation algorithm for modelling airborne electromagnetic (AEM) data acquired over resistive environments, where the position and orientation of a dipole conductor is allowed to vary in three dimensions. The algorithm assumes that the magnetic fields produced from compact vortex currents are expressed as a linear combinations of the fields arising from dipoles in the subsurface oriented parallel to the three orthonormal Cartesian axes. In this manner, AEM responses can be represented as 12 terms. The relative size of each term in the decomposition can be used to determine geometrical information about the orientation of the subsurface conductivity structure. The geometrical parameters of the dipole (location, depth, dip, strike) are estimated using a combination of a look-up table and a matrix inverted in a least-squares sense.

Tests on synthetic models and field examples show that the algorithm is capable of extracting the correct geometrical parameters of a dipole conductor using a three-component receiver and one-component transmitter system. The algorithm is unstable when the conductor approaches axial-symmetry with respect to the traverse line. In light of this observation, we design a novel multicomponent-transmitter-receiver system capable of predicting the correct parameters for all conductor geometries.

Title: Maximizing Subsurface Information Using a Multi-Parameter Airborne Survey Platform

Presenter/First Author: Peter Tschirhart, Sander Geophysics Ltd, Ottawa,

Presenter/First Author Email: ptschirhart@sgl.com

Co-authors: Luc Lafrenière, Sander Geophysics Ltd., Ottawa, Canada; Malcolm Argyle, Sander Geophysics Ltd., Ottawa, ON, Canada

Abstract Body: Sander Geophysics owns and operates a DHC-6 Twin Otter survey aircraft that is capable of acquiring multiple geophysical parameters simultaneously. Several complementary geophysical techniques including frequency domain electromagnetics, gravity, magnetics and gamma-ray spectrometry are used together to maximize subsurface information. Associated aircraft GPS data as well as radar and laser altimeter data are also recorded. The electromagnetic data is provided by SGL's SGFEM system, which is designed for high resolution, relatively shallow mapping, and consists of a four frequency (912, 3,005, 11,962, and 24,510 Hz) transmitter mounted in a wingtip pod and a receiver mounted in a pod on the opposite wing. Gravity data is provided by AIRGrav, a total field gravimeter designed and built by SGL specifically for the airborne environment, which is mounted inside the aircraft cabin. A total field magnetometer mounted in a rigid tail stinger provides the magnetic data, and a gamma-ray spectrometer with up to 3 boxes (50.4 litres downward facing, 8.4 litres upward facing) of sodium iodide crystals provides the radiometric data. A survey using this multi-parameter system was flown over the Reid-Mahaffy geophysical test site in Ontario to demonstrate the system's capabilities over a typical mineral exploration target with known geology and good depth control. Using a primary (traverse) line spacing of 200 m, a total of 315 lkm were flown over the test site and surrounding area at a speed of 90 knots (167 km/h) and at an altitude of 52m. The electromagnetic data have been reprocessed using new tools and techniques thereby significantly improving target details. An analysis using the electromagnetic data along with gravity, magnetic and radiometric data is presented and compared with forward models to illustrate the capabilities of this system.

Title: Mining data from the mining industry: advice and possibilities for academic researchers

Presenter/First Author: Mark Shore, Magma Geosciences Inc, Nepean, ON

Presenter/First Author Email: mark.shore@rogers.com

Abstract Body: Cooperation between academic researchers and mineral exploration companies has been a productive avenue in many areas of economic geology, geophysics, and geochemistry. Over the past decade, structural changes in the mining industry and (at times severe) financial pressures on companies from small mineral exploration 'juniors' to giant integrated multinational mining companies has reduced the number and scope of such collaborative efforts.

However there are still opportunities for useful interchange between industry and academia. Some of the data available (much of which could be classified as 'grey' data or literature) will be described and strategies to identify, locate and obtain it will be described.

Mineral exploration often generates vast amounts of data that may be examined intently by a small corporate group for a very specific purpose over a short period, then set aside. Such data may be of great value to other potential users. Typical examples include airborne geophysical surveys collecting data on the Earth's magnetic field, gravity, conductivity and radioactivity, which can be invaluable in mapping bedrock or surficial deposits over large areas and delineating large and small scale faults and folds.

Other data may include large-scale surveys of soil, water or lake sediment geochemistry and whole rock or trace element analyses of rock in outcrop or drill core. Samples may be collected from otherwise inaccessible or very costly sites, such as in remote field areas, in deeply weathered or glaciated terrain, underground mines, or deep drill holes.

Researchers must recognize the limitations of such data. Analytical work may not be performed to the levels of accuracy expected in research, samples collected for one purpose may not be entirely suited for another, and timetables and goals may be very different between a company exploring for a mineral deposit and a Ph.D. candidate working on a thesis project. I will describe strategies to minimize such conflicts.

Title: Economic aspects of Terrestrial Impact Structures

Presenter/First Author: John G Spray, University of New Brunswick, Fredericton, NB

Presenter/First Author Email: jgs@unb.ca

Abstract Body: Impact structures on Earth have played a significant role in the creation and preservation of economic deposits, including metal ores and hydrocarbons. In Canada, well-known structures include Sudbury, renowned for its world-class Cu-Ni sulfides and associated platinum group element deposits; Manicouagan for facilitating a ~6000 MW hydroelectric generating capability; and Steen River for multizone oil and gas potential, along with numerous buried craters within the Williston Basin (e.g., Viewfield, Sakatchewan). Key processes associated with economic deposit development include (1) fusion of crustal rocks to create a melt body that fractionates and so concentrates immiscible and/or dense phases that are rich in metals; (2) creation of fractured, permeable rock volumes to act as reservoirs for hydrocarbons; (3) creation of basins that can preferentially accumulate hydrocarbons; (4) formation of traps and seals through generation of impact melt sheets and/or impermeable frictionally-fused fault systems; (5) creation of hot rock-water hydrothermal systems that can precipitate economic volumes of metals (e.g., within the Onaping Formation at Sudbury). Critical to exploiting the economic potential of impact craters is to understand their internal structure, especially in terms of syn- to post-impact tectonics. Many of the larger surviving craters on Earth have been modified since their formation, making the distinction between impact-generated features and subsequent overprinting effects challenging. This presentation will review examples of terrestrial impact structures exhibiting economic potential; both proven and pending. Key structural controls will be reviewed as a guide to exploration rationale for both metals and hydrocarbons, as well as other uses (e.g., waste storage).

Title: Structural evolution of the Otish Basin: a Paleoproterozoic polymetallic-uranium rich meteorite impact structure, Québec, Canada

Presenter/First Author: Normand Goulet, University of Quebec Montreal, Montreal,

Presenter/First Author Email: goulet.normand@uqam.ca

Co-authors: Serge Genest, , Crabtree, QC, Canada; Francine Robert, Groupe Omegalpha Inc, Crabtree, QC, Canada

Abstract Body: The evolution of the Palaeoproterozoic sedimentary Otish Basin (OB), located in northern Québec, was mainly developed on the southeastern margin of the Superior craton. The OB lay unconformably on the Archean basement, covering an area of about 5200 km², averaging a thickness of 2,4 km and sitting north of the Mesoproterozoic Grenville province. The evolution of the OB has been disturbed by a major meteorite impact responsible for a widespread gabbro emplacement at around 2.1Ga. Shocked derived material (glass and PDFs) are observed in the sediments under the gabbro sheet and inside the large enclaves found in the gabbro itself that could be interpreted has a melt/breccia sheet. The gabbro has been emplaced in an extrusive manner according to their distribution and their physical relationship with the sediments.

A regional brittle-ductile deformation, possibly related to the Hudsonian orogeny (1.85 Ga), affected all the units of the OB. The main stress component was oriented NW-SE producing folding and overthrusting to the NW. The OB is an overturned syncline with a shallow plunge to the SW and later offset by NW and NNE conjugate faults. A correlation with the timing of the deformation of the Sudbury structure could possibly be proposed. The major deformation is pre-Grenvillian and post-Archean. Major faults and fractures were developed or reactivated along some ring or radial dykes formed during the meteorite impact. The morphological oval shape of the OB combine with the arc shape of the Mistassini Basin (MB), adjacent to the SW, with shatter cones of uncertain age, lead us to consider the MB as an element of our puzzling huge structure for which the postulated radius of the relevant structure is well over 250 km.

Mineralised hydrothermal fluid rich in uranium (1.7 Ga) and polymetallic (Cu, Au, Pb, Ag) deposits are filling early Proterozoic fractures and faults zones affecting both the OB and the Archean basement.

Title: Meteorite Impact Related Uranium Occurrences in the Otish Basin, Quebec, Canada.

Presenter/First Author: Serge Genest, , Crabtree, QC

Presenter/First Author Email: groupeomegalpha@bellnet.ca

Co-authors: Francine Robert, Groupe Omegalpha Inc, Crabtree, QC, Canada

Abstract Body: The Proterozoic Otish Basin is well known for its uranium potential. Although the unconformity model has been used for prospection since its beginning, the main bodies discovered within the basin are obviously derived from strong hydrothermally driven enriched fluids. The Lavoie uranium ore body defined in 1985 and its neighbouring Epsilon showings clearly show a structural pattern relevant to a tangential tectonic transport towards the northwest. The surrounding rock units have suffered strong and pervasive alterations. The alteration pathways were mainly controlled by the capping of the sedimentary rock pile by a thick gabbroic unit. The presence of a carbonate unit reaching locally 50 meters in thickness favoured the stacking northwesterly. For many decades the tectonic modelling was founded around the hudsonian event as well as the Grenville Front because of its proximity to the basin. The exploration in this area now faces new facts. The recent discovery of planar deformation features (PDFs) must be taken into account for enlightening the mechanics involved in ore genesis in the Otish basin. PDFs have been found within the sandstone units in the eastern half of the basin up to 1000 meters in depth. The distribution of those PDFs in sandstone seems to be limited to the west by a major N010°-N020° faulting zone, i.e. the Indicator discontinuity. PDFs have also been observed in a large plurimetric enclave observed at the base of the overlying gabbroic unit. This later unit is interpreted here as a melt sheet related to a major meteorite impact event which is tentatively dated at 2,1 Ga, an interpretation also supported by the absence of feeding dykes noted throughout the basin as well as by its spatial relationship with the PDFs distribution in the underlying sandstone units.

Title: A Meteorite Impact Origin for the Chibougamau Formation, Québec, Canada: towards a New Interpretation of the Chibougamau-Mistassini Mining Camp.

Presenter/First Author: Francine Robert, Groupe Omegalpha Inc, Crabtree, QC

Presenter/First Author Email: moradin99@gmail.com

Co-authors: Serge Genest, , Crabtree, QC, Canada; Guillaume Courtois, , , ; Normand Goulet, University of Quebec Montreal, Montreal, Canada

Abstract Body: The Chibougamau Formation (CF) is an assemblage of conglomerate, arkosic sandstone, graded laminite and diamictite resting unconformably on the Archaean basement. The main outcrops of the CF occur around the Chibougamau area. They are bounded by SW-NE faults in a kind of semi-grabben. The upward movement of the southeastern compartments has been related to a subsequent tectonic event. The CF has been firstly described as a mixture of sediments with an igneous component such as diabase. Later, it has been compared to the Gowganda Formation (GF, Cobalt Group, Ontario) and interpreted as a glaciogenic rock. Because of the correlation between the GF and the CF, and the lack of carbonate fragments, the CF has been dated pre-Mistassini Group (which is rich in dolomite). Glaciogenic tenant searchers have never found a striated fragment or a specific iron-shaped one. While participating to a field trip organized by the CIM in 1984, the second author noted some sedimentary incongruities within the diamictite. Since then, the CF has been the subject of studies by our group and subsequently interpreted as a meteorite impact fallout. More recently, a master thesis work dealing with petrography on three sites of the CF has been performed by the third author in order to validate the new interpretation. Results cannot be more

conclusive: shock metamorphism has affected numerous large fragments and micro-fragments in the matrix (planar deformation features (PDFs), maskelinite and glass). Further studies of the CF yielded more information: up to 3 sets of PDFs in feldspars, quartz and other minerals, ballen texture, toasting on feldspars and quartz, brown glass fragments, some of calcitic origin, and some spherules. Moreover, a large outcrop observed in the Mt Radar area shows micro-breccias associated with flowing glass in a carbon-rich fine grain matrix. The finding of well expressed black carbonate fragments in the CF is of interest. Did the CF postdated the Mistassini Group?

Title: Progress in the Search for a Major Meteorite Impact Structure in the Palaeoproterozoic Kisseynew Domain and Flanking Volcanic Belts, Manitoba, Canada

Presenter/First Author: Eckart Buhlmann, Organization Not Listed, Flin Flon,

Presenter/First Author Email: banya1nc@hotmail.ca

Abstract Body: Central Manitoba is underlain by the Kisseynew Domain, a basinal structure flanked by the Palaeoproterozoic Flin Flon- and Snow Lake volcanic belts to the south and the Lynn Lake and Leaf Rapids volcanic belts to the north. The volcanic belts are important present and past metal producers from VMS type copper-zinc-gold deposits. Lithogeochemical data of host rock to VMS ores were examined. It was found that the Flin Flon and Lynn Lake deposits have a strong magmatic component. Tholeiitic volcanics and gabbros pre-concentrate copper and produce copper-rich hydrous fluids. The open question is the source of the thermal energy to create large volumes of iron-rich magma. Meteorite impacts would deliver sufficient energy to generate the required temperatures and melt volumes. Some indirect pointers to a major crater were observed: In the Palaeoproterozoic Kisseynew basin at several locations outliers of Ordovician limestone are noted, suggesting local depression. Several VMS deposits along the boundary between underlying Amisk volcanic and overlying Missi clastic sediments show large scale signs of fluidization. This is expressed in major pegmatoidal bulges of pegmatized and dispersed ore along the otherwise sheet like ore horizons. Many graphitized fault zones can be traced for tens of kilometers and suggest possible remnants of a transient crater. The VMS deposits derive their copper from mafic volcanic and gabbroic rocks. A large impact would have created the necessary volume of high temperature melt. The various signs observed lend support to the hypothesis for a major impact as the energy source. Future work will benefit by using the impact hypothesis to refine our understanding of the process. This will lead to defining targets of higher potential for future ore searches.

Title: Impact-Generated Hydrothermal Systems and Associated Mineralization: A Case Study at Manicouagan

Presenter/First Author: Sarinya Paisarnsombat, University of New Brunswick, Fredericton, NB

Presenter/First Author Email: sarinya.p@unb.ca

Abstract Body: Impact-associated hydrothermal alteration is manifest in various locations within the Manicouagan structure of Quebec, Canada. Major hydrothermal systems are developed in the east of the structure, where associated mineralization is manifest as veins, vugs, and geodes. This work focuses on zeolitization (the predominant hydrothermal activity) and SiO_2-phase mineralization. Within the central uplift (comprised of anorthositic gneiss), thomsonite and natrolite (Thm-Ntr) have been deposited as veins (thickness of ~2-3 cm) in more intact host rocks, and as more pervasively distributed occurrences in more fractured rocks. Analcime is mainly associated with shock veins, which locally pervade the central uplift. Thm-Ntr is also commonly developed as veins within basal suevite (melt-bearing brecciated rock) as a result of labradorite alteration occurring beneath the impact melt sheet; IMS (i.e., between the IMS and footwall rocks). SiO_2 phases occur as colourless and purple (amethyst) varieties at different locations within the IMS. Fluid inclusion and oxygen isotope determinations reveal that mineralization of SiO_2 phases occurred at ~225 to 430°C. High salinity fluids (14-26 wt% NaCl eq.) in the absence of salt (NaCl) crystals suggests Ca^{2+}-rich hydrothermal activity (with more limited Na^{+} mobilization). The $\delta^{18}O$ values indicate that magmatic fluid was involved in the production of SiO_2 phases within the upper unit of the IMS ($\delta^{18}O_{fluid}$ range from +0.81 to +7.67‰), while fluids involved in geode formation at the base of the IMS were derived from metamorphic origins ($\delta^{18}O_{fluid}$ range from +17 to +23.17‰). Both formations appear to be closed systems, and are not connected; which suggests low permeability of the IMS body. Based on the $\delta^{18}O$ results, there is no evidence of meteoric water being involved in the hydrothermal phases at Manicouagan.

Title: Deformation and Structural Controls at the Broken Hammer Deposit: Sudbury, Ontario

Presenter/First Author: Marshall Francis Hall, Laurentian University, Lively,

Presenter/First Author Email: mz_hall@laurentian.ca

Co-authors: Bruno Lafrance, MERC, The Goodman School of Mines, Laurentian University, Sudbury, ON, Canada; Harold Lorne Gibson, MERC, Department of Earth Sciences, The Goodman School of Mines, Laurentian University, Sudbury, ON, Canada

Abstract Body: In the Sudbury District, Cu-Ni-Platinum Group Element (PGE) footwall deposits are hosted by the basement rocks underlying the ca. 1.85 Ga Sudbury Igneous Complex (SIC). The SIC is interpreted as a differentiated impact melt sheet, which was flattened into its present elliptical shape during the 1.85 Ga – 1.80 Ga Penokean Orogeny. Footwall deposits are subdivided into "sharp-walled" vein and "low-sulphide" PGE-rich mineralization, the latter expressed by thin sulphide veinlets and disseminations. The Broken Hammer deposit, which is located in Archean rocks in the North Range of the SIC, is a hybrid footwall-type deposit containing sharp-walled massive sulphide vein and low-sulphide PGE-rich mineralization. It contains an indicated resource of 259, 500 tonnes grading 0.88% Cu, 0.1% Ni, and 12.14 g/tonne total precious metals (TPM). The deposit is mined as an open pit operation, which provides a unique opportunity to study the 3D geometry and the emplacement of the veins. The veins range in thickness from 1 to 50 cm and are composed primarily of chalcopyrite, millerite and platinum group minerals. The dip on the veins ranges from steep (>60°) to moderate (40° to 50°) and the veins are typically thicker where they change orientation to more shallow dips. The veins have three main strike orientations: 070°, 130°, and 190°. The intersection of all these veins is coincident with the trend (220°) and plunge (30°) of the main ore body, suggesting that the veins formed during a single deformation event. The latter corresponds either to the collapse of the floor of the Sudbury structure during the modification stage of the impact, to the Penokean orogeny, or to a combination of both occurring simulataneously.

Title: Magnetotelluric and Controlled-Source Electromagnetic Study of Aquistore CO_2 Sequestration Site, near Estevan, Saskatchewan

Presenter: Jim Craven, Natural Resources Canada, Ottawa, ON

Presenter Email: jim.craven@nrcan-rncan.gc.ca

First Author: Joe McLeod, University of Manitoba, Winnipeg, MB

First Author Email: ummcleo6@myumanitoba.ca

First Author Student?: No

Co-authors: Ian J Ferguson, University of Manitoba, Winnipeg, MB, Canada

Published Material: Preliminary results of this research were included in a poster presentation at the EMIW meeting in Weimar, Germany, August, 2014

Abstract Body: Pre-injection magnetotelluric (MT) and controlled-source electromagnetic (CSEM) surveys at the Aquistore carbon sequestration site, Estevan, Saskatchewan are being used to determine the capability of surface electromagnetic (EM) methods for monitoring an injected CO_2 plume. MT is being used to characterize the background resistivity structure of the Williston Basin and local EM noise conditions, and CSEM is being tested for its ability to delineate the target and the overlying resistivity structure. There are a number of challenges in imaging the CO_2 plume with surface EM techniques, including the > 3 km depth of the storage complex, conductive Mesozoic rocks above the target, and the high EM noise environment. Analysis of pre-injection MT data from surveys conducted in 2013 and 2014 demonstrates the ability to measure accurate MT responses across the site, defines a dominantly 1-D resistivity structure, and delineates a period band (0.125 to 6.667 s) of strong EM noise. Theoretical modeling shows that for a colinear electric-dipole transmitter and receiver configuration, and offsets of < 10 km, the CSEM response is sensitive to shallow (<1 km) resistivity but provides limited resolution of a resistive plume at the injection depth. Analysis of CSEM data collected at the site in 2013 using frequency-domain and time-domain methods shows that the signal from a 0.5 Hz, 29400 A.m bipole source can be accurately detected to offsets of at least 4 km.

Title: Combining Spatial Components and Hilbert Transforms to Interpret Ground-Time-Domain-Electromagnetic Data

Presenter/First Author: Jacques Kontak Desmarais, University of Saskatchewan, Saskatoon, SK

Presenter/First Author Email: jk_desmarais@laurentian.ca

Co-authors: Richard Stuart Smith, University of North Carolina at Chapel Hill, Chapel Hill, NC

Published Material: This is a presentation which deals with a paper that was submitted to GEOPHYSICS. The paper is currently under review.

Abstract Body: We present a method for displaying or imaging data from a ground-time-domain-electromagnetic system and for extracting the geometrical parameters of a small conductor. The parameters are determined directly from the data using combinations of the spatial components of the secondary fields and their Hilbert transforms. The position of the target coincides with the peaks of the Energy Envelope or the T-component of the response. Here, the Energy Envelope is the square root of the sum of the squares of the three spatial components and their Hilbert transforms, whereas the T-component response is an analogous quantity that excludes the Hilbert transform terms. Studies on synthetic models indicate that the T-component response is sharper than the Energy Envelope in the majority of possible target orientations. Once the position of the body has been determined using the peak of the T-component response, the dip of the target can be quantified using the ratio of the full width at half magnitudes of the T-component response and the T-component Hilbert transform response, which is analogous to the Energy Envelope, but excludes the untransformed quantities. Finally, once all other geometrical parameters have been determined, the depth of the target can be evaluated using the full width at half magnitude of the T-component response. The proposed modeling method was tested over an anomaly acquired at the Coulon field site during an InfiniTEM survey in the Abitibi greenstone belt of Quebec. The extracted geometrical parameters are consistent with the available geological information.

Title: Tools Used in Mineral Exploration for Measuring the Conductivity and the Resistivity in Drill-Holes and on Drill Core: Observations on Their Range of Sensitivity.

Presenter/First Author: Richard Stuart Smith, University of North Carolina at Chapel Hill, Chapel Hill, NC

Presenter/First Author Email: rssmith@laurentian.ca

Co-authors: Devon Parry, , , ; Omid Mahmoodi, , ,

Published Material: This paper has been submitted to Exploration Geophysics and is undergoing revision

Abstract Body: A study has been undertaken to acquire conductivity data using the EM39 low-induction-number conductivity tool. Measurements were taken in three holes in the Sudbury, Ontario, area: at Victoria in the south west part of the Sudbury structure; at Levack, in the North Range; and at the Lady Violet deposit near Copper Cliff. These data were compared with pre-existing data acquired using other tools and measurements taken on core extracted from the holes. The comparison shows that each tool has a finite range of sensitivity. The resistivity tool used by DGI is sensitive to conductivities in the range 0.01 to 100 mS/m; the EM39 is sensitive to conductivities in the range of ~30 mS/m to 3000 mS/m and the IFG to conductivities greater than 30 mS/m. In the sub-ranges where the ranges of two instruments overlap, one might expect a good correlation between the measurements derived from the two tools. However, this is not always the case, as the instruments can have a different volume of sensitivity: the EM39 has a coil separation of 50 cm and will see material greater than 20 cm away from the hole; whereas the IFG conductivity tool seems to have a smaller spatial scale of sensitivity due to its 10 cm coil separation. The handheld instruments used to log the conductivity of the core are sensitive to more conductive material (greater than about 1 S/m). The scale of the sensors of these handheld instruments is a few cm, so they are focussing on a very local estimate. The spatial characteristics of the handheld instruments are similar to the IFG tool, so there is a reasonable linear correlation between the conductivities derived from these three different instruments. However, the slopes are not unity; for example, the GDD instrument giving values three times greater than the KT-10. When selecting tools for measuring the resistivity and conductivity, ensure that the values that you expect to measure fall within the range of sensitivity of the instrument and that the features sought are comparable in size to the volume of sensitivity.

Title: Empirical Discrimination Between Graphitic And Sulfide-Rich EM Conductors And Application To VMS Exploration In Abitibi, Québec

Presenter/First Author: Silvain Rafini, CONSOREM, Chicoutimi, QC

Presenter/First Author Email: silraf@hotmail.com

Abstract Body: For historical reasons, the exploration of VMS in Abitibi always focused on the bimodal-mafic type, such that strategies were restricted to isolated EM anomalies and coexisting mafic and felsic volcanics. EM anomalies located along formational or structural linear conductors into sedimentary and mafic environments, which constitutes 90 % of Abitibi volcanics, hence were occulted and their potential for less conventional pelitic and mafic-pelitic VMS ignored.

In these environments, a major exploration problem is to detect the occurrences of massive sulfide bodies embedded into graphitic formations. Two avenues are investigated in an attempt to solve this issue:

Numerous MEGATEM anomalies that are caused by conductors of known geochemistry and/or mineral composition were compiled in order to empirically analyze the correlations between the attributes of these anomalies and the graphite vs sulfide component of the conductor, using advanced statistical methods. This led to the introduction an original index, I1, equal to the ratio of *ontime* on *offtime* early channels. I1 is statistically shown to encompass most of the total variability of EM responses and to have a potential for graphite/sulfide discrimination.

The second avenue consists in analyzing the EM longitudinal variations along some graphitic linear conductors into which massive sulfides occurrences are known from drillholes, in the aim of constraining their EM signature in such highly conductive environment. The hypothesis tested here was that the superposition of vortexes induced separately by graphite and the massive sulfides should generate a sudden increase of the EM response, exceeding the background longitudinal variations caused by progressive changes of the graphitic or primary sulfides component. This theory turned to be remarkably validated. The known massive sulfide bodies were very confidently identified by abrupt changes in three parameters: the total energy envelope at channel 12, the decay constant TAU, and the I1 index.

This demonstrated that massive sulfide bodies along graphitic conductors can be detected by analyzing the 1D longitudinal variations of EM responses which, in other words, simply comes to raise the base level. The original methodology was hence used to generate numerous first class exploration targets in Abitibi.

Title: Delineation of Extension of Uranium Mineralization using Noise Assisted Empirical Mode Decomposition of VLF EM data

Presenter/First Author: Anand Singh, Indian Institute of Technology Kharagpur, Kharagpur,

Presenter/First Author Email: anand@gg.iitkgp.ernet.in

Co-authors: Shashi Prakash Sharma, Department of Geology and Geophysics, Indian Institute of Technology, Kharagpur, India

Abstract Body: The Beldih open cast mine of the South Purulia Shear Zone (SPSZ) in Eastern India is well known for apatite deposits associated with Nb–rare-earth-element–uranium mineralization within steeply dipping, altered ferruginous kaolinite and quartz–magnetite– apatite rocks with E–W strikes at the contact of altered mafic–ultramafic and granite/quartzite rocks. A detailed Very Low-Frequency Electromagnetic (VLF-EM) study has been carried out around South Purulia Shear Zone to investigate the lateral extension and depth extent of the subsurface structures associated with uranium mineralization. The VLF-EM data in the study area was contaminated by non-stationary and nonlinear noises (mainly power line disturbances) where the noises could not be removed by conventional filtering methods. Therefore, to recover signals with considerable geologic information is must. For this purpose present work used empirical mode decomposition (EMD) technique. With the help of this data processing technique, the VLF-EM data was enhanced toward quantitative inversion results with satisfying accuracy. The analyses have been accurate in depicting the possible structures associated with uranium mineralization. Accuracy of the present data processing technique is also demonstrated on synthetic data. In the present work actual current density has been optimized at actual depth using a new computational procedure.

Title: Lithological and Structural Control of the Emerald Occurrences South of Singhbhum Shear Zone within the Singhbhum Crustal Province, Eastern Indian Craton

Presenter/First Author: Shreeram Suman Sahu, Indian School of Mines, Dhanbad,

Abstract Body: Emerald is the chromium and vanadium bearing variety of beryl (Be3 Al2Si6O18) with a "grass green" primary hue and a slender yellow or blue secondary hue. Globally, this gem variety is known to be hosted by Pegmatites, schists with or without pegmatites and within veins and breccia of black shale. In this work we have reported new area of emerald occurrences, where mineralization occur within the schist with or without pegmatities as intrusive, along a north-south oriented 25km long belt near Singhbhum Shear zone within the Eastern Indian Craton. Emerald occurrences in the study area is confined within biotite schist, talc-actinolite schist and show evidences of lithological and structural control. The detailed microstructural and chemical analysis of beryl, emerald, amphibole, mica, tourmaline, quartz and chlorite indicate that the syn to post tectonic mineralization may be correlated with magmatic activities, post-magmatic hydrothermal activities and regional-metamorphic event. These rocks contain 3000–5000 ppm Cr, and behave as source rocks to supply the Chromium for the crystallization of emeralds. The basement rocks within the area is an ensemble of migmatised gneisses, mica schists, granite gneisses and amphibolites along with widely scattered small bodies of ultramafic rocks, intensely invaded by pegmatite and quartz veins. This work reveal that regional metamorphism and tectono-metamorphic processes during shear zone deformation might have played a significant role in the formation of emerald deposits. The Singhbhum shear zone provides an ideal condition for emerald crystal growth, where the beryllium bearing hydrothermal fluid interacts with chromium bearing mica schist or ultramafic rocks.

Title: Geology and Initial Resource Estimate of the Zoned, Complex-Type, Li-rich Pakeagama Lake Pegmatite, Northwestern Ontario, Canada

Presenter/First Author: Steve Ray Beyer, Queen's University, Kingston,

Presenter/First Author Email: beyer@geol.queensu.ca

Co-authors: Garth L Drever, Raven Minerals Corp., Toronto, ON, Canada; Peter J Vanstone, , , ; T Kurtis Kyser, Queen's University, Kingston, ON, Canada

Abstract Body: The Pakeagama Lake pegmatite is a zoned, Li-Cs-Ta (LCT) pegmatite located 175 km north of Red Lake, Ontario. The pegmatite occurs near the margin of the Pakeagama Lake granitic pluton, which intruded proximal to the Bearhead Lake Fault Zone that separates the Sachigo and Berens River domains of the Superior Province. More than 2,400 metres of drilling in 14 drill holes and 21 channel cuts have revealed a significant Li deposit, with an inferred resource estimate of 6.8 Mt averaging 1.56% Li_2O, 105 ppm Ta_2O_5, and 0.30% Rb_2O.

Mineralogically similar to the Tanco pegmatite in southeastern Manitoba, the Pakeagama Lake pegmatite displays intermittent wall zones and three main intermediate zones, which are the Upper Intermediate Zone (UIZ), Central Intermediate Zone (CIZ), and Lower Intermediate Zone (LIZ). The UIZ is dominated by spodumene + quartz intergrowth (SQUI) after primary petalite with lesser grey K-feldspar + mica, and represents the highest grade Li zone within the pegmatite (including 4.2% Li_2O over 18 m). The CIZ consists of predominantly coarse (up to 0.5 m in length) K-feldspar with lesser quartz and mica. Significant portions of this zone display replacement of K-feldspar by a dark to purple-coloured lithian mica + quartz assemblage which hosts euhedral blue apatite. These micaceous zones also contain pollucite (the primary ore mineral of Cs) blebs and the highest Ta grades found to date in the pegmatite (including 236 ppm Ta_2O_5 over 19 m). The LIZ comprises the bulk of the exposed pegmatite and contains predominantly K-feldspar, Na-feldspar, SQUI, lithian muscovite, and rare pollucite. Based on electron probe microanalysis (EPMA), spodumene throughout the pegmatite contains low concentrations of impurities such as Fe, making the ore suitable for use in the manufacture of specialty glass and ceramic products. Lithian micas contain high Rb contents based on EPMA, with concentrations as high as 2.75 wt.% Rb_2O.

The pegmatite has an elongated oval shape striking in a northwesterly direction and dipping steeply to subvertical to the southwest, and is in contact with metasediments along the footwall. Initial indications are the pegmatite represents at least the second intrusion event along a linear structure that had previously been intruded by tantaliferous (up to 1350 ppm Ta_2O_5 in a grab sample) banded sodic aplite.

Title: Feldspar and Quartz Crystals Unveil the Petrogenesis of the Lithium-rich Moblan Pegmatite (Quebec)

Presenter/First Author: Victoria Maneta, McGill University, Montreal,

Presenter/First Author Email: viktoria.maneta@mail.mcgill.ca

Co-authors: Don R Baker, McGill University, Montreal, QC, Canada; William G Minarik, McGill University, Montreal, QC, Canada

Published Material: Experimental evidence for the supersaturation of pegmatite-forming melts in Li-aluminosilicates was presented in the GSA meeting in Vancouver in October 2014 and the GAC-MAC conference in Fredericton in May 2014. Part of the findings summarized in this abstract have been submitted for publication to the journal Contributions to Mineralogy and Petrology.

Abstract Body: The main sill of the Moblan spodumene-pegmatite in Quebec is characterized by simple aplite and albite-rich wall zones that surround a central core rich in quartz and spodumene. The Li concentration of the core is estimated at approximately 13000 ppm with feldspar and quartz crystals from various zones of the pegmatite incorporating up to 350 ppm Li. The simple mineralogy and restricted dimensions of the wall zones, the elevated Li concentration of quartz and feldspar crystals and the unusually high Li content of the core suggest extreme enrichment of the pegmatite-forming melt in Li prior to emplacement.

The Li concentration of the main minerals from different zones of the Moblan pegmatite is used in combination with experimental results in order to evaluate the Li enrichment of the granitic melt that generated the central sill. The Li concentration of the melt that coexisted with Li-rich feldspar and quartz crystals can reach up to ~7000 ppm, suggesting supersaturation of the pegmatite-forming melt in Li-aluminosilicate phases. In addition, the uncommon geochemical signature of Li in feldspar can be used as a useful exploration tool for the identification and targeting of Li-rich pegmatites.

Title: Location and Characterization of Pegmatites in the Southern Baffin Island Region, Nunavut: Field and Satellite Observations

Presenter/First Author: Alia Bigio, University of New Brunswick, Fredericton, NB

Presenter/First Author Email: alia.bigio@aandc.gc.ca

Co-authors: David Richard Lentz, University of New Brunswick, Fredericton, Canada; Paul Budkewitsch, , ,

Published Material: The paper on which this poster is based will have been published by the time the conference occurs, in the Summary of Activities 2014, Canada-Nunavut Geoscience Office.

Abstract Body: A number of granitic pegmatite dykes intrude the country rock on Hall Peninsula, southern Baffin Island, Nunavut. The aim of this project is to study the distribution, composition and petrogenesis of a select number of these pegmatites and evaluate their metallogenic potential. We anticipate that this research will highlight any rare metal, rare-earth element, and/or gem potential in pegmatites on Hall Peninsula, to companies that are interested in those commodities, with an emphasis on Sn, Li, Cs and Ta in particular.

This project will also include an examination of the source of parent melts, relative paragenesis, timing with respect to late orogenic evolution, and absolute ages of emplacement. Lithogeochemical and mineral-chemical analysis of the pegmatites is being done using whole-rock geochemistry and laser-ablation, multiple-collector, inductively coupled plasma–mass spectrometry (LA-MC-ICP-MS). In-situ field analysis of pegmatites for higher-than-background radioactivity also took place using a GR-135 Plus spectrometer in order to prioritize pegmatites for geochronological work.

A broader regional context has been added to this project through the use of pegmatite samples obtained from both the Cumberland and Meta Incognita peninsulas. As pegmatites are not generally large targets, and can be easily overlooked in larger scale mapping projects, an attempt is being made to develop an approach that can identify them using various remote sensing methods.

Title: Platinum-group Element and Associated Trace Elements Distribution in Pyrrhotite, Pentlandite, Pyrite and Chalcopyrite - Implications for the Formation and the Exploration for Magmatic Nickel and PGE Deposits.

Presenter/First Author: Sarah-Jane Barnes, Université du Québec à Chicoutimi, Saguenay, QC

Presenter/First Author Email: sjbarnes@uqac.ca

Published Material: Contribution Mineralogy Petrology 06, Chemical Geology 08, Economic Geology 11, 12, 13 Mineralium Deposita, 10, 11, 12 Canadian Mineralogists, 13

Abstract Body: In order to fully exploit the vast potential of the LA-ICP-MS analysis in studying Ni and Platinum-group element (PGE) ore deposits it is necessary to understand which mineral is controlling the element of interest. This is particularly important for the PGE as they can be present both in sulphide minerals and in platinum-group minerals (PGM). With the aim of establishing which minerals control which PGE we have studied well characterized samples from type-examples of Ni and PGE deposits. By considering: the petrography, the whole rock composition, and the trace element content of the sulphide minerals we can calculate a mass balance and deduce which mineral is controlling each element and try to deduce which process was important in the controlling each element.

Pyrrhotite, pentlandite and pyrite host most of the Re, Os, Ir, Ru and Rh, except if As is present, in which case Ni, Co, Ir and Rh arsenides or sulfarsenides form. Pentlandite contains 20-40% of the Pd present in most deposits, with the balance in PGM. Almost all of the Pt is present as Pt minerals, although some can be present in pyrite. Pyrite also contains most of the elements that pyrrhotite contains. Chalcopyrite contains very little of the PGE budget. These results are consistent with collection of the PGE by a magmatic sulphide liquid followed by partitioning of Re, Os, Ir, Ru and Rh into the first sulphide mineral to crystallize (MSS). MSS exsolves to form pyrrhotite and pentlandite at lower temperatures and the minerals inherit the PGE that were present in MSS. Platinum and Pd generally concentrate into the fractionated sulfide liquid and crystallize as PGM from this liquid. Pyrite replaces pyrrhotite and in some case pentlandite in some deposits.

The distribution of the PGE among the sulphide minerals and PGM can also used in exploitation of the deposits, in particular the importance of pyrite as host for Rh has not been fully recognized. Although sulphide minerals do not survive transport very well if they are present in a heavy stream or glacial mineral separate then high Rh contents in pyrite would be a good indicator of the presence of a nearby Ni or PGE deposit. Similarly if pentlandite or pyrrhotite are present and they contain Os, Ir, Ru, Rh and, in the case of pentlandite, Pd this is a positive sign for a Ni or PGE deposit.

Title: The Use of Pentlandite and Pyrite Compositions for Exploration

Presenter/First Author: Charley Duran, University of Quebec at Chicoutimi UQAC, Chicoutimi,

Presenter/First Author Email: charley.duran@hotmail.fr

Co-authors: Sarah-Jane Barnes, Université du Québec à Chicoutimi, Saguenay, QC, Canada; John Corkery, , ,

Abstract Body: We have analyzed pentlandites and pyrites of sulfide-rich pods from the Lac des Iles Pd-deposits (Western Ontario, Canada) using LA-ICP-MS. In comparing our data with those from the literature, we noticed that pentlandites from primary PGE deposits are significantly enriched in Pd and Rh relative to pentlandites from Ni-Cu sulfide deposits. We also noticed that pyrites found in magmatic Ni-Cu-PGE deposits are enriched in Co and Se and depleted in Sb and As relative to pyrites found in low-temperature hydrothermal deposits (e.g. orogenic gold deposits and volcanogenic-hosted massive sulfides). A plot of Pd vs Rh in pentlandite appears to be effective at distinguishing pentlandites from primary PGE deposits to those from Ni-Cu deposits. In addition, a plot of Co/Se vs Sb/As in pyrite allows to distinguish pyrites from magmatic settings to those from hydrothermal settings. In detrital rocks such as tills, pentlandite and pyrite can be found in the heavy mineral fraction. Therefore, the two plots that we developed can be used in exploration to fingerprint potential targets. Furthermore, we identified that the primitive-mantle normalized patterns of pentlandites derived from primitive magmas (e.g. layered intrusions, flood basalts, and ultramafic intrusions and flows) are different to those of pentlandites derived from evolved magmas (e.g. andesites). Thus, the geochemical signature of pentlandite may be used to infer the nature of its parental magma. This result can be of key importance to adapt exploration strategies.
